Laboratory testing usually reveals an autoantibody to phospholipids (anticardiolipin, anti–β_2-glycoprotein 1, or prothrombin), but "antibody-negative" aPLA syndrome has been described.[42,45] False-positive test results for syphilis and a lupus anticoagulant are common. A prolonged prothrombin or partial thromboplastin time that does not correct when plasma is diluted 1:1 with normal plasma is found in such circumstances. Antiphospholipid antibodies may cross-react with platelet factor 4–heparin complex and thus may generate a false positive antibody test in heparin-induced thrombocytopenia. Mild thrombocytopenia is common (platelet counts about 100,000/mm^3 but usually not less than 80,000/mm^3). Thrombocytopenia may be an in vitro phenomenon related to the effect of the aPLA antibody on platelet membrane biology. Lymphocytopenia is common in patients with SLE and aPLA syndrome. A mild hemolytic anemia (Coombs negative or positive) may coexist, giving rise to confusion with thrombotic thrombocytopenic purpura, hemolytic uremic syndrome, and Evans syndrome. A frank microangiopathic hemolytic anemia is relatively uncommon. Patients with aPLA syndrome and reduced ADAMTS13 activity may be at higher risk for thrombotic events.[48] Anti-C1q autoantibodies are found frequently in primary aPLA syndrome and might contribute to abnormal complement activation, particularly in severe refractory cases.

Kidney manifestations of aPLA syndrome are broad and may include renal artery/vein thrombosis, hypertension, small vessel microangiopathy, including glomerular capillaries, and allograft thrombosis (Fig. 29.5). In primary aPLA syndrome, overt kidney manifestations are generally mild and are frequently absent. Nephrotic syndrome is relatively rare. In aPLA syndrome associated with SLE, the kidney manifestations are determined largely by the underlying glomerular disease severity, but the coexistence of aPLA syndrome contributes to a worse prognosis and extrarenal manifestations (neurologic, cardiovascular, osseous, ophthalmologic, pulmonary, hepatic, visceral, and obstetric; see Chapter 27). A strong association of aPLA with alveolar hemorrhage exists in SLE.[40]

The therapy for primary aPLA syndrome and that accompanying SLE is controversial. Immunosuppressive agents, such as steroids or cytotoxic agents, even when they are used to control SLE, have yielded disappointing results. Symptomatic patients are best treated with

anticoagulation. Aspirin (or clopidogrel) can be used in mild cases. Combinations of aspirin and low-dose warfarin might be effective, but the risk for bleeding is increased. Vitamin K antagonism is the mainstay of treatment in severe cases, with the international normalized ratio (INR) adjusted to a level depending on symptoms; INR between 2.0 and 3.5 may be required. Low-molecular-weight heparin (subcutaneous or intravenous [IV]) is the treatment of choice for pregnancy complicated by aPLA syndrome and is also useful in alleviating migraine headache. Aspirin therapy in pregnancy with an aPLA-like syndrome does not appear to be effective. Long-term use of hydroxychloroquine can be beneficial in patients with primary aPLA syndrome without evidence of SLE.[49] A meta-analysis showed similar venous thrombosis rates in patients treated with direct-acting oral anticoagulants (DOAC) and warfarin but a higher rate of arterial thrombosis with DOAC treatment.[50]

Sirolimus has been suggested for treatment of aPLA syndrome,[47] but it may increase the risk for thrombosis in susceptible individuals. High-dose IV IgG (IVIG) can have dramatic beneficial effects, especially in acutely evolving disease associated with SLE. Combinations of plasma exchange and IVIG seem to be beneficial in high-risk pregnancy with aPLA syndrome,[51] and plasma exchange alone can be helpful in CAPS.[52] Given reported TLR activation, plaquenil, which inhibits TLR-7, has been tried and reportedly reduced aPLA in patients with SLE. None of these novel strategies have been tested in controlled trials.

The benefits of immunomodulating agents such as rituximab have not been adequately evaluated in aPLA syndrome, but preliminary reports are encouraging when used alone or with plasma exchange. In severe, life-threatening disease, combinations of rituximab and plasma exchange should be seriously considered. Intensive plasma exchange (plus immunosuppression) has been used in other circumstances, such as in aPLA syndrome associated with SLE, with variable degrees of success. Monoclonal antibodies to C5 (eculizumab) or to CD20 (rituximab) also have been used to treat CAPS with some success.[53,54]

Other novel therapeutic approaches to the aPLA syndrome, such as coenzyme Q10, statins, *N*-acetylcysteine, phosphodiesterase inhibitors, and factor XI inhibitors have not been thoroughly tested for safety and efficacy.

OTHER UNCOMMON GLOMERULAR DISORDERS

Fibrillary Glomerulonephritis (DNAJB9 Deposition Disease)

Fibrillary glomerulonephritis (FGN) is encountered in about 0.5% to 1% of native kidney biopsies, most commonly in older adults, usually in the sixth decade of life, with females affected more than males.[55] Proteinuria (including nephrotic syndrome), hypertension, hematuria, and reduced GFR are typically found at presentation. Autoimmune phenomenon, including RA, Sjögren syndrome, lupus-like disorders, and serologic abnormalities (+ANA, ANCA) are seen in 10% to 30% of cases, but hypocomplementemia is rare. Hematologic or nonhematologic malignancies occur in about 8% of cases and may be coincidental. Concomitant hepatitis C virus (HCV) infection is present in about 15% of cases and a small minority (<10%) may have a paraprotein disorder[55] (see Chapters 22 and 28). Familial forms have been described.

On LM, an MPGN or MesPGN pattern is often seen with superimposed crescents in about 25% of cases.[55,56] IF shows irregular or granular IgG deposition, which occasionally may be coarsely linear, resembling anti-GBM disease, or rarely absent by IF.[57] The defining characteristic is glomerular fibrillary deposits seen by EM, usually predominantly in the subendothelial and mesangial areas (Fig. 29.6). These fibrils are nonbranching, haphazardly arranged, 15nM in average diameter (range, 9–25nM), and typically Congo Red negative, although 5% may be Congo Red positive.[55,56,58] The deposits contain codeposited IgG, usually polytypic, complement, and DNAJB9 (Dnaj homolog subfamily member 9).[55,56] The finding of DNAJB9 deposition is pathognomonic and now required for a correct diagnosis of FGN, leading to a revised nosology for the disease as DNAJB9 deposition disease.[55,56,59] Elevated serum levels of the DNAJB9 protein may be found; although the specificity of this finding is high (>95%), the low sensitivity (about 67%) precludes employment as a noninvasive screening or diagnostic test.[60] Thus, the diagnosis of FGN rests on finding DNAJB9-containing glomerular deposits, and this may preclude the need for an EM search for fibrils. A comparison of monoclonal and nonmonoclonal forms of glomerular disease with fibrillary deposits is presented in Chapter 28 (see Table 28.1).

FGN tends to be progressive, and full remissions are rare. Progression to kidney failure within 2 to 5 years occurs in over 50% of cases, especially in males or those with superimposed crescentic disease and reduced GFR at presentation. Very rarely, anti-GBM disease may coexist with FGN, but such cases have not been proven to be DNAJB9 positive.[61] Therapy is uncertain, but rituximab is associated with stabilization of GFR,[55,62] even though proteinuria is unaffected. If HCV infection is present, antiviral therapy likely is indicated (see Chapter 57). FGN uncommonly recurs in kidney transplants, usually with late onset and an indolent course.[63]

Lipoprotein Glomerulopathy

Lipoprotein glomerulopathy (LPG) is a kidney lipidosis associated with apolipoprotein gene mutations in an autosomal dominant pattern with incomplete penetrance.[64,65] LPG may be caused by an abnormality in lipoprotein metabolism and/or a lipoprotein secondary structure conformational change related to molecular thermodynamic instability. Most patients harbor mutations of apolipoprotein E (ApoE), usually a heterozygous E2/E3 or E2/E4 phenotype, but homozygosity for ApoE2 or ApoE3 also has been observed. ApoE3 mutations usually are associated with type III hyperlipoproteinemia.[66] *APOE*-Sendai and *APOE*-Kyoto are the most frequent variants and frequently are in or around the low-density lipoprotein (LDL) receptor binding region. The disease may be associated with psoriasis and hypertensive emergencies accompanied by TMA. Otherwise, there are no distinctive clinical features. Clinically, there usually is heavy proteinuria with nephrotic syndrome and microhematuria may be present.

Histologically LPG is characterized by intracapillary accumulation of apolipoproteins A, B, and E in the glomeruli (mostly ApoE), leading to greatly expanded lumens filled with PAS-negative, bubbly to foamy lipoprotein pseudothrombi, which may be vaguely lamellated and stain positively with oil red O (Fig. 29.7). Foam cells are not a typical feature, and when present more often indicate crystal-storing histiocytosis, macrophage activation syndrome, ApoE2 glomerulopathy, or lecithin–cholesterol acyltransferase deficiency (see later discussion).[67] IF stains for ApoE are strongly positive, but immunoglobulins and complement are absent.[64,68] EM reveals lipid accumulation in capillary lumens and there may be subendothelial, mesangial, and, rarely, subepithelial lipid deposition.

Treatment with bezafibrate or fenofibrate may be effective and is the initial treatment of choice.[69] About three-quarters of patients with nephrotic syndrome treated with fibrates will achieve a complete or partial remission. Treatment with heparin-induced extracorporeal lipoprotein precipitation-apheresis systems also can confer a complete remission in some patients.[70]

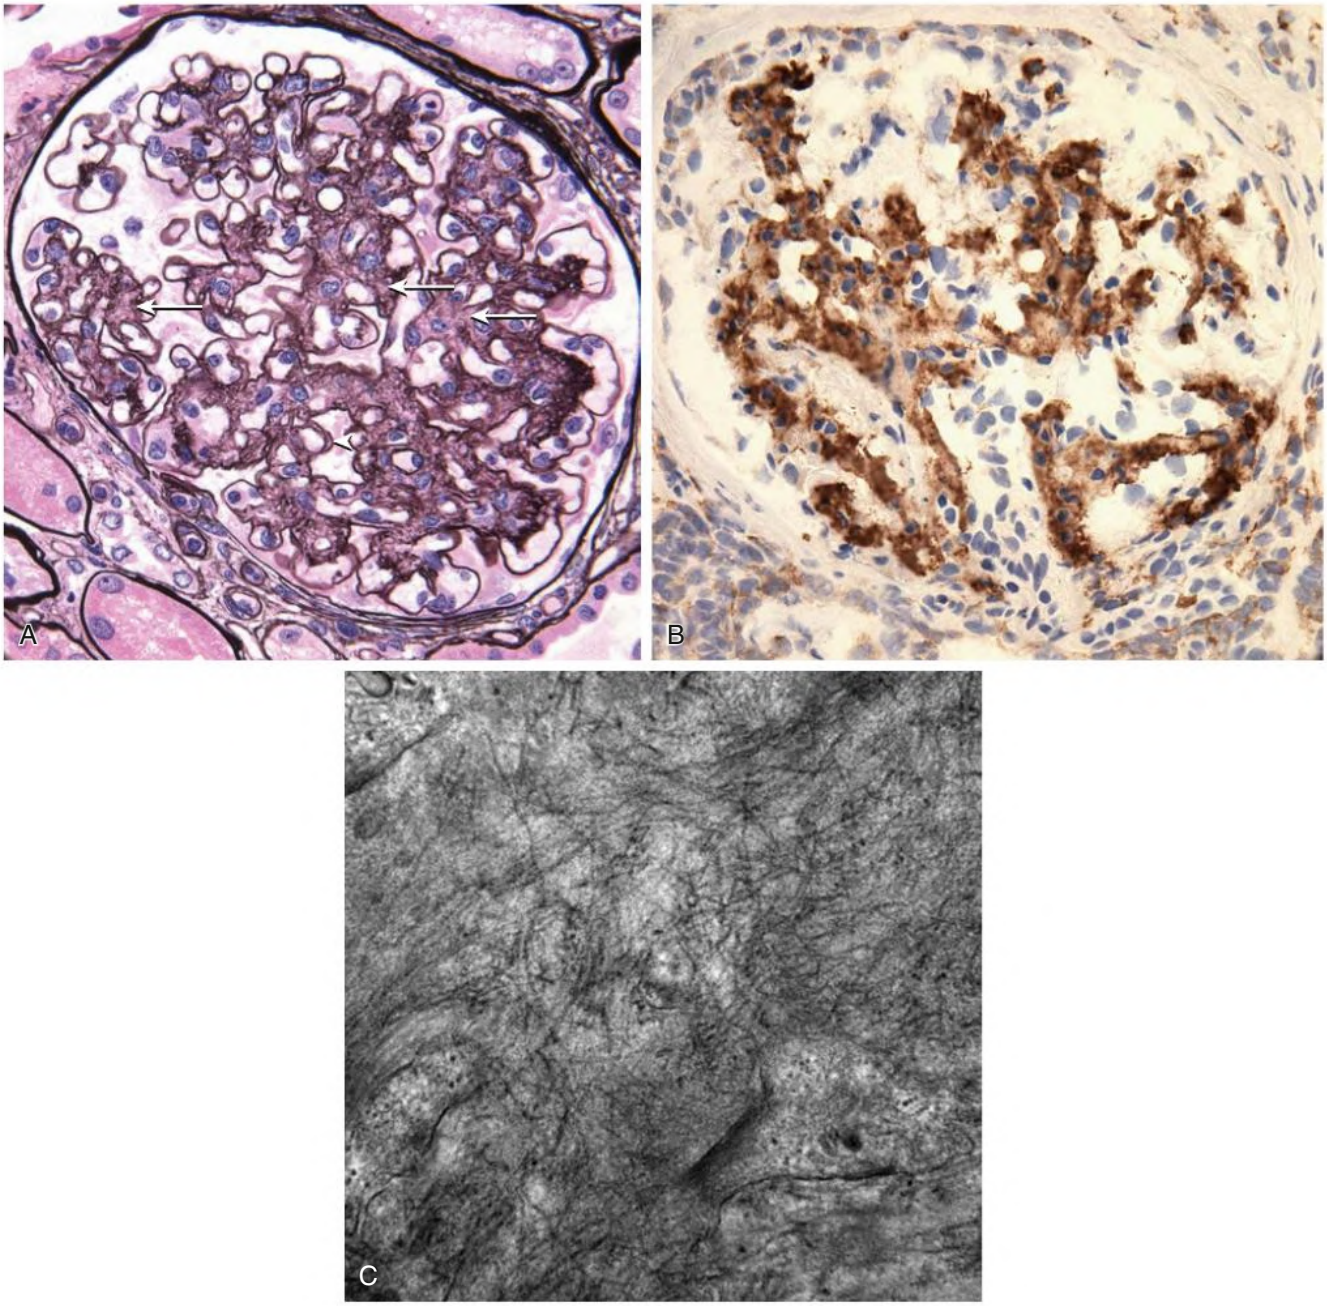

Fig. 29.6 Fibrillary Glomerulonephritis (DNAJB9 Glomerulonephritis). (A) Glomerulus with mesangial expansion because of silver weakly positive to negative material *(arrows)* and rare capillary wall double contours *(arrowhead)*. (B) Mesangial staining for DNAJB9 by immunohistochemistry. (C) Electron microscopy shows haphazardly arranged fibrils measuring 13 to 19 nm in the mesangial matrix.

Lecithin–Cholesterol Acyltransferase Deficiency

Lecithin cholesterol acyltransferase (LCAT) is a key enzyme in cholesterol metabolism. It catalyzes the esterification of free cholesterol on the surface of lipoproteins, which is necessary for cholesterol transport. LCAT deficiency is an autosomal recessive disorder associated with two clinical syndromes. Both present with very low plasma high-density lipoprotein (HDL) cholesterol levels but variable and often low frequency of cardiovascular disease in carriers[71,72] (see Chapter 20). More than 70 LCAT mutations have been reported causing total LCAT deficiency. This is termed familial LCAT deficiency (FLD), clinically manifesting with corneal opacities (misty deposits, known as "fish eye"), splenomegaly, normocytic normochromic anemia (with target cells), low HDL cholesterol, ApoA-I and ApoA-II levels, and elevated triglyceride levels. It is likely that glomerular accumulation of oxidized phospholipids and entrapment of an abnormal cholesterol-rich multilamellar particle called lipoprotein-X are pathogenic.[73] At least 18 LCAT mutations have been reported to cause the second type of LCAT deficiency called "fish-eye disease" (FED) in which LCAT activity is markedly reduced but not absent. FED patients have reduced plasma HDL and corneal opacities but lack anemia, splenomegaly, or kidney disease.

In FLD, kidney disease is characterized by proteinuria, including nephrotic syndrome, and hypertension. On LM, glomeruli have irregularly thickened, bubbly appearing GBMs, which may have double contours. Mesangial regions are expanded and may have a foamy

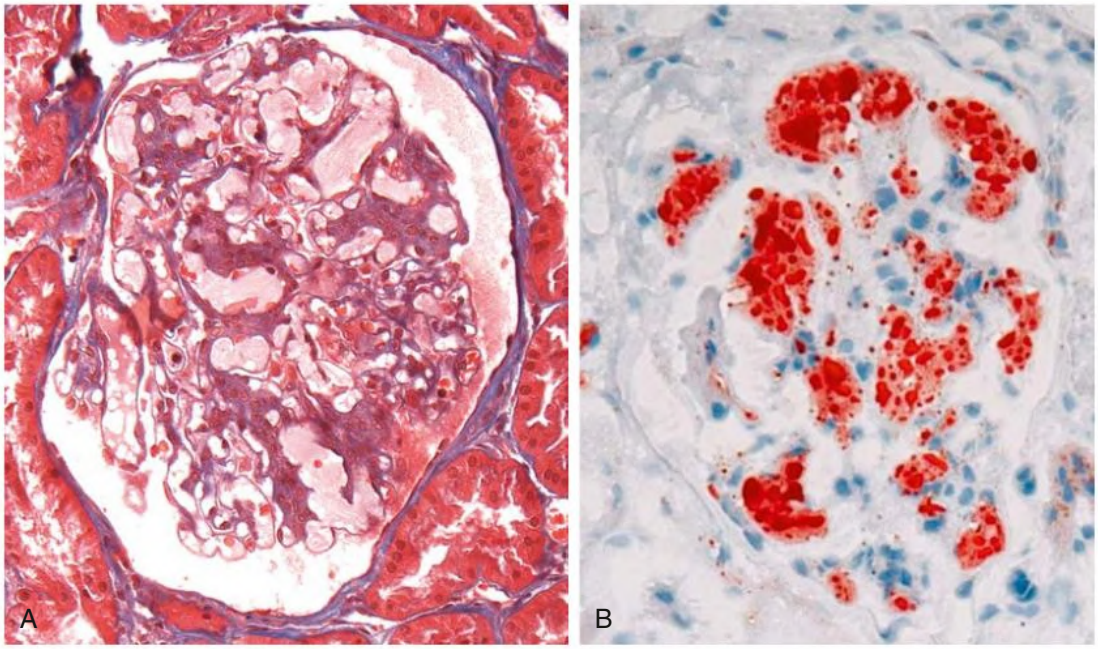

Fig. 29.7 Lipoprotein Glomerulopathy. (A) Dilated capillary lumens contain aggregates of pale, trichrome-stained, mesh-like to granular material. (B) The intraluminal material stains positively with oil red O, confirming its lipid composition.

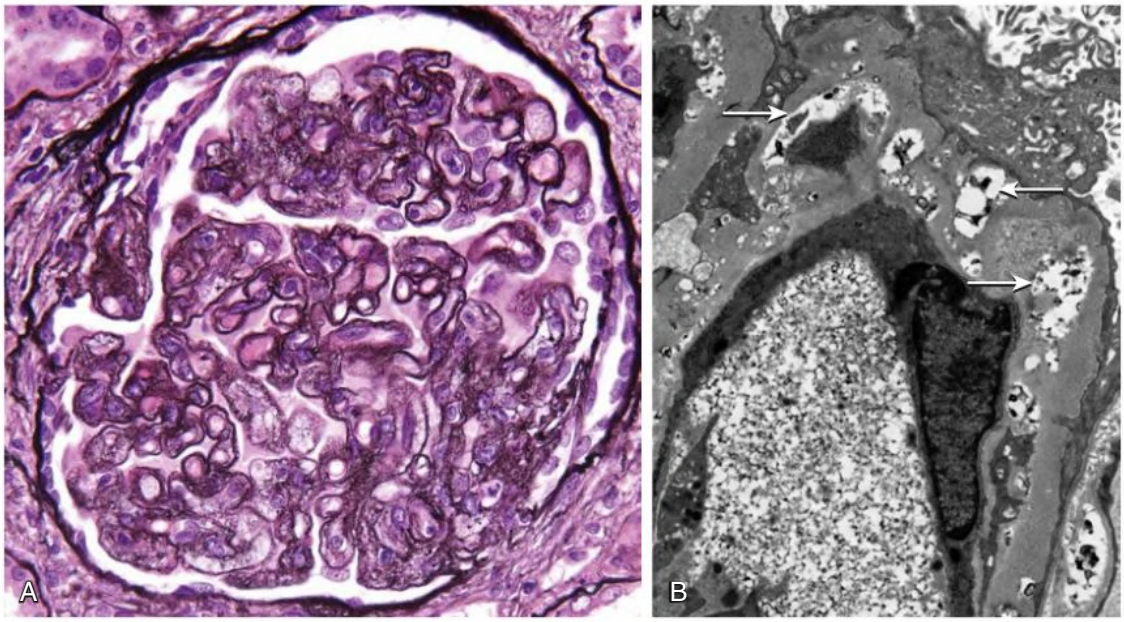

Fig. 29.8 Lecithin–Cholesterol Acyltransferase (LCAT) Deficiency. (A) Irregular, thickened and double contoured glomerular capillary walls containing clear vacuoles, which are characteristic of LCAT deficiency. (B) Electron microscopy reveals electron dense lipid material in electron lucent lacunae *(arrows)* within the glomerular basement membranes.

appearance with mild hypercellularity. There may be nonspecific granular glomerular staining for C3. Ultrastructurally, the mesangial matrix and GBMs contain electron-dense lipid particles in electron lucent lacunae (Fig. 29.8). Most patients have slow, insidious progressive kidney failure, which is usually detected in the fourth decade of life. In a report of 18 patients followed for a mean of 12 years, 50% of patients developed ESKD by age 46 years.[72]

Supportive treatment is indicated for proteinuria and hypertension but does not prevent progression. In an LCAT deficiency mouse model, the HDL cholesterol mimetic CER-001 eliminated circulating and kidney LpX, reducing albuminuria. A clinical trial of this agent is registered for treatment of familial hyperlipidemia and atherosclerotic disease (https://clinicaltrials.gov/ct2/show/NCT02697136). Recombinant human LCAT infusions were safe in a phase I clinical trial targeting patients with stable cardiovascular disease (ClinicalTrials.gov NCT01554800). In one patient with LCAT deficiency, it improved anemia and plasma HDL levels and possibly stabilized kidney function.[74] The disease can recur in kidney transplants, and sequential kidney-liver transplantation might be curative.[75]

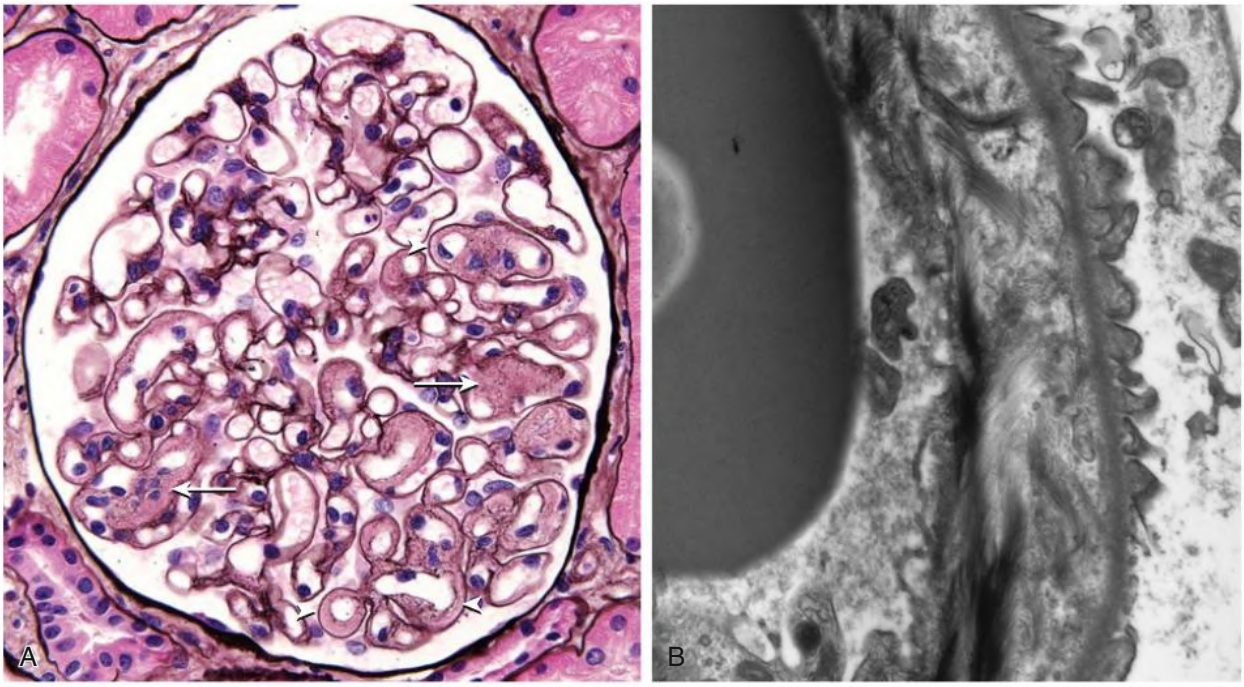

Fig. 29.9 Collagen III (Collagenofibrotic) Glomerulopathy. (A) Mesangial *(arrows)* and subendothelial *(arrowheads)* expansion due to silver negative material without hypercellularity. (B) Subendothelial fibrils are randomly oriented with an average 30 nm in diameter and are highlighted with phosphotungstic acid staining.

Collagen III Glomerulopathy

Collagen III glomerulopathy, also known as collagenofibrotic glomerulopathy, is an autosomal recessive systemic disorder with prominent kidney manifestations that may be a forme fruste of nail-patella syndrome (see Chapter 48), which has similar glomerular features.[76] However, patients with collagen III glomerulopathy lack the skeletal abnormalities associated with nail-patella syndrome. Although most cases appear to be sporadic, autosomal recessive disease has been reported in children, and *LMX1B* gene mutations are thought to be causative.[77] Patients present with proteinuria, hypertension, frequent microscopic hematuria, and slowly progressive kidney failure. The disease is more common in Asian populations, patients may be of any age, and there is no sex predilection. Marked elevation of serum hyaluronan concentration and N-terminal procollagen III propeptide may be found and, combined with rare autopsy reports of abnormal type III collagen fibrils seen in liver, spleen, myocardium, and thyroid by EM, suggests that this condition may be because of a systemic defect in type III collagen metabolism.[78]

Kidney biopsy is required for diagnosis. By LM, glomeruli are enlarged with weakly PAS positive, silver negative, Congo red negative material in expanded mesangial regions and widened subendothelial areas (Fig. 29.9). IF is typically negative or has nonspecific weak staining for immune reactants, although there is strong staining with antisera to collagen type III. EM shows bundles of irregularly arranged, frayed, and curvilinear fibrils showing 60 nm periodicity characteristic of type III collagen,[79] highlighted with phosphotungstic acid staining.[80] There is no effective treatment, and there is one report of this disease occurring in a living related kidney transplant.

Fibronectin Glomerulopathy

Fibronectin glomerulopathy is a rare, autosomal dominant, glomerular disease usually presenting in early adolescence with proteinuria, microhematuria, hypertension, distal (type 4) renal tubular acidosis, and slowly progressive kidney failure, reaching ESKD between the second and sixth decades of life.[81] Mutations occur in the *FN1* gene, which maps to chromosome 2q32.[82] Kidney pathology demonstrates enlarged, lobular, and normocellular glomeruli with PAS positive, Congo red negative material expanding mesangial and subendothelial areas (Fig. 29.10). IF is negative or shows low-grade immunoglobulin and complement glomerular staining but is strongly positively with antifibronectin antibody. EM shows usually large finely granular to occasionally fibrillary mesangial and subendothelial deposits with randomly oriented fibrils. The pathogenesis may involve mutations affecting fibronectin tertiary structure, folding, and molecular functionality.[83] The differential diagnosis includes other disorders associated with fibril deposition (see Chapter 28). There is no effective treatment and fibronectin glomerulopathy can recur in kidney allografts.

Nephropathic Cystinosis

Cystinosis is an autosomal recessive lysosomal storage disease with mutations in the cystinosin gene (*CTNS*). Patients with cystinosis often have blond hair, photophobia, hypothyroidism, retinal and corneal deposits, and rickets. They also may develop myopathy, dysphagia, diabetes mellitus, pancreatic exocrine deficiency, pulmonary dysfunction, male hypogonadism, pseudotumor cerebri, and cerebral and vascular calcifications. In the infantile form, Fanconi syndrome starts in the first year of life with tubular proteinuria or nephrogenic diabetes insipidus (see Chapter 50). Before the advent of cysteamine therapy, proteinuria developed within a few years and ESKD by 10 years of age. Adolescent cystinosis, a variant of pediatric cystinosis with symptom onset into the third decade of life, causes a milder phenotype, although nephrotic syndrome may occur.[84,85] Treatment of children with cysteamine has resulted in initial presentations with kidney disease in adults as late as age 50 years or beyond. A separate adult form is ocular limited. Cystinosin deficiency results in accumulation of intralysosomal cysteine crystals with subsequent monocyte/macrophage activation. There is damage to glomerular epithelial cells, which

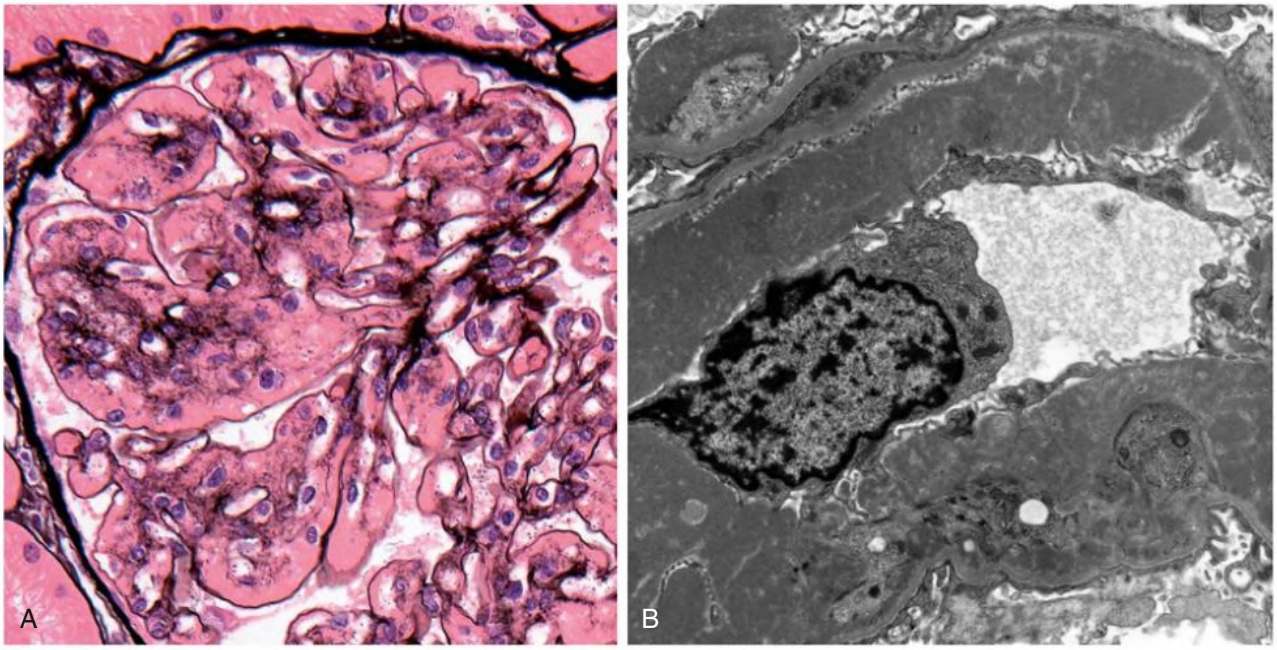

Fig. 29.10 Fibronectin Glomerulopathy. (A) Extensive expansion of mesangial and subendothelial regions due to infiltrating silver negative material with minimal hypercellularity. (B) Electron microscopy shows large subendothelial and adjacent mesangial finely granular deposits.

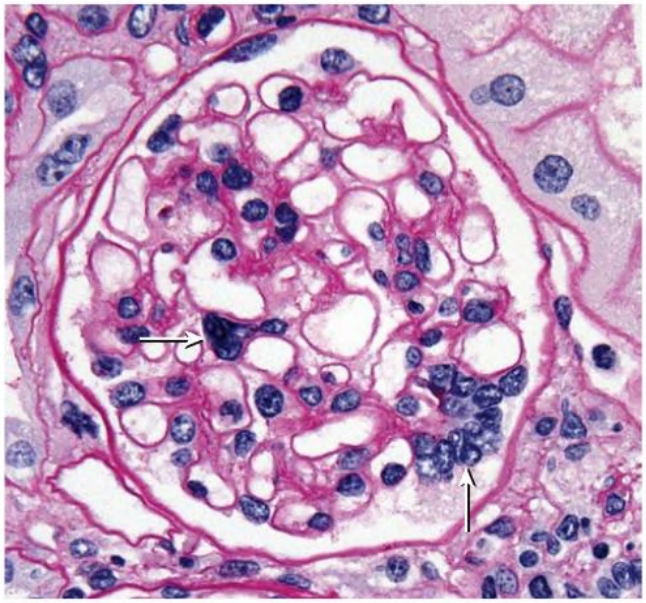

Fig. 29.11 Cystinosis. The glomerulus has segmental multinucleated podocytes *(arrows)*.

become multinucleated, more often seen in the infantile form, with podocyte foot process effacement and progression to FSGS and global glomerulosclerosis[86,87,88] (Fig. 29.11). Cysteine crystals may be found in glomerular epithelial and endothelial cells, tubular epithelial cells, and infiltrating interstitial macrophages. The treatment is long-term cysteamine administration.[89]

Miscellaneous Storage Diseases Rarely Associated With Glomerular Lesions

Diseases associated with tissue storage of abnormal lipids or carbohydrates may rarely provoke glomerular lesions, usually in infants and children. Glomerular endothelial cell inclusions may be found in Niemann-Pick disease and neuronal ceroid lipofuscinosis, whereas mesangial cell inclusions occur with gangliosidosis. Diseases with podocyte vacuolization include Hurler syndrome (type I mucopolysaccharidoses), aspartylglucosaminuria, mannosidosis, Refsum disease, nephrosialidosis and I cell disease (mucolipidosis type II). Infiltrating macrophages containing inclusions may occur in Gaucher disease, and enzyme replacement therapy has been reported to induce complete remission from Gaucher-induced nephrotic syndrome.[90] FSGS has been reported in those with von Gierke disease (glycogen storage disease). In storage diseases for which a recombinant enzyme treatment is available, controversy exists regarding the relative benefits of enzyme replacement, substrate reduction, and/or hematopoietic stem cell transplantation. The central nervous system (CNS) is not protected by enzyme replacement therapy because of blood-brain barrier impermeability.

Juvenile malabsorption of vitamin B_{12} with megaloblastic anemia (Imerslund-Grasbeck syndrome; cubulin deficiency) may cause prolonged glomerular proteinuria (albuminuria), but progressive kidney disease does not develop. Patients with cubulin mutations with proteinuria but without megaloblastic anemia have also been reported. Asphyxiating thoracic dystrophy (Jeune syndrome) is associated with glomerular, tubular, and interstitial abnormalities. Hereditary osteolysis causing wrist and ankle arthralgias and deformities can be accompanied by chronic GN.

Idiopathic (Nondiabetic) Nodular Glomerulosclerosis

Nodular glomerulosclerosis, an intercapillary nodular mesangial expansion encroaching on glomerular capillary lumens, is most commonly associated with diabetes mellitus (Kimmelstiel-Wilson lesion) and proliferative diabetic retinopathy (see Chapter 31). Similar LM lesions are reported in patients with impaired glucose tolerance not meeting criteria for diabetes mellitus or may persist after marked weight loss with remission of glycemic abnormalities, masking previous type 2 diabetes. Other diseases potentially associated with a nodular glomerulosclerosis pattern include monoclonal paraproteins (light chain and heavy chain, including Waldenström macroglobulinemia; see Chapter 28);

cystic fibrosis; hepatitis C; cigarette smoking; chronic cyanotic/ischemic syndromes; chronic thrombotic microangiopathy; protein-folding diseases such as amyloidosis, FGN, and immunotactoid GN; collagenofibrotic glomerulopathy; and fibronectin glomerulopathy.

Idiopathic nodular glomerulosclerosis was first described in 1989. Its pathogenesis is unknown, and it is a diagnosis of exclusion. It may be related to smoking, obesity, longstanding hypertension, and intermittent TMA; the term smoking-related glomerulopathy has been suggested.[91,92] Recent data suggest potential contributions from a mechanism that is common to diabetic and nondiabetic nodular glomerulosclerosis and involves epigenetic changes in the annexin gene, leading to collagen type VI secretion and deposition by glomerular endothelial cells.[93]

The clinical features are nonspecific and nondiagnostic. The average age of patients with idiopathic nodular glomerulosclerosis is approximately 70 years; most are male and presentation with nephrotic syndrome is common. LM shows nodular glomerulosclerosis identical to the diabetes-associated Kimmelstiel-Wilson lesions, often with neovascularization within the nodules. GBMs are thickened and there may be subendothelial lucencies with capillary double contour formation. There are varying degrees of arteriolonephrosclerosis and hyalinosis. No electron-dense or organized deposits are seen on EM. The GBMs and tubular basement membranes may have pseudolinear staining for IgG and albumin on IF, similar to diabetic kidney disease.

The prognosis is poor and relates to persistence of nephrotic-range proteinuria. Most patients with idiopathic nodular glomerulosclerosis will progress to ESKD, sometimes quite rapidly, with 50% kidney survival 1 year after diagnosis in those who continue to smoke heavily. There is no known therapy other than angiotensin inhibition to reduce the proteinuria and smoking cessation where relevant.

Macrophage Activation Syndrome/Histiocytic Glomerulopathy

Macrophage activation syndrome (MAS) and hematophagocytic lymphohistiocytosis (HLH) are uncommon disorders, both characterized by massive expansion and activation of T-lymphocytes and tissue macrophages with hematophagocytic capacity, leading to overproduction of cytokines and cytokine storm. The bone marrow shows expansion of histiocytes expressing CD163, with active hemophagocytosis. By convention, HLH is a primary disease associated with causative, usually autosomal recessive, mutations. MAS, also known as secondary HLH, presents similarly, but is often associated with an underlying triggering condition. MAS occurs in approximately 15% of patients with systemic juvenile idiopathic arthritis (SJIA) and less frequently in patients with SLE, other autoimmune disorders, neoplasms, and infections (especially EBV, CMV, and SARS CoV-2). Two separate but overlapping criteria for the diagnoses of HLH and MAS are published.[94,95]

Typically, patients present with pancytopenia, fever, rash, coagulopathy, liver function abnormalities, adenopathy, hepatosplenomegaly, erythrophagocytosis, and/or TMA. Excessive production of cytokines (TNF-α and IL-1, -4, -6, -8, -10), extreme hyperferritinemia, marked hypertriglyceridemia, and hypofibrinogenemia are common findings often leading to the correct diagnosis. The erythrocyte sedimentation rate may be low. A clinical diagnosis should be confirmed by bone marrow biopsy.

Kidney manifestations include AKI and nephrotic syndrome. Collapsing FSGS has been reported. Histiocytic glomerulopathy is more specific to MAS and HLH, characterized by extensive glomerular capillary infiltration with macrophages with or without erythrocyte phagocytosis or foam cells and often associated with endothelial cell swelling and features of TMA[96] (Fig. 29.12). There are no immune deposits by IF.

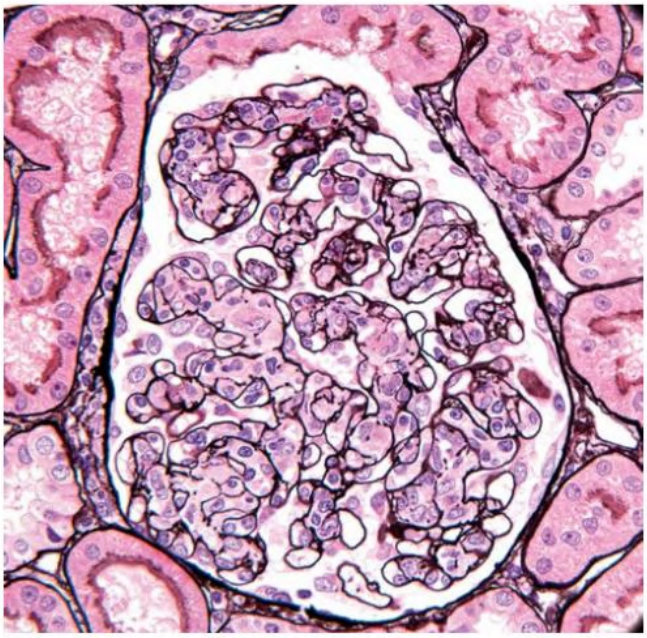

Fig. 29.12 Histiocytic Glomerulopathy. Capillary lumens and less often mesangial regions contain many monocyte/macrophages, which stain positively for CD68 and CD163 in immunohistologic examinations.

The mortality rate of MAS is high and treatment is difficult, initially consisting of removing the triggering agent (if possible). High-dose steroids, calcineurin inhibitors, IVIG, TNF-α and IL-6 antagonists, and IL-1 receptor antagonists (anakinra) are the most commonly used therapies. Rituximab, alemtuzumab, and plasma exchange have also been used with varying degrees of success.[97] In children with a genetic mutation causing primary HLH, bone-marrow transplantation may be lifesaving.[98]

DRESS Syndrome

DRESS (drug reaction with eosinophilia and systemic symptoms) syndrome is an uncommon manifestation of severe drug hypersensitivity characterized by extensive mucocutaneous rashes, fever, lymphadenopathy, hepatitis, eosinophilia, and atypical lymphocytosis with multisystem organ injury.[99] Reactions to aromatic anticonvulsants, such as phenytoin and carbamazepine, are a common cause but several medications, including antibiotics and allopurinol, have been implicated. AKI and proteinuria can be seen, and kidney biopsy usually reveals acute tubulointerstitial nephritis containing numerous eosinophils. Untreated, DRESS syndrome can be fatal. For severe cases, parenteral and oral steroids are indicated.[100]

Kimura Disease

Kimura disease (angiolymphoid hyperplasia with eosinophilia [ALHE]) is a rare disorder characterized by nonmalignant masses in the head and neck, lymphadenopathy, marked eosinophilia, elevation of serum IgE, and immune thrombocytopenia, predominantly in patients of Asian ancestry.[101] Kidney involvement with nephrotic syndrome because of MN, FSGS (tip lesion variant), or MesPGN is common. Steroid therapy is successful in most cases, although relapse upon tapering is common. Use of concomitant steroid-sparing agents including *Tripterygium wilfordii,* leflunomide, tacrolimus, vincristine, and mycophenolate have been anecdotally reported.

SELF-ASSESSMENT QUESTIONS

1. A 42-year-old man is discovered to have proteinuria, impaired kidney function (serum creatinine 2.3 mg/dL), and normocytic normochromic anemia (hemoglobin 8.2 g/dL). The physical examination shows hypertension (150/98 mm Hg), mild obesity (body mass index 31 kg/m^2), bilateral corneal opacities, and 1+ edema. The albumin is 3.2 g/dL, total cholesterol 120 mg/dL, low-density lipoprotein cholesterol 80 mg/dL, high-density lipoprotein cholesterol 15 mg/dL, and triglycerides 200 mg/dL. Serum C3 is normal. A fasting blood sugar is 120 mg/dL. Urinary total protein excretion is 4.6 g/day. Which of the following is the *most likely* diagnosis?
   A. Alport syndrome
   B. Adult-onset cystinosis
   C. Lecithin–cholesterol acyltransferase deficiency
   D. C3 glomerulopathy
   E. Obesity-related glomerulopathy
2. Which of the following can be an effective treatment of lipoprotein glomerulopathy?
   A. Cyclosporine
   B. Bezafibrate
   C. Atorvastatin
   D. Corticosteroids
   E. Plasma infusions
3. A 65-year-old woman is found to have nephrotic syndrome, and kidney biopsy shows membranous nephropathy. Serum C3 is normal, and ANA is 1:80. Anti-dsDNA is negative. Immunofluorescence staining of the biopsy reveals extensive deposits of IgG4 and weak deposits of IgG1 and IgG3. Serologic studies for hepatitis B are negative. Which of the following is the *most likely* diagnosis?
   A. Membranous lupus nephritis
   B. Membranous nephropathy secondary to cancer
   C. Idiopathic (primary) membranous nephropathy
   D. Membranous nephropathy secondary to hepatitis C infection
4. A 46-year-old woman complains of frequent "migraine" headaches. She is found to be anemic (hemoglobin 9.8 g/dL), and serum creatinine is elevated to 1.6 mg/dL. Her blood pressure is 156/94 mm Hg. Urinalysis reveals 2+ protein and a trace of blood. The serum C3 and C4 are normal, and ANA is negative. She takes an NSAID for headache. She has had three miscarriages and is presently amenorrheic. Her physical examination is otherwise unremarkable. There are no localizing neurologic findings. Which of the following tests would be *most* appropriate as a next step in the diagnostic evaluation of this patient?
   A. Anti-dsDNA autoantibody
   B. Magnetic resonance imaging of the brain
   C. Serum iron and iron-binding capacity
   D. Antiphospholipid antibody test
   E. Serum protein electrophoresis

Thrombotic Microangiopathies, Including Hemolytic Uremic Syndrome

Marina Noris, Piero L. Ruggenenti, Giuseppe Remuzzi

DEFINITIONS

Thrombotic microangiopathy (TMA) is a lesion of arteriolar and capillary vessel wall thickening with intraluminal platelet thrombosis and a partial or complete obstruction of the vessel lumina. Laboratory features of thrombocytopenia and microangiopathic hemolytic anemia are almost invariably present. Depending on whether kidney or brain lesions prevail, two pathologically indistinguishable but clinically different entities have been described: hemolytic uremic syndrome (HUS) and thrombotic thrombocytopenic purpura (TTP). Because HUS can involve extrarenal manifestations and TTP may be associated with severe kidney disease, the two can be difficult to distinguish on clinical grounds.[1] Compared with HUS, TTP is associated with more severe thrombocytopenia and less severe acute kidney injury (AKI), but changes in platelet count and kidney function largely overlap in HUS and TTP. Composite scores such as the PLASMIC score have been proposed to identify TTP patients[2]; however, there are no cut-off values that definitely discriminate the two syndromes. The identified pathophysiologic mechanisms have allowed for the differentiation of the two syndromes on a pathogenetic basis and have paved the way to specific diagnosis and treatment (Table 30.1 and Fig. 30.1).

The term HUS was introduced in 1955 by Gasser and coworkers for an acute fatal syndrome characterized by hemolytic anemia, thrombocytopenia, and severe AKI. HUS occurs most frequently in children younger than 5 years (incidence 5–6 per 100,000 children per year compared with an overall incidence of 0.5–1 per 100,000 per year). About 90% of cases are associated with infection by Shiga-like toxin (Stx) producing *Escherichia coli* (STEC) and, less frequently, with sepsis by *Shigella dysenteriae.* STEC-HUS in 90% of cases is preceded by diarrhea, often bloody. STEC-HUS occurs primarily in children, except in epidemics, when it may occur in patients with a wider range of ages. In 2011 Northern Germany experienced one of the largest STEC-HUS outbreaks ever reported, with 3816 cases of *E. coli* O104:H4 infection, of whom 845 developed STEC-HUS. Almost 90% of affected patients were adults, in particular women.[3] Approximately 10% of HUS cases are not caused by Stx-producing bacteria and have been classified as atypical.[4]

Atypical HUS has an annual incidence of 0.5 to 2 per million per year, can occur at any age, and is a very severe disease. Before the introduction of complement inhibition therapy, 50% of patients with atypical HUS progressed to end-stage kidney disease (ESKD), 30% had neurologic symptoms, and 25% died in the acute phase.[5] Pulmonary, cardiac, and gastrointestinal (GI) manifestations also can occur.

TTP was first described in 1925 by Moschcowitz in a teenage girl with fever, hemolytic anemia, bleeding, AKI, neurologic involvement, and a fulminant clinical course. Pathologic changes were characterized by widespread hyaline thrombosis of small vessels. TTP has an annual incidence between 1.5 and 6 cases per million in Europe and the United States.[5] TTP is more common in adults aged 40 years on average but can affect any age group and classically presents with the pentad of thrombocytopenia, microangiopathic hemolytic anemia, fever, and neurologic and kidney dysfunction. Central nervous system (CNS) involvement is seen in over 90% of patients and is characterized by thromboocclusive disease of the gray matter. Clinical features include headache, cranial nerve palsies, confusion, stupor, and coma. Up to half of patients with neurologic involvement may be left with sequelae. Up to 25% of patients exhibit creatinine clearance of less than 40 mL/min during long-term follow-up. Cardiac involvement is common in TTP, ranging from elevation of biomarkers to heart failure, infarction, and sudden cardiac death.[6]

LABORATORY FINDINGS

Thrombocytopenia and microangiopathic hemolytic anemia are almost invariably present in TMA patients.[4] Thrombocytopenia occurs because of platelet consumption by platelet-rich thrombi in the microcirculation evidenced by giant platelets in the peripheral smear, reduced platelet survival time, or both. Thrombocytopenia may be severe but is usually less so in patients with predominant kidney involvement. In children with STEC-HUS, the duration of thrombocytopenia is variable and does not correlate with the course of kidney disease. Microangiopathic hemolysis is likely caused by the passage of blood through the damaged capillaries and arterioles occluded by thrombi, but other explanations have been suggested.[7] Hemoglobin levels are low (<10 g/dL shiftenterin >90% of patients). The peripheral smear reveals reticulocytosis, increased schistocyte numbers, with polychromasia and often nucleated red blood cells (RBCs). Detection of fragmented erythrocytes is crucial to confirm the microangiopathic hemolytic anemia—provided that valvular heart disease and other arterial abnormalities causing erythrocyte fragmentation are excluded. Other indicators of intravascular hemolysis include elevated lactate dehydrogenase (LDH), increased indirect bilirubin, and low haptoglobin levels.[4] The Coombs test is negative. Serum C3 levels may be low during the acute phase of STEC and atypical HUS and in TTP. Moderate leukocytosis may be present. Bone marrow biopsy shows erythroid hyperplasia and increased megakaryocytes. The normal prothrombin time, partial thromboplastin time, fibrinogen level, and coagulation factors differentiate TMA from disseminated intravascular coagulation. Mild fibrinolysis with minimal elevation in fibrin degradation products may be observed.

Kidney involvement is present in all patients with HUS (by definition) and in about 25% of patients with TTP[1,8] and manifests with hematuria, proteinuria, occasionally in the nephrotic range, and kidney failure of variable severity. Hemoglobinuria is a sensitive marker of ongoing hemolysis and monitoring for it may help early detection of disease recurrence.

TABLE 30.1 Classification of Hemolytic Uremic Syndrome and Thrombotic Thrombocytopenic Purpura According to Underlying Etiology

Clinical Presentation	Etiology
Hemolytic Uremic Syndrome	
Stx associated	Infections by Shiga toxin–producing bacteria
Atypical hemolytic uremic syndrome	Complement gene abnormalities: 60% overall *CFH*, 20%–30%; *CFI*, 4–8%; *C3*, 8%–10%; *MCP*, 8%–10%; *THBD*, 3%–4%; *CFB*, 1%–2% *CFH/CFHR* hybrid genes: 3%–5% *DGKE*: 10% of patients <1 year old anti-CFH antibodies: 5%–10%
Secondary Hemolytic Uremic Syndrome	
Streptococcus pneumoniae	Desialylation of cells by neuroaminidase Complement gene abnormalities: 20%–30%
Pregnancy associated	Complement gene abnormalities: 50%–60%
Malignant hypertension	Complement gene abnormalities: 35%–65%
Transplantation (de novo HUS)	Calcineurin inhibitors, ischemia, immune response Complement gene abnormalities: 30%
BM/HSC transplantation	Immunosuppression, chemotherapy, GVHD, radiation, infections Complement gene abnormalities: 20%–60%
Autoimmune and systemic diseases	Autoimmune endothelial damage, secondary complement activation Complement gene abnormalities: around 10%
Drugs	Direct toxicity to endothelial cells Complement gene abnormalities rare: <1%
Infections	Endothelial injury, complement activation Complement gene abnormalities: variable %
Malignancies	Unknown
Cobalamin C deficiency	*MMACHC* mutations
Thrombotic Thrombocytopenic Purpura	
Genetic	Homozygous or compound heterozygous mutations in *ADAMTS13* gene
Acquired	Anti-ADAMTS13 autoantibodies

BM/HSC, Bone marrow/hematopoietic stem cell; *CFH,* complement factor H; *GVHD*, graft-versus-host disease; *HUS,* hemolytic uremic syndrome.

PATHOLOGY

TMA manifests as widening of the subendothelial space and microvascular thrombosis. Electron microscopy (EM) shows characteristic lesions of swelling and detachment of the endothelial cells from the basement membrane and the accumulation of fluffy material in the subendothelium, intraluminal platelet thrombi, and partial or complete obstruction of vessel lumina (Figs. 30.2 and 30.3).[9] These lesions are similar to scleroderma, malignant nephrosclerosis, chronic transplant rejection, and calcineurin inhibitor nephrotoxicity. Microthrombi are present primarily in the kidneys in HUS and in brain in TTP. In very young children and in those with STEC-HUS, the glomerular injury predominates (Fig. 30.4).[9]

Thrombi and leukocyte infiltration are common in the early phases and usually resolve after 2 to 3 weeks. Patchy cortical necrosis may be present in severe cases; crescent formation is uncommon. In idiopathic and familial forms and in adults, the injury mostly involves arteries and arterioles, with thrombosis and intimal thickening (Fig. 30.5; see also Fig. 30.3), secondary glomerular ischemia, and retraction of the glomerular tuft (Fig. 30.6). Focal segmental glomerulosclerosis may follow acute HUS and is usually seen in children with long-lasting hypertension and progressive chronic kidney disease (CKD).

The typical pathologic changes of TTP are widespread occlusive capillary and arteriolar thrombi most commonly detected in kidneys, pancreas, heart, adrenals, and brain. Compared with HUS, pathologic changes of TTP are more extensively distributed.

MECHANISMS, CLINICAL FEATURES, AND MANAGEMENT OF SPECIFIC FORMS OF THROMBOTIC MICROANGIOPATHY

Shiga Toxin–Producing *Escherichia coli*–Associated Hemolytic Uremic Syndrome

Mechanisms

STEC-HUS may follow GI infections by certain strains of *E. coli* or *S. dysenteriae* that produce Stxs 1 and 2 (see Fig. 30.1 and Table 30.1).[10] Most patients present with bloody diarrhea that may still be present or resolved at the time of presentation of HUS. Multiple strains of *E. coli* isolated from human cases with diarrhea produce Stxs (STEC). Before 2007, more than 70% of US cases of STEC-HUS were ascribed to the serotype O157:H7. However, starting from 2005, the reports of cases caused by non-O157 STEC increased and during 2010 to 2017, more than half of cases have been associated with infections by about 200 non-O157 STEC, with the predominance of serogroups O26, O103, O111, O121, O145, O45, O91, O146, and O113.[11,12] The natural reservoir of STEC is the GI tract of ruminants (mainly cattle). Most STEC-infected cattle remain free of disease because they lack vascular Stx receptors. Undercooked ground beef, meat patties, raw vegetables, fruit, milk, and recreational or drinking water contaminated by ruminants' excreta have been implicated in the transmission of STEC.

E. coli O157:H7 and other STECs have been responsible for multiple outbreaks worldwide.[10] The very large HUS outbreak in Germany in 2011 was caused by ingestion of fenugreek sprouts contaminated by an unusual STEC strain, O104:H4 related to fecal contamination of the seeds in Egypt.[3] Because no O104:H4 strains were detected in cattle feces collected in the outbreak area, infected ruminants are unlikely to be the cause of the O104:H4 STEC outbreak.

After food or water is ingested, STEC colonize the intestinal mucosa through an attaching/effacing lesion, characterized by the disruption of microvilli and attachment of the bacteria to the enterocytes.[13] This promotes diarrhea and intestinal inflammation. Released Stxs damage blood vessels in the colon. Very low levels of Stxs occur in the sera of HUS patients; however, Stxs can bind to blood cells or blood-derived microvesicles, which carry Stx from the intestine to target organs. Erythrocytes, platelets, and monocytes bind Stxs via specific globotriaosylceramide (Gb3) receptors, whereas human neutrophils interact with Stxs through the toll-like receptor 4.[13]

In the kidney, Stxs bind mainly to specific Gb3 receptors on glomerular endothelial cells but also to podocytes, mesangial cells, and proximal tubular cells. Bound toxin is internalized and inhibits protein synthesis, causing cell death. Treatment of endothelial cells with sublethal doses of Stx increased mRNA and protein expression of chemokines and cell adhesion molecules, favoring leukocyte-dependent

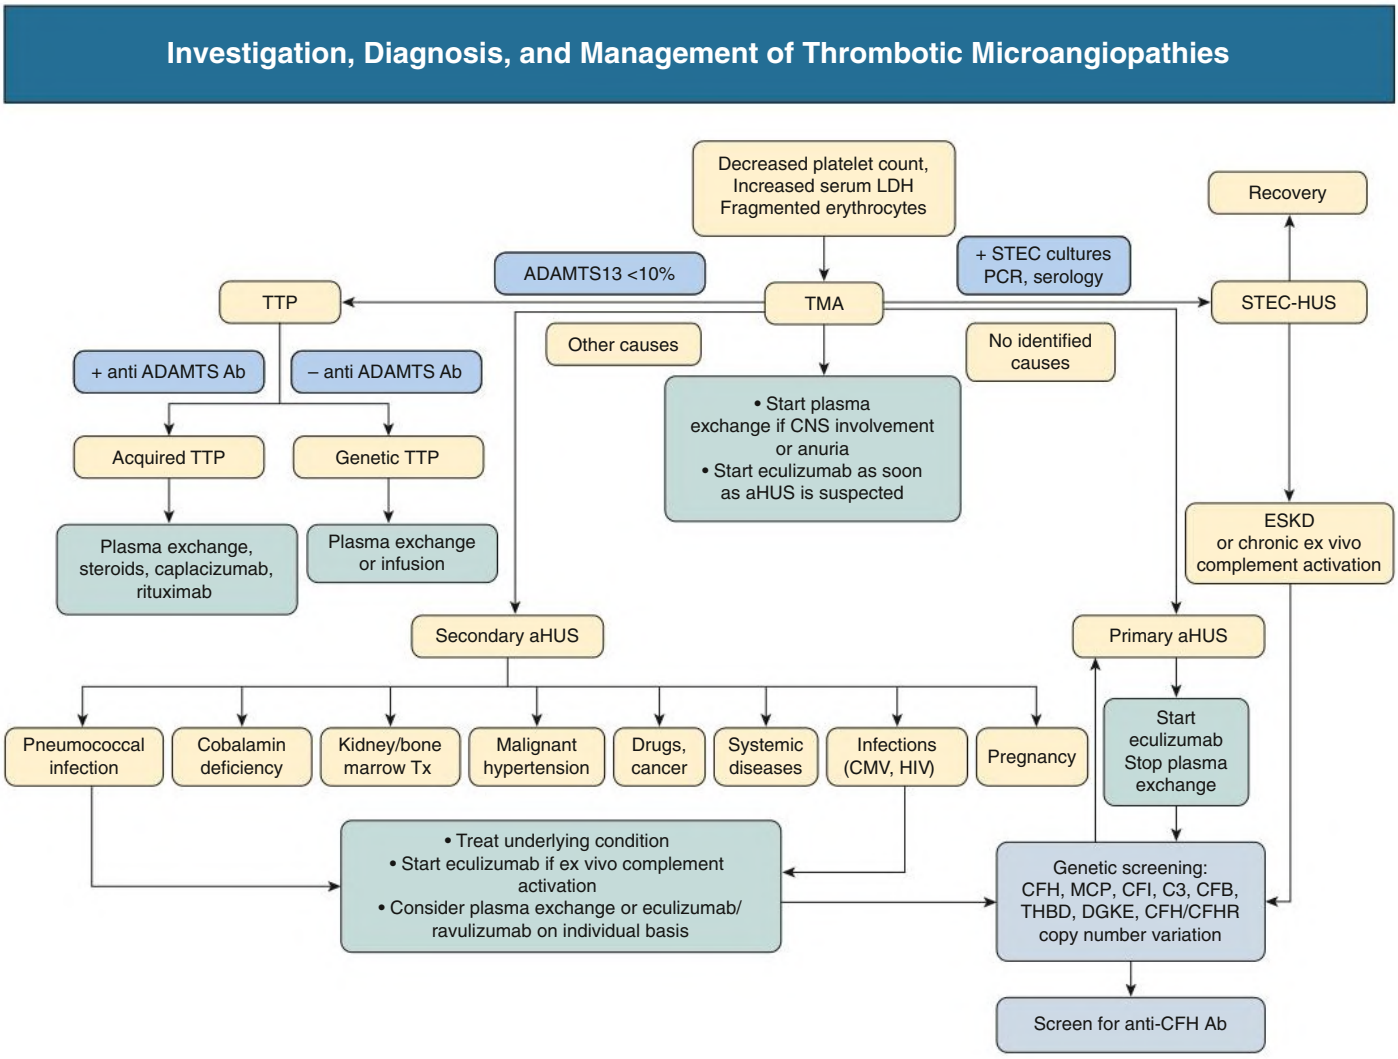

Fig. 30.1 Investigation, Diagnosis, and Management of Thrombotic Microangiopathies. We recommend empirical treatment with eculizumab in particular if there is evidence for in vivo complement activation (and ideally ex vivo complement activation if such diagnostic testing is available). This latter testing involves evaluating for serum-induced complement deposition on cultured endothelial cells and is done only in a few specialized centers. *Ab,* Antibody; *aHUS,* atypical hemolytic uremic syndrome; *CFB,* complement regulatory factor B; *CFH,* complement regulatory factor H; *CFI,* complement regulatory factor I; *CMV,* cytomegalovirus; *CNS,* central nervous system; *DGKE,* diacylglycerol kinase epsilon; *ESKD,* end-stage kidney disease; *HIV,* human immunodeficiency virus; *LDH,* lactate dehydrogenase; *MCP,* membrane cofactor protein (CD46); *MLPA,* multiplex ligation-dependent probe amplification; *STEC-HUS,* Shiga toxin–producing *Escherichia coli*–associated hemolytic uremic syndrome; *THBD,* thrombomodulin; *TMA,* thrombotic microangiopathy; *TTP,* thrombotic thrombocytopenic purpura; *Tx,* transplantation.

inflammation and inducing loss of thromboresistance in endothelial cells.

Complement activation at the renal endothelial level may contribute to microangiopathic lesions in STEC-HUS. Low serum levels of C3 and increased plasma levels of C3b, C3c, and C3d occur in children with STEC-HUS. High levels of complement activation products Bb and C5b-9 indicate complement activation via the alternative pathway.[13] In addition, C3 and C9 deposit on the surface of blood-derived microparticles from STEC-HUS patients. Stxs might directly contribute to complement activation on endothelial cells, which contributed to loss of thromboresistance.[14] Stx2 also caused the formation of platelet-leukocyte aggregates with surface-bound C3 and C9. After exposure to Stx/lipopolysaccharide (LPS), factor B–deficient mice that cannot activate the alternative pathway of complement exhibited less thrombocytopenia and were protected against glomerular abnormalities and kidney function impairment.[14] Another glomerular target for Stx-induced complement activation is the podocyte, as documented by podocyte depletion—a potential cause of proteinuria—in Stx/LPS mice, which was limited by treatment with a C3a receptor antagonist.[14]

Tubular epithelial and mesangial cells are also susceptible to the cytotoxic effects of Stxs. Stxs inhibit water absorption across human renal tubular epithelial cell monolayers, which may contribute to the early events underlying kidney dysfunction in STEC-HUS.

Diagnosis

Diagnosis depends on the detection of *E. coli* O157:H7 and other STECs and their products in stool cultures (see Fig. 30.1). When infection with STEC is suspected, physicians should ensure that stool specimens are collected promptly and specifically cultured for STEC.[10] Unlike most other *E. coli*, serotype O157:H7 does not

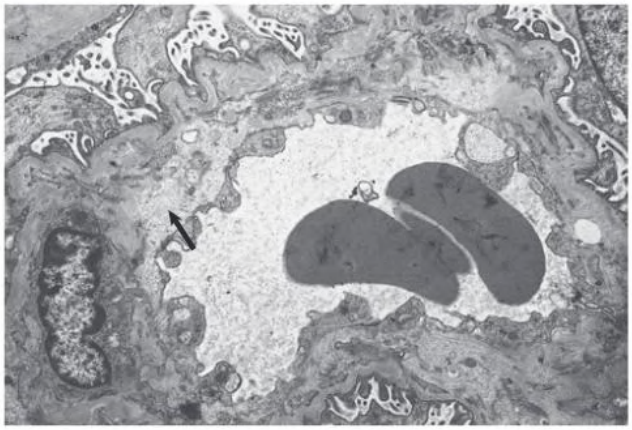

Fig. 30.2 Electron Micrograph of a Glomerular Capillary in Hemolytic-Uremic Syndrome. The endothelium is detached from the glomerular basement membrane (GBM); the subendothelial space is widened and occupied by electron-lucent fluffy material and cell debris *(arrow)*. Beneath the endothelium is a thin layer of newly formed GBM.

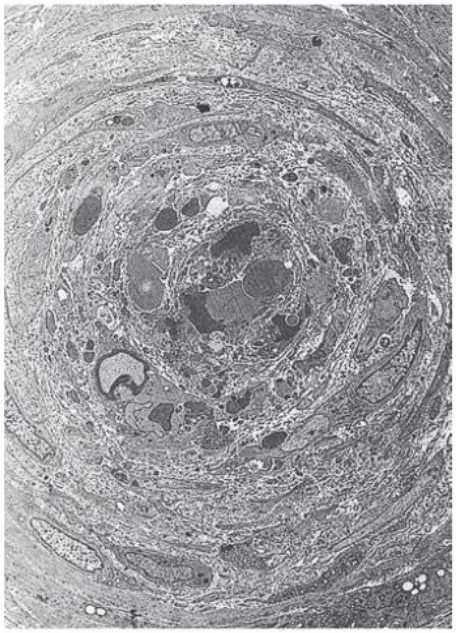

Fig. 30.3 Electron Micrograph of a Renal Arteriole in Hemolytic Uremic Syndrome. The vascular lumen is completely occluded by thrombi. There is marked intimal edema with consequent separation of myointimal cells.

ferment sorbitol rapidly and thus forms colorless colonies on sorbitol containing MacConkey agar (SMAC). The use of SMAC provides a simple, inexpensive, and generally reliable method of screening stools for *E. coli* O157. The polymerase chain reaction to detect Stx-encoding genes using DNA directly isolated from stool specimens has substantially improved the identification of non-O157-H7 STEC strains. Convalescent-phase serum samples can be assayed for antibodies to O157 or other specific strain-derived LPS; however, false-positive results may occur because of antibodies preformed during antecedent STEC exposure.[10]

Clinical Course

After exposure to STEC, 38% to 61% of individuals develop hemorrhagic colitis and 3% to 9% (in sporadic infections) to 20% (in epidemic forms) progress to overt HUS (Fig. 30.7).[10]

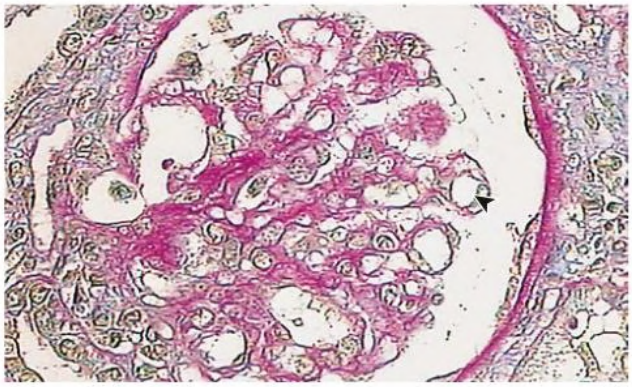

Fig. 30.4 Glomerulus From a Patient With Shiga Toxin–Producing *Escherichia coli*–Associated Hemolytic Uremic Syndrome. A marked thickening of the glomerular capillary wall occurs with many double contours *(arrowhead)*.

STEC-induced hemorrhagic colitis without HUS is self-limiting and is not associated with a long-term risk for CKD. STEC-HUS is characterized by prodromal diarrhea followed by AKI. The average interval between *E. coli* exposure and illness is 3 days. Illness typically begins with abdominal cramps and nonbloody diarrhea; diarrhea may become hemorrhagic in 70% of cases, usually within 1 or 2 days.[10] Vomiting occurs in 30% to 60% of cases and fever in 30%. HUS is usually diagnosed 6 to 10 days after the onset of diarrhea. Of those who develop HUS, 70% HUS require RBC transfusions, 40% to 50% need dialysis for an average duration of 10 days, and the remainder have milder kidney involvement.[10,15] About 25% of patients with STEC-HUS have neurologic involvement, including lethargy, apnea, cortical blindness, hemiparesis, stroke, seizures, and coma. GI complications include bowel ischemia/necrosis and perforation. Rare complications include pancreatitis, diabetes mellitus, myocardial ischemia because of TMA in coronary arteries and microvasculature, and pleural and pericardial effusions[16]; 1% to 4% of patients die during the acute phase.

About 70% of childhood cases of STEC-HUS fully recover from the acute disease. Those who do not fully recover may have persistent proteinuria (15%–30% of patients), hypertension (5%–15%), CKD (9%–18%), or ESKD (3%).[15]

Compared with previous STEC epidemics, during the STEC O104:H4 German outbreak, there was a higher incidence of dialysis-dependent AKI (20% vs. 6%) and death (6% vs. 1%).[3] Nearly half of the patients presented with neurologic symptoms and 20% had seizures. The severe clinical phenotype was explained by the lack of previous immunity to this novel STEC strain and its exceptional virulence.[3]

Therapy

Typical pediatric STEC-HUS treatment relies on supportive management of anemia, kidney failure, hypertension, and electrolyte and water imbalance (see Fig. 30.1). Intravenous (IV) isotonic volume expansion as soon as an *E. coli* O157:H7 infection is suspected, even before culture results are available, may limit the severity of AKI and the need for kidney replacement therapy.[17] Up to 80% of patients need RBC transfusions. Heparin and antithrombotic agents increase the risk for bleeding and should be avoided. Patients with severe STEC-HUS require careful monitoring, including urine output, weight, volume status, cardiovascular/respiratory function, and early signs of CNS or other organ involvement. Bowel rest (i.e., complete parenteral nutrition) is important for the enterohemorrhagic colitis associated with STEC-HUS. Antimotility agents should be avoided because they may prolong the persistence of *E. coli* in the intestinal lumen and therefore increase patient exposure to its toxin.

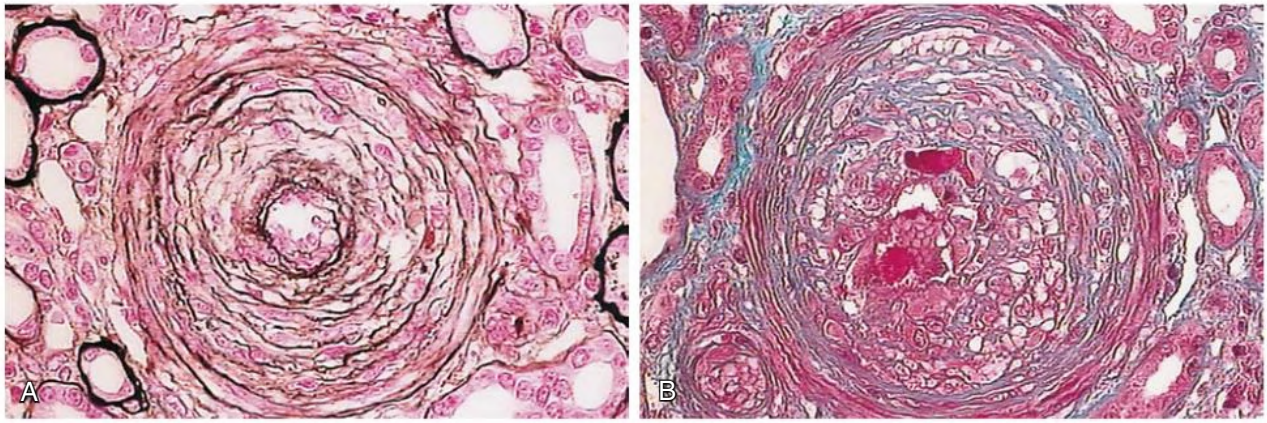

Fig. 30.5 Interlobular Artery in a Case of Hemolytic-Uremic Syndrome With Severe Vascular Involvement. (A) The vascular lumen is almost completely occluded. Changes include myointimal proliferation and reduplication of the lamina elastica. (B) Thrombotic material and erythrocytes can be seen in the lumen and within the vascular wall.

Fig. 30.6 Glomerulus From a Patient With Atypical Hemolytic Uremic Syndrome With Predominant Vascular Involvement. Severe ischemic changes have occurred. Note the shrinkage of the glomerular tuft and marked thickening and wrinkling of the capillary wall.

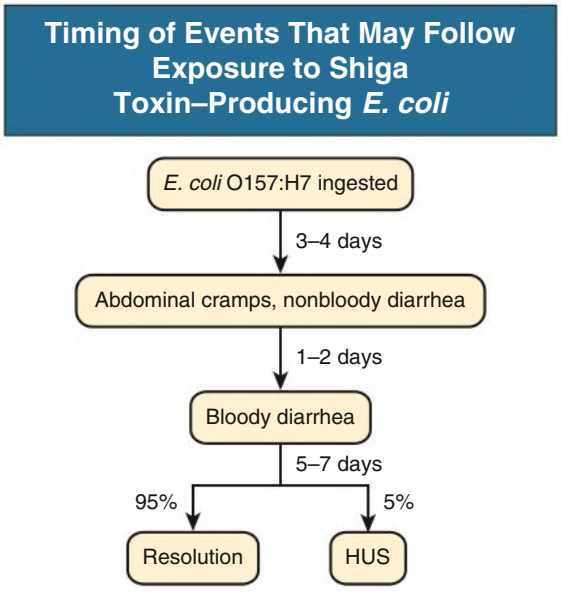

Fig. 30.7 Timing of events that may follow exposure to Shiga toxin producing *E. coli*. *HUS,* Hemolytic uremic syndrome.

Antibiotics should be restricted to the rare patients presenting with bacteremia because, at least in children with gastroenteritis, antibiotic treatment may increase the risk for HUS 17-fold, possibly related to acute release of large amounts of preformed toxin from lysed bacteria.[18] Alternatively, antibiotics might give *E. coli* O157:H7 a selective growth advantage. Moreover, several antimicrobial drugs, particularly the quinolones, trimethoprim, and furazolidone, are potent inducers of the expression of the Stx gene. Azithromycin may be an exception because its use reduced the duration of bacterial shedding in adults in the German O104:H4 epidemic.[19] In contrast to STEC-HUS, hemorrhagic colitis and HUS caused by *S. dysenteriae* bacteremia and sepsis should be treated with antibiotics because treatment shortens the duration of diarrhea, decreases the incidence of complications, and reduces the risk for transmission.

Careful blood pressure control and renin-angiotensin system blockade may be beneficial in the long term for patients who develop CKD after an episode of STEC-HUS.

Newer potential treatments for STEC-HUS, including Stx-binding agents and Stx-neutralizing antibodies, have been abandoned because of lack of efficacy. The only published data on the Stx-binding agent SYNSORB Pk failed to show benefits.[17] Other potential therapeutics under development are designed to limit Stx receptor expression or to prevent toxin binding, trafficking, or activity within the cells.[20]

The efficacy of specific treatments in adult patients is difficult to evaluate because most information is derived from uncontrolled series that may include atypical HUS cases. No prospective randomized trials demonstrate whether plasma infusion or exchange are superior to supportive treatment alone (Table 30.2). However, comparative analyses of two large series of patients treated[21] or not treated[22] with plasma suggest that plasma therapy may dramatically decrease overall mortality of STEC 0157:H7–associated HUS. Plasma exchange should therefore be considered in adult patients with severe AKI and CNS involvement.

Kidney transplantation is safe for children who develop ESKD. Recurrence rates range from 0% to 10%, and graft survival at 10 years is better than in children with other causes of ESKD.

Evidence that uncontrolled complement activation may contribute to microangiopathic lesions of STEC-HUS[14] led to complement inhibitor therapy with the anti-C5 monoclonal antibody eculizumab in three children with severe STEC-HUS who fully recovered. However, eculizumab therapy plus plasma exchange in the German STEC O104:H4 outbreak did not improve outcomes compared with plasma exchange alone.[23] These data, however, were retrospectively collected

TABLE 30.2 HUS and TTP: Specific Therapies, Dosing, and Efficacy

Therapy	Dosing	Efficacy
Immunosuppressives		
Prednisone	200 mg tapered to 60 mg/day, then 5 mg reduction per wk	Probably effective in addition to plasma exchange in patients with TTP and anti-ADAMST13 autoantibodies or in aHUS with anti–factor H autoantibodies and in forms associated with autoimmune diseases. Lack of evidence from controlled trials in immune-mediated HUS or TTP.
Prednisolone	200 mg, tapered to 60 mg/day, then 5 mg reduction per wk	
Immunoglobulins	400 mg/kg/day	
CD20 cell depleting antibody (rituximab)	375 mg/m^2/wk up to CD20 and/or CD19 cell depletion	Effective in treatment or prevention of TTP associated with immune-mediated ADAMTS13 deficiency resistant to or relapsing after immunosuppressive therapy.
Fresh frozen plasma		
Exchange	1–2 plasma volumes/day	First-line therapy in TTP. Unproven efficacy in childhood STEC-HUS. Possibly effective in aHUS if eculizumab is not available.
Infusion	20–30 mL/kg followed by 10–20 mL/kg/day	To be considered if plasma exchange is not available.
Cryosupernatant	See plasma infusion/exchanges	To replace whole plasma in case of resistance to plasma infusion or sensitization.
Solvent-detergent–treated plasma	See plasma infusion/exchanges	To limit the risk for infections.
Caplacizumab	10–11 mg IV loading dose, then 10–11 mg SC daily combined with plasma exchange and immunosuppression	Reported efficacy in acquired TTP.
Liver-kidney transplant	Perioperative plasma infusion/exchange and eculizumab	To prevent CFH-associated HUS recurrence posttransplant; about 20% mortality risk.
Complement inhibition (eculizumab)	900 mg/wk for the first 4 wk 1200 mg every 14 days up to 6 mo in adults and chidren with body weight >40 kg. In smaller children the dose is adjusted on the basis of body weight.	First-line therapy in primary aHUS.

aHUS, Atypical hemolytic uremic syndrome (HUS); *CFH,* complement factor H; *IV,* intravenous; *SC,* subcutaneous; *STEC-HUS,* Shiga toxin–producing *Escherichia coli*–associated HUS; *TTP,* thrombotic thrombocytopenic purpura.

and patients given eculizumab were the most severely ill. Two double-blind placebo controlled trials, ECUSTEC in UK (ISRCTN89553116) and ECULISHU in France (NCT02205541), in severe forms of STEC-HUS will be finalized soon.

Atypical Hemolytic Uremic Syndrome

The term atypical HUS (aHUS) has been used to define any form of HUS that is not caused by STEC.[4] Several other classifications each carry caveats.[24] Currently, the term aHUS is used when a genetic or autoimmune abnormality causing complement dysregulation is strongly suspected (see Fig. 30.1 and Table 30.1)[4,25] and other causes have been excluded. Secondary HUS instead includes a broad group of patients in whom TMA occurs in the context of another condition such as malignant hypertension, autoimmune disease, certain infections, malignancy, transplantation, or drugs. However, this differentiation is not absolute because in more than 50% of patients with primary aHUS and genetic risk factors, a trigger is required for disease to manifest, such as viral and bacterial infections or pregnancy.[4,25] Conversely, complement gene abnormalities have been identified in subgroups of patients with secondary HUS, indicating the relevance of genetic background for disease susceptibility.[25,26] Consistently, measurement of circulating complement parameters and ex vivo assays of complement deposition on cultured endothelial cells with serum and plasma from patients supported a role of complement activation in the etiology of several forms of secondary HUS.[27]

Primary aHUS[4,25] is usually sporadic, and fewer than 20% of cases are familial. Although some are in siblings, suggesting autosomal recessive transmission, others occur across two or three generations, indicating an autosomal dominant mode. Incomplete penetrance of the disease in mutation carriers is a common feature that confounds the interpretation of inheritance. Indeed, many sporadic cases of aHUS inherited the genetic defect from an unaffected parent.[28]

Mechanisms

About 50% of aHUS patients exhibit reduced serum levels of C3 with normal C4.[29] C3 consumption is documented by high levels of activated products and C3 deposits in glomeruli and other kidney vessels. The complement pathways—classic, lectin, and alternative pathways (see Fig. 17.6)—are discussed in Chapter 17. The alternative pathway (Fig. 30.8) is initiated spontaneously in plasma by C3 hydrolysis responsible for deposition of a low amount of C3b onto all plasma-exposed surfaces. On bacterial surfaces, C3b leads to phagocytosis by neutrophils and macrophages. Without regulation, a small initiating stimulus is quickly amplified to a self-harming response until complement

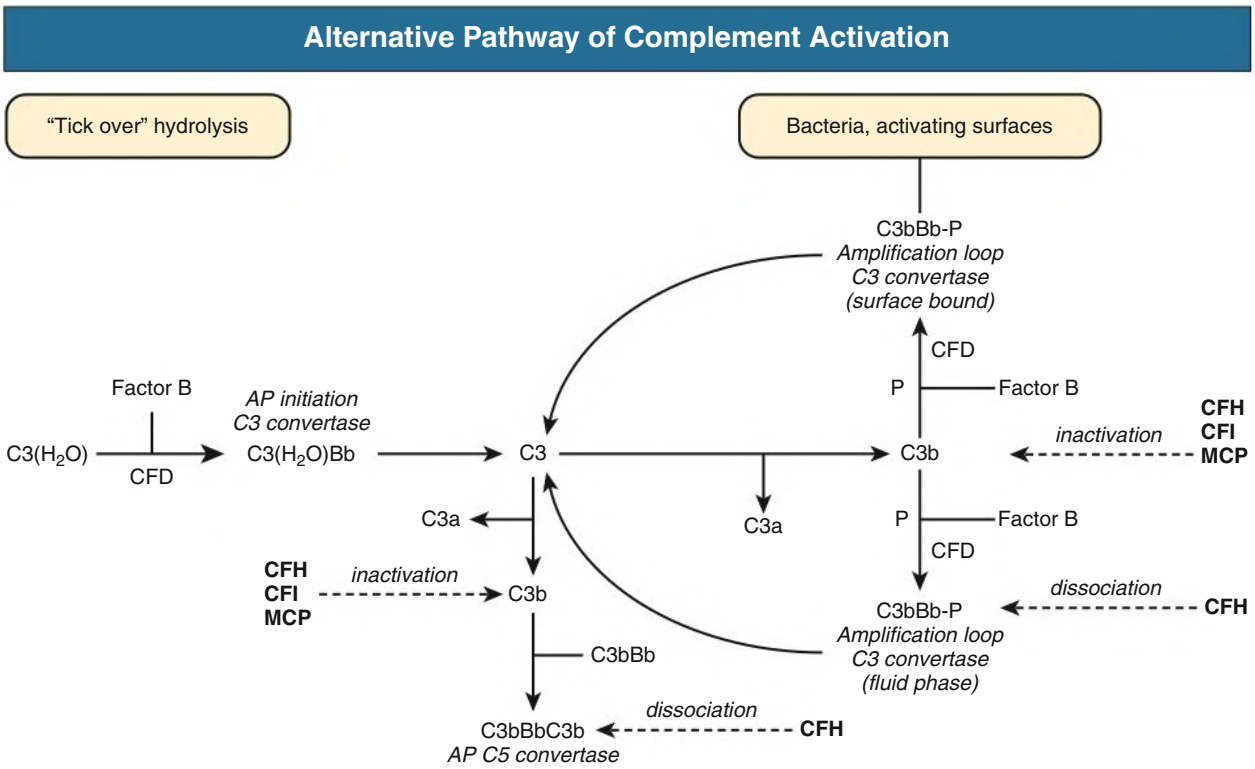

Fig. 30.8 Alternative Pathway of Complement Activation. The alternative pathway (AP) is continuously activated in plasma by low-grade hydrolysis of C3. The latter binds factor B, to form a $C3(H_2O)B$ complex. Factor D (CFD) cleaves factor B to form the AP initiation C3 convertase that cleaves C3 to C3b. The activation is then amplified by the covalent binding of a small amount of C3b to hydroxyl groups on cell surface carbohydrates and proteins of target cells such as bacterial cells. This C3b binds factor B to form the amplification loop C3 convertase C3bBb. C3 convertase enzymes cleave many molecules of C3, resulting in a positive feedback amplification loop. C3b also binds to the C3 convertase, forming the C5 convertase enzyme $C3b_2Bb$. The AP is highly regulated to prevent nonspecific damage to host cells and limit the deposition of complement to the surface of pathogens. This fine regulation occurs through a number of membrane-anchored and fluid phase regulators. *CFH,* Complement factor H (acts as cofactor for factor I for C3b cleavage and favors the decay of the C3 convertase of the AP); *CFI,* complement factor I (degrades C3b and C4b); *CR1,* complement receptor 1 (has decay accelerating activity and cofactor activity for factor I–mediated cleavage of C3b and C4b); *DAF,* decay accelerating factor (destabilizes the C3 and C5 convertases of the classic and alternative pathways); *MCP,* membrane cofactor protein (binds C3b and C4b and has cofactor activity for both the classic and alternative pathways).

components are depleted. On host cells, such a dangerous cascade is controlled by membrane-anchored and fluid-phase regulators (see Fig. 30.8). They both favor the cleavage of C3b to inactive iC3b by the plasma serine protease factor I (CFI, cofactor activity) and dissociate the C3 and C5 convertases (decay acceleration activity). Foreign targets and injured cells that either lack membrane-bound regulators or cannot bind soluble regulators are attacked by complement.

The C3 convertases of the classic/lectin pathways are formed by C2 and C4 fragments, whereas the alternative pathway convertase requires cleavage of C3 only (see Fig. 30.8). Thus, low serum C3 levels in aHUS with normal C4 indicated selective alternative pathway activation.[29]

Several genetic abnormalities in members of the alternative pathway of complement have been described in aHUS, which account for about 60% of cases (see Table 30.1). Functional studies revealed that aHUS-associated mutations mainly result in complement activation that is restricted on the cell surface—which explains the normal circulating complement profile in about half of patients—and proceeds until the formation of C5b-9.[27]

Complement factor H. Complement factor H (CFH) regulates the alternative pathway both in the fluid phase and on the cell surface by acting as a cofactor for CFI and enhancing dissociation of C3 convertase (see Fig. 30.8). Over 120 *CFH* pathogenetic or likely pathogenetic variants (Database of Complement Gene Variants; www.complement-db.org) have been identified in aHUS patients (mutation frequency about 30%).[28] These genetic abnormalities most commonly are associated with normal CFH levels but instead result in dysfunctional protein that cannot bind to and regulate complement on endothelial cells and platelets.[30] A high degree of sequence identity between *CFH* and the genes *CFHR1-5* for five factor H–related proteins (CFHR) located in tandem to *CFH* may predispose to gene conversions and genomic rearrangements.[31] Hybrid *CFH/CFHR1* and *CFH/CFHR3* genes, coding abnormal FH proteins in which the carboxy-terminal domains that mediate complement regulation on cell surface are substituted for those of FHR1 or by the entire FHR3, occur in 3% to 5% of patients with aHUS. The resulting hybrid CFH molecules exhibit decreased complement regulatory activity on endothelial surfaces.[31] Different gene conversion events between the CFH and CFHR1 genes have been reported in unrelated aHUS patients, which convert the FHR-1 C-terminus into that of CFH. The resulting FHR1 mutant strongly competes with CFH for cell surface binding.

Anti-CFH inhibitory antibodies have been reported in 5% to 10% of aHUS patients and around 25% to 50% of pediatric cases.[32] These autoantibodies predominantly target the C-terminal end, impairing complement regulation on host cell surfaces. The development of CFH autoantibodies in aHUS has a genetic predisposition, being strongly associated with the homozygous deletion of the *CFHR1* and *CFHR3* genes.[32] Complement gene variants identified in a quarter of patients with anti-CFH antibodies may affect disease severity and outcome.

Membrane cofactor protein. Membrane cofactor protein (MCP) is a transmembrane complement regulator widely expressed on all cells apart from erythrocytes. MCP serves as a cofactor for CFI to cleave C3b and C4b (see Fig. 30.8). *MCP* gene abnormalities account for 8% to 10% of aHUS cases.[28] Most are heterozygous (www.complement-db.org). The majority cluster in critical extracellular modules for regulation. Expression on blood leukocytes was reduced for about 75% of mutants. Other MCP mutants have low C3b-binding capability and decreased cofactor activity.[28]

Complement factor I. CFI is a plasma serine protease that regulates the three complement pathways by cleaving C3b and C4b in the presence of cofactor proteins (see Figs. 17.6 and 30.8). *CFI* pathogenetic variants affect 4% to 8% of patients. All mutations are heterozygous; 80% cluster in the serine-protease domain. Approximately 50% of mutants are not secreted in blood; however, some mutants are secreted but have impaired proteolytic activity.[28]

Complement factor B and C3. Gain-of-function mutations can affect genes encoding the alternative pathway C3 convertase components, complement factor B (CFB) and C3. *CFB* variants are rare (1%–2%). Some CFB mutants have excess C3b affinity and form a hyperactive C3 convertase resistant to dissociation; however, about 60% of mutants have normal activity and are likely unrelated to aHUS pathogenesis.[33]

About 9% of aHUS patients carry heterozygous variants in *C3*, usually with low C3 levels. Most mutations reduce C3b binding to complement regulators, severely impairing its inactivation and result in increased C3 deposition on endothelial cells.

Thrombomodulin. Heterozygous mutations in the gene *THBD* encoding thrombomodulin, an endothelial surface anticoagulant protein that also modulates complement on cell surfaces, have been found in 3% to 4% of patients with aHUS.[34] Cells expressing *THBD* variants inactivate C3b less efficiently.[34]

Determinants of disease penetrance. Incomplete penetrance of aHUS in carriers of complement gene abnormalities ranges from 20% to 50%.[28] A further mutation in one of the aforementioned genes occurs in approximately 10% of aHUS patients and increases the risk for developing the disease.[35] Common genetic risk variants (single-nucleotide polymorphisms [SNPs] and haplotype blocks) in *CFH, MCP,* and *CFHR1* have been shown to act as susceptibility factors for the development of aHUS.[35] In a study of 103 aHUS pedigrees, the concurrent presence of two pathogenetic variants and the *CFH* and *MCP* risk haplotypes resulted in 100% penetrance.[36]

Diacylglycerol kinase ε. Homozygous or compound heterozygous mutations in *DGKE,* which encodes the intracellular protein diacylglycerol kinase ε, have been recently associated with infantile recessive aHUS.[37] Mutation carriers presented with aHUS before 1 year of age (see Table 30.1), with hypertension, hematuria, and severe proteinuria, often in nephrotic range. *DGKE* is expressed in endothelium, platelets, and podocytes; is involved in terminating diacylglycerol signaling; and is not directly linked to complement. However, a subgroup of patients exhibits systemic complement activation, with or without concomitant rare complement gene variants.

Diagnosis of Atypical Hemolytic Uremic Syndrome and Testing for Genetic Mutations

Differential diagnosis of aHUS requires exclusion of infections by STEC or concomitant diseases and conditions or ADAMTS13 deficiency or autoantibodies against ADAMTS13 (see Fig. 30.1).[25] Full analysis of disease-associated genes and testing for anti-CFH antibodies is recommended because the nature of the underlying complement defect influences disease progression, the risk of relapses after kidney transplantation, and responses to therapies. Reference laboratories in several countries are equipped for genetic and antibody testing. Although new sequencing techniques have reduced cost and time, a complete evaluation still requires several weeks. Treatment of acute episodes (plasma therapy or eculizumab when available; see later discussion) should be started rapidly after clinical diagnosis, without waiting for results of genetic and anti-CFH antibody tests.

Clinical Course

Of all patients with aHUS, 60% are affected during childhood, irrespective of mutation type.[28] Almost all patients with anti-CFH antibodies develop the disease before 16 years of age. Acute episodes manifest with severe hemolytic anemia, thrombocytopenia, and AKI. Extrarenal involvement (CNS or multivisceral) occurs in 20% of cases.[4,28] Before the introduction of anti-C5 therapy, 50% to 70% of patients with *CFH, CF, C3, CFB,* or *THBD* mutations and 40% of children with anti-CFH autoantibodies lost kidney function, died during the presenting episode, or developed ESKD after relapses.[4,28] Chronic complement dysregulation may lead to atheroma-like lesions enhancing cardiovascular morbidity and mortality. In *MCP*-mutation carriers, recurrences were frequent but long-term outcome was good and 80% of patients remained dialysis-free.[4,28] However, rare patients with *MCP* mutations had severe disease, immediate ESKD, intractable hypertension, and coma, possibly because of concurrent genetic abnormalities.[35]

Therapy

Fresh frozen plasma. Plasma therapy (plasma exchange, 1–2 plasma volumes/day; plasma infusion, 20–30 mL/kg/day; see Table 30.2) should be started within 24 hours of diagnosis and then continued until remission or a declaration of nonresponse.[4] Plasma infusion or exchange provides normal CFH to patients carrying *CFH* mutations.[28] Long-term treatment, however, may fail as a result of development of plasma resistance. Heterozygous *CFH* mutation carriers usually have normal levels of CFH, half of which is dysfunctional. The beneficial effect of plasma is strongly dependent on the amount, frequency, and modality of administration, with plasma exchange being superior to plasma infusion by removing the mutant CFH that could antagonize the normal protein. Plasma exchange in association with immunosuppressive therapy (induction with corticosteroids and cyclophosphamide and maintenance with azathioprine or mycophenolate mofetil) is recommended in patients with anti-CFH antibodies to remove the inhibitory antibodies[25,32] and allowed long-term dialysis-free survival in 60% to 70% of patients.[32] Data on the effect of rituximab in such circumstances are scanty and inconsistent: of five patients treated with rituximab alone or with plasma exchange, only two showed disappearance of anti-CFH antibodies.[32]

Patients with *CFI* mutations showed a partial response to plasma[4,28]; 30% to 40% of patients with *CFB* mutations and 50% of those with *C3* mutations responded to plasma infusion or exchange.[4] Possibly these patients need frequent large-volume plasma exchange to clear the hyper-functional mutant *CFB* and *C3*.[4] Because MCP is a cell-associated protein, effects of plasma are unlikely in patients with *MCP* mutations. Indeed, 80% of patients with an *MCP* mutation underwent spontaneous remission independently of plasma treatment.[4,28]

Kidney transplantation. Disease recurred in 60% to 80% of transplanted patients with mutations in complement-circulating proteins (CFH, CFI, CFB, and C3), and graft failure occurred in 80% to 90%.[38] The risk for post-transplant aHUS recurrence in patients with anti-CFH autoantibodies is not well known.[32] Recurrence of HUS was documented in 30% of cases. A reduction in autoantibody levels with plasma exchange, steroids, and/or rituximab enabled successful kidney transplantation in few patients.[32]

The lowest incidence of recurrence was observed in patients with *MCP* and *DGKE* mutations.[37,38] *MCP* and *DGKE* are highly expressed in the kidney, and a graft that brings normal proteins corrects the defect. However, about 20% of patients with *MCP* mutations also carry a mutation in another complement gene. Such patients have a worse graft outcome with higher incidence of recurrences than patients with an isolated *MCP* mutation.[35]

Testing affected patients for mutations on all disease-associated genes should allow patients and clinicians to make informed decisions regarding listing for transplantation based on risk for recurrence.

Most studies have shown that plasma exchange therapy fails to prevent graft loss in patients with recurrent posttransplant aHUS.[38] A preemptive plasma infusion or exchange strategy has been successful in preventing recurrent aHUS in kidney transplant recipients,[39] although aHUS recurred in some when plasma therapy was tapered.

Living-related kidney donation is contraindicated given the high risk for recurrence, and it even may be risky to donors because unine-phrectomy may precipitate aHUS if they are complement gene mutation carriers.

Complement inhibitors. The humanized anti-C5 monoclonal antibody eculizumab induces remission of acute episodes of aHUS and maintains long-term remission, both in native kidneys and in the kidney grafts, as documented in two prospective clinical trials of primarily adult patients with plasma-dependent or plasma-resistant aHUS[40] and in a pediatric trial in 22 children, of whom 12 had no prior plasma treatment. Eculizumab is now widely used as a first-line therapy for aHUS, provided that other causes of TMA are excluded (see Fig. 30.1 and Table 30.2).[25]

DGKE-mediated aHUS is generally nonresponsive to eculizumab, with the exception of patients who also present with concomitant complement abnormalities.

Eculizumab prophylaxis is used to prevent aHUS relapses after kidney transplantation. In a study of 126 kidney transplants, eculizumab prophylaxis was independently associated with longer graft survival.[41] However, this was a retrospective study and controlled prospective studies are required to evaluate the advantage, if any, of eculizumab prophylaxis versus eculizumab treatment at the time of overt aHUS recurrence in kidney transplant patients.[39]

Ravulizumab, an anti-C5 antibody engineered from eculizumab to prolong half-life, has been recently approved for the treatment of aHUS. In clinical trials, rates of remission were similar to those observed in eculizumab trials; however, fewer patients in the ravulizumab study were able to stop dialysis, possibly because of differences in patient cohorts.[42]

The main concern with eculizumab and ravulizumab is increased susceptibility to infection with encapsulated organisms, particularly *Neisseria* infections. For this reason, patients must receive meningococcal vaccination. Patients should receive vaccination against meningococcus, including type B; however, vaccination should not delay the start of eculizumab. Antibiotic prophylaxis is mandated during the first 2 weeks and is recommended for the overall treatment duration because not all serotypes are covered by vaccination.[25]

It is not clear how long anti-C5 therapy should be extended, a relevant issue because of the very high cost of the drug. In addition, the risk for sensitization associated with chronic eculizumab exposure or with its deposition in tissue suggest that careful tapering to withdrawal whenever possible should be attempted, under tight control of disease and complement activity. In a prospective multicenter study of eculizumab discontinuation in 55 children and adults with aHUS, 13 patients experienced a relapse and this was predicted by the presence of a rare complement gene variant.[43] Different clinical courses before eculizumab therapy, and different residual complement activity while on eculizumab therapy, should be taken into consideration when strategies of chronic eculizumab therapy or discontinuation are planned. Reliable biomarkers of early relapse are strongly needed. In this regard, abnormally elevated serum-induced C5b-9 deposition on cultured endothelial cells highlighted aHUS relapses during eculizumab tapering/discontinuation.[27] At present, however, this test is available in only very few specialized centers.

Liver-kidney transplant. In patients with *CFH* mutations, combined liver-kidney transplant is aimed at correcting the genetic complement defect, thus preventing disease recurrence in the transplanted kidney (see Table 30.2). Liver transplantation cures aHUS without the need for specific therapies other than standard immunosuppression to prevent graft rejection. The short-term mortality risk associated with acute complement activation in the liver graft observed in initial attempts has been substantially reduced with prophylactic plasma exchange and perioperative eculizumab. Over 80% of patients with aHUS who received liver transplants to date with the previously described preparative regimen have had excellent long-term outcomes.[44,45] However, the risks of kidney and liver transplantation have limited the widespread dissemination of this option.

SECONDARY HEMOLYTIC UREMIC SYNDROME

See Fig. 30.1 and Table 30.1.

Streptococcus pneumoniae–Associated HUS

Streptococcus pneumoniae accounts for 5% to 20% of reported pediatric HUS cases not associated with STEC.[46] Neuraminidase produced by *S. pneumoniae* cleaves N-acetylneuraminic acid from the glycoproteins on the cell membrane of erythrocytes, platelets, and glomerular cells; this exposes the normally hidden Thomsen-Friedenreich antigen (T antigen), which can then react with anti-T IgM antibodies naturally present in human serum. This reaction occurs more frequently in infants and children and causes polyagglutination of RBCs in vitro, so the Coombs test is often—although not always—positive, unlike in other forms of HUS. T-antigen exposure on RBCs is detected using the lectin *Hypogaea.* However, T-antigen exposure alone does not seem to be sufficient in causing HUS. Desialylation of cells also triggers complement activation via the alternative pathway. Severe consumption of complement components in serum during the acute phase and the identification of complement-related gene mutations in a few patients suggest a role for complement dysregulation in this form of HUS.[46]

Patients, usually younger than 2 years, present with severe illness, including respiratory distress, neurologic involvement, and coma. The acute mortality rate is about 25%. The outcome hinges on the effectiveness of antibiotic therapy. In theory, plasma infusion or exchange is contraindicated because adult plasma contains antibodies against the T antigen that may accelerate polyagglutination and hemolysis. Thus, patients should be treated with only antibiotics, washed RBCs, and fluid and kidney replacement therapy. In some cases, plasma therapy with or without steroids has been associated with recovery.

Pregnancy-Associated HUS

HUS associated with pregnancy tends to occur at term or postpartum, within 3 months of delivery in most cases. This form is associated with genetic complement abnormalities in 50% to 60% of cases[47] and massive ex vivo serum-induced C5b-9 formation on endothelium[48] and should be included in the primary aHUS group, with pregnancy acting as a trigger on a predisposed genetic background. Consistently, around 90% of published patients with pregnancy-associated HUS underwent remission with eculizumab and the drug can be given safely during pregnancy.[49]

HUS and Malignant Hypertension

Complement activation should also be suspected in patients with HUS in the setting of malignant hypertension.[26] Variants in complement genes have been reported in 35% to 65% of patients, and ex vivo serum-induced C5b-9 deposition on endothelial cells was increased, whereas it was normal in patients with malignant hypertension alone.[27,50]

Blood pressure control is fundamental. Good response to eculizumab has been reported in a small series of patients. Early detection of complement activation via the endothelial assay or by elevation of plasma sC5b-9 is crucial to identify patients who would benefit from complement inhibition, especially when the disease does not improve with blood pressure control.

Posttransplant HUS

De novo posttransplant HUS has been reported in patients receiving kidney transplants or other solid organs and has been related to calcineurin inhibitors or humoral rejection. It occurs in 5% to 10% of kidney transplant patients receiving cyclosporine and in approximately 1% of those on tacrolimus. Withdrawal of the immunosuppressive agents is usually the first line of treatment. Underlying abnormalities in complement genes have been reported in one-third of cases. Anticomplement therapy with eculizumab is effective in some but not all cases.[51] Positive C5b-9 staining in kidney biopsy and/or complement genetic abnormalities could be indications for eculizumab.

HUS complicates 10% to 40% of allogeneic bone marrow/hematopoietic stem cell transplants and is associated with high mortality.[52] The disease is multifactorial. Risk factors include immunosuppressive drugs, graft versus host disease, chemotherapy, radiation, and infections. In a large study, around 60% of patients with HSCT and HUS had at least one complement gene variant compared with 9% of patients without HUS,[53] and plasma sC5b-9 levels were elevated in the former. Other authors reported a lower incidence of complement gene abnormalities (20%–30%). Treatment remains controversial. Favorable outcomes with eculizumab have been described in a few cases.

HUS Associated With Autoimmune and Systemic Diseases

Several autoimmune diseases can be associated with HUS, including systemic lupus erythematosus (SLE), antiphospholipid syndrome, and scleroderma. The pathophysiology of HUS in these diseases is multifactorial. Although genetic complement abnormalities are rare in these patients,[54] complement activation via the classical or the alternative pathways occurs secondary to the underlying autoimmune disease (see Fig. 30.1 and Table 30.1).

Treatment of the concomitant disease should be the first line of intervention. Plasma therapy should always be attempted, even though its efficacy is poorly defined. In a few patients with persistent HUS despite treatment of SLE, the use of eculizumab was associated with an improvement in hematologic indices and/or kidney function.[26,55]

In the antiphospholipid syndrome (APS; see Chapter 29), oral anticoagulation remains the only treatment of proven efficacy to prevent and treat microvascular and macrovascular thrombosis. Rituximab may be efficacious, but further controlled studies are needed.[56] Less than 1% of patients with APS develop catastrophic APS (defined as intravascular thrombosis affecting three or more systems despite any treatments). Eculizumab has been used to treat these refractory cases, and published data showed improvement or stabilization.[26] Blood pressure control is fundamental in TMA associated with scleroderma crisis.

Drug-Induced HUS

Drug-induced HUS may result from direct toxicity of the drug to endothelial cells or is immune mediated (see Fig. 30.1 and Table 30.1). TMA, commonly resembling HUS, occurs in 2% to 10% of cancer patients treated with mitomycin C and usually in remission from their malignancy.[57] The fatality rate is about 70%; patients surviving the acute phase often remain on chronic dialysis or die later of recurrence of the tumor or metastases. Preventing the disease by corticosteroids during mitomycin treatment has been suggested and needs to be confirmed. Plasma exchange is usually attempted, but its effectiveness is unproven.

Quinine is one of the most common drugs associated with HUS.[57] It is generally used to treat muscle cramps but is also contained in beverages and nutrition health products. Quinine-dependent platelet, erythrocyte, granulocyte, lymphocyte, and endothelial antibodies may contribute to the pathogenesis. Severe kidney impairment is frequent, and hemodialysis is required in most cases. High rates of death and CKD have been reported. Quinine cessation and plasma therapy should be initiated rapidly.

TMA associated with interferon alfa is characterized by predominant kidney impairment. Recovery of the disease is common in cases of early discontinuation of the drug and prompt supportive therapy. However, kidney prognosis is usually poor, with ESKD reported in about 42% of cases.

Variants in complement genes are rare in drug-induced HUS (prevalence not different from controls) and the response after drug withdrawal was not different in patients treated with plasma, corticosteroids, or eculizumab.[26,54]

Infection-Associated HUS

HUS can occur in infections by viral (cytomegalovirus [CMV], Epstein-Barr virus, varicella zoster virus, parvovirus, human immunodeficiency virus [HIV], West Nile virus), bacterial, and other agents (Bordetella pertussis, Mycoplasma pneumoniae, toxoplasma gondii, plasmodium vivax).[26] Mechanisms are complex and include direct endothelial injury and complement activation involving any of the three activation pathways. The incidence of alternative pathway genetic abnormalities is low and varies according to the type of infection.[26]

In COVID-19 disease (see Chapter 59), there is increasing evidence that unrestrained complement activation induced by the virus in the lungs and other organs is one of the mechanisms of tissue injury, endothelial dysfunction, and TMA-like thrombosis.[58] Elevated levels of sC5b-9 and C5a have been reported in the plasma of severe COVID-19 patients, indicating terminal complement activation, and preliminary data of C5 or C5a inhibition in a few patients with severe COVID-19 are encouraging. More than 10 clinical trials of complement inhibition in COVID-19 are underway.[58]

Malignancy

Spontaneous TMA complicates almost 6% of cases of metastatic gastric carcinoma, which, in turn, accounts for about 50% of all malignant

disease–associated TMA (see Fig. 30.1 and Table 30.1). The prognosis is extremely poor. Therapy is minimally effective.

Cobalamin C Deficiency–Associated HUS

HUS can manifest in methylmalonic aciduria and homocystinuria caused by recessive mutations in the *MMACHC* gene, which result in deficiency of cobalamin C type (cblC), the most common genetic functional variant of cobalamin (vitamin B_{12}) (see Fig. 30.1 and Table 30.1). It is a rare condition, and around 40 cases of HUS associated with cblC defect have been reported. Pulmonary hypertension may accompany the disease. Diagnosis is facilitated by finding elevated plasma homocysteine and methylmalonic aciduria. HUS usually presents in early infancy, although adult onset has also been reported. Mortality is high if untreated, but metabolic therapy with hydroxocobalamin is very effective.

In summary, the term secondary HUS (or secondary TMA) includes a very heterogeneous group of conditions. Complement activity tests, like the serum-induced C5b-9 formation on endothelium, and genetic screening could allow us to reclassify each patient on etiology basis and determine whether and to what extent complement activation plays a role in the disease. Massive ex vivo C5b-9 formation on endothelium during acute episodes[27] indicates complement as a driving factor and may be used to select patients for complement inhibition. Those patients also carrying genetic complement abnormalities and/or showing chronically increased C5b-9 formation in remission[27] are most likely primary aHUS cases genetically predisposed to complement dysregulation, in whom the coexisting condition acted as a trigger of the acute episode (see Fig. 30.1 and Table 30.1).

Thrombotic Thrombocytopenic Purpura

In the microvasculature of patients with TTP, systemic platelet thrombi develop, mainly formed by platelets and von Willebrand factor (vWF). vWF plays a major role in primary hemostasis, forming platelet plugs at sites of vascular injury under high shear stress. vWF is synthesized in vascular endothelial cells and megakaryocytes as a high-molecular-weight polymer and is stored in the Weibel-Palade bodies. On stimulation, vWF is secreted by endothelial cells as ultra-large (UL) multimers that form string-like structures attached to the endothelial cells, possibly through interaction with P-selectin. Under fluid shear stress, the UL-vWF strings are cleaved to generate the range of vWF multimer sizes that normally circulate in the blood.[59] The proteolytic cleavage of vWF multimers appears to be critical to prevent thrombosis in the microvasculature.

Liver-derived ADAMTS13 is the protease responsible for cleaving vWF, creating 140- and 176-kDa fragments (Fig. 30.9). ADAMTS13 is also expressed at lower levels in renal podocytes and tubular cells, vascular endothelial cells, and platelets. The plasma concentration of ADAMTS13 is approximately 1 μg/mL (5 nmol/L). The elimination half-life of ADAMTS13 is 1 to 2 days in the circulation.

Mechanisms

ADAMTS13 is severely deficient in patients with primary TTP, leading to accumulation of UL-vWF multimers that are highly reactive with platelets.[60] Exposure of UL-vWF multimers and platelets to shear stress leads to platelet aggregation. vWF and platelets have a propensity to form aggregates at the levels of shear stress found in normal arterioles and capillaries, and this needs to be constantly regulated. By cleaving UL-vWF multimers before they are activated by shear stress to cause platelet aggregation, ADAMTS13 prevents spontaneous microvascular thrombosis in the normal circulation (see Fig. 30.9). The platelet aggregation observed in patients with TTP and ADAMTS13 deficiency is thus a direct consequence of the accumulation of UL-vWF multimers. Consequently, microvascular thrombi occur in almost all organ vessels, resulting in diffuse organ ischemia and thrombocytopenia secondary to platelet consumption.

Two mechanisms for deficiency of the ADAMTS13 activity include an acquired deficiency secondary to the formation of anti-ADAMTS13 autoantibodies (acquired TTP) and a genetic deficiency resulting from homozygous or compound heterozygous mutations in *ADAMTS13* (genetic TTP; see Fig. 30.1).

TTP associated with Anti-ADAMTS13 antibodies. This form accounts for the majority of acute cases (60%–90%) and is characterized by severe functional deficiency of ADAMTS13 because of transient, specific autoantibodies that tend to disappear during remission, and this is paralleled by normalization of ADAMTS13 activity (see Fig. 30.1 and Table 30.1).[60] Patients with TTP secondary to malignancies or HIV infection rarely have severe ADAMTS13 deficiency and inhibitory IgG antibodies.[61] Severe ADAMTS13 deficiency and ADAMTS13 inhibitory antibodies were detected in 80% to 90% of patients with ticlopidine-associated TTP and in a few patients with clopidogrel-induced TTP (see Table 30.1). The deficiency resolved after the drugs were discontinued. TTP diagnosed during pregnancy—most frequently during the second and third trimesters—accounts for 10% to 30% of all adult cases of TTP.[49] Most of these cases have acquired ADAMTS13 deficiency, but pregnancy also has been reported as a triggering event in patients with genetic ADAMTS13 deficiency (see later discussion).

TTP associated with genetic deficiency of ADAMTS13. This shiftenterrare inherited form of TTP is associated with homozygous or compound heterozygous mutation in the *ADAMTS13* gene and accounts for about 5% of all of cases of TTP (see Table 30.1). The disease is inherited as a recessive trait in patients with and without a family history of TTP[62]; more than 120 *ADAMTS13* mutations have been identified. Studies on secretion and activity of the mutated forms of *ADAMTS13* showed that most of these mutations led to impaired secretion of the protease from the cells, and when the mutated protein is secreted, the proteolytic activity is greatly reduced.

Most patients are carriers of compound heterozygous mutations; only 20% of mutations have been observed in homozygous form.

Clinical Course

Compared with patients with less severe ADAMTS13 deficiency, severely deficient patients experience a higher proportion of therapy-induced remissions (82%–88% vs. 20%–75%) and lower mortality (8%–18% vs. 18%–80%).[61] The high mortality risk in non–severely deficient patients may be because of the higher proportion of secondary causes and death from underlying diseases, such as patients with hematologic malignancies.

Among patients who have a severe ADAMTS13 deficiency, those with inhibitory antibodies experience more severe disease, take a substantially longer time to achieve clinical remission, and require a higher plasma volume than patients with genetic ADAMTS13 deficiency. In patients with inhibitory antibodies, up to 50% develop relapses and undetectable ADAMTS13 activity and persistence of anti-ADAMTS13 inhibitors during remission predict recurrences.

TTP has been reported in 1 in every 1600 to 5000 patients treated with ticlopidine, and 11 cases have been reported during treatment with clopidogrel. The overall survival rate is 67% and is improved by early treatment withdrawal and plasma therapy.

Approximately 60% of patients with genetic deficiency of ADAMTS13 experience their first acute TTP episode in the neonatal period or during infancy. A second group (10%–20%) manifests the disease after the third decade of life. TTP relapses occur in 80% of patients, but their frequency varies widely. Whereas some patients

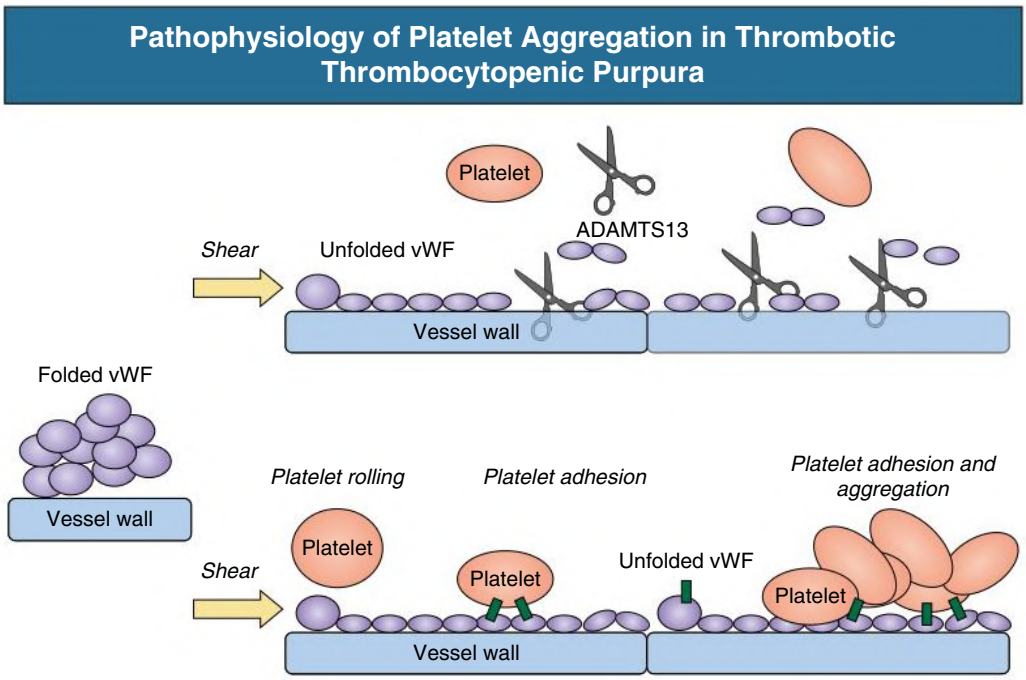

Fig. 30.9 The Pathophysiology of Platelet Aggregation in Thrombotic Thrombocytopenic Purpura. Von Willebrand factor (vWF) is synthesized and stored as ultra-large (UL) multimers in endothelial cells and megakaryocytes. On stimulation, UL-vWF multimers are secreted by endothelial cells into the circulation in a folded structure. On exposure to enhanced shear stress, UL multimers form string-like structures that adhere to endothelial cells. Normally, UL-vWF strings are cleaved by ADAMTS13 to generate vWF multimers from 500 kDa to 20 million Da and prevent thrombosis in the microvasculature *(upper panel).* When the ADAMTS13 proteolytic activity is defective because of the inhibitory effect of anti-ADAMTS13 autoantibodies or congenital defective synthesis of the protease, UL-vWF multimers accumulate and interact with activated platelets to facilitate platelet adhesion and aggregation, with thrombi formation and occlusion of the vascular lumen *(lower panel).*

with genetic ADAMTS13 deficiency depend on frequent chronic plasma infusions to prevent relapses, others remain free of disease for long periods after plasma discontinuation. The type and location of *ADAMTS13* mutations may influence the age of onset of TTP and the penetrance of the disease in mutation carriers. Mutations resulting in very low residual ADAMTS13 activity (<1%) were associated with childhood onset, relapsing disease, and kidney impairment.[8]

Environmental factors may contribute to induce full-blown manifestation of the disease. According to this two-hit model, deficiency of ADAMTS13 predisposes to microvascular thrombosis and TMA supervenes after a triggering event that activates microvascular endothelial cells and causes the secretion of UL-vWF multimers. Potential triggers of these phenomena are infections and pregnancy.

Therapy

In patients with acquired TTP, plasma is the cornerstone of therapy in an acute episode because it replaces defective protease activity. Plasma exchange, compared with infusion, also rapidly removes anti-ADAMTS13 antibodies (see Table 30.2).

Because of the potential for sudden clinical deterioration, treatment should be initiated as soon as possible after diagnosis. Treatment consists of a daily 1 to 2 plasma volume exchanges until clinical symptoms have resolved and the platelet count is stably at least 150,000/μL. Fresh-frozen plasma and cryosupernatant plasma are considered equivalent because of comparable levels of ADAMTS13.

Corticosteroids (see Table 30.2) given in combination with plasma therapy may benefit autoimmune forms of TTP by inhibiting the synthesis of anti-ADAMTS13 autoantibodies; plasma exchange will have only a temporary effect on the autoimmune basis of the disease. Two randomized clinical trials (phase 2 TITAN study and phase 3 HERCULES trial) in patients with acquired TTP found that caplacizumab, an anti-vWF humanized single variable domain immunoglobulin (nanobody), combined with plasma exchange and immunosuppressive therapy (see later), was associated with a shorter time to normalization of the platelet count than plasma exchange and immunosuppression plus placebo.[63] Caplacizumab also improved thromboembolic event rate, death rate, and relapse rate in acquired TTP.[64] Caplacizumab reduces microvascular thrombosis by inhibiting interaction between vWF multimers and platelets, but it does not affect the production of anti-ADAMTS13 autoantibodies. Thus, plasma exchange and immunosuppressive treatment are still an essential part of TTP treatment.

Prospective studies have used rituximab (see Table 30.2) in patients who failed to respond to standard daily plasma exchange and methylprednisolone and in patients with relapsed acute TTP who previously had antibodies to ADAMTS13. Treatment was associated with clinical remission, disappearance of anti-ADAMTS13 antibodies, and increase of ADAMTS13 activity to levels greater than 10%. Time to remission has been variable, from 1 to 4 weeks after the first dose. The duration of remission has ranged between 9 months and 4 years, with relapses reported in approximately 10%. Rituximab also has been used electively to prevent relapses in patients with autoantibodies.[65] Longitudinal evaluation of ADAMTS13 activity and autoantibody levels may help monitor patient responses to treatment. Retreatment with rituximab should be considered when ADAMTS13 activity decreases and inhibitors reappear into the circulation to prevent a relapse.

In genetic forms of TTP, ADAMTS13 is constitutively lacking and can be replaced by plasma therapy. During acute episodes, patients often require plasma exchange. Providing enough ADAMTS13 to achieve 5% normal enzymatic activity may be sufficient to degrade large vWF multimers—which may induce remission of the microangiopathic process—and this effect is sustained over time. Infused ADAMTS13 has a plasma half-life of 2 to 3 days in vivo, and although plasma levels fall below 5% within 3 to 7 days after plasma administration, the effect of plasma on platelet counts and clinical parameters may last up to 3 weeks, suggesting that ADAMTS13 remains available, for example, on platelets and endothelial cells. Patients with genetic ADAMTS13 deficiency tend to relapse. Patients with frequent relapses, a severe clinical course with neurologic sequelae, kidney insufficiency, and siblings who have died of TTP should be put on regular prophylactic plasma infusions every 2 to 3 weeks, which prevents episodes of acute TTP and maintains the patients in good health for years. Recombinant ADAMTS13 has demonstrated efficacy in increasing ADAMTS13 activity in a phase I/II study in patients with genetic TTP. A phase III clinical trial is ongoing (NCT03393975).

SELF-ASSESSMENT QUESTIONS

1. Which are the common clinical features characterizing patients with thrombotic microangiopathies?
   - **A.** Thrombocytopenia and nonimmune hemolytic anemia, with or without neurologic and/or renal dysfunction
   - **B.** Diarrhea and kidney dysfunction
   - **C.** Anemia, antiplatelet antibodies, and purpura
   - **D.** Disseminated intravascular coagulation
2. Which is the *most* common form of thrombotic microangiopathy?
   - **A.** Atypical hemolytic uremic syndrome
   - **B.** Shiga toxin *E. coli*–associated hemolytic uremic syndrome
   - **C.** Thrombotic thrombocytopenic purpura
   - **D.** Antiphospholipid syndrome
3. Which is the *most* common genetic abnormality associated with aHUS?
   - **A.** *C3* mutations
   - **B.** *ADAMT13* mutations
   - **C.** *CFH* mutations
   - **D.** *CFTR* mutations
4. Which of the following is *not* indicated for treatment of aHUS?
   - **A.** Conservative therapy
   - **B.** Eculizumab
   - **C.** Plasma exchange
   - **D.** Antibiotics
5. For which of the following is there an indication for rituximab?
   - **A.** TTP with congenital ADAMTS13 deficiency
   - **B.** Shiga-toxin producing *Escherichia coli*–associated HUS
   - **C.** TTP with anti-ADAMTS13 antibodies
   - **D.** aHUS associated with *MCP* mutations

Pathogenesis, Clinical Manifestations, and Natural History of Diabetic Kidney Disease

Sydney C.W. Tang, Kumar Sharma

INTRODUCTION

Diabetic kidney disease (DKD) is the leading cause of kidney failure in high-income countries. It can develop in the course of either type 1 or type 2 diabetes mellitus (DM). *Type 1 diabetes* (T1D) is an autoimmune disease characterized by antibody-mediated and cell-mediated destruction of pancreatic islets. T1D may occur at any age but usually presents before the age of 30 years. *Type 2 diabetes* (T2D) is characterized by a combination of insulin resistance and insulin deficiency. The *metabolic syndrome* (insulin resistance, visceral obesity, hypertension, hyperuricemia, and dyslipidemia) is often followed by T2D. For a long period, insulin resistance is compensated by increased insulin secretion, but a gradual decline in pancreatic β-cell mass and function finally culminates in hyperglycemia, and patients with T2D may require treatment with insulin. T2D is increasingly seen in younger adults, adolescents, and even children. Other types of DM include maturity-onset diabetes of the young, gestational diabetes, diabetes secondary to various metabolic disorders, and iatrogenic diabetes resulting from corticosteroid or other immunomodulatory treatments.

PATHOGENESIS OF DIABETIC KIDNEY DISEASE

Genetic and Environmental Factors

The risk of developing DKD is equal in T1D and T2D, and only 30% to 40% of patients with T1D or T2D will ultimately develop nephropathy. The prevalence of nephropathy in diabetic patients varies among different racial and ethnic groups such that it is relatively increased in African Americans, Native Americans, Mexican Americans, Polynesians, Aboriginal Australians, and urbanized South Asian immigrants in the United Kingdom compared with Whites. Although barriers to care likely account for some of these interpopulation differences, polygenetic factors likely also contribute.

Familial clustering of DKD has been reported in T1D and T2D and in White and non-White populations. In a person with T1D who has a first-degree relative with diabetes and nephropathy, the risk for development of DKD is 83%. The frequency is only 17% if there is a first-degree relative with diabetes but without nephropathy.[1] In T2D, familial clustering has been well documented in Pima Indians.[2] A familial determinant is also suggested by higher albumin excretion rates in offspring of patients with T2D with nephropathy. The risk is particularly high in the offspring if the mother had been hyperglycemic during pregnancy, perhaps because this causes reduced formation of nephrons ("nephron underdosing") in the offspring.[3,4] Low birthweight and nephron underdosing are also associated with hypertension, metabolic syndrome, and perhaps DKD. Nephron underdosing[5] is believed to lead to compensatory glomerular hypertrophy and increased single-nephron glomerular filtration rate (GFR), thus aggravating glomerular injury in diabetes.

The risk for DKD does not follow simple mendelian inheritance, and multiple genes are presumably involved. In patients with T1D the estimate of heritability for nephropathy was 35%; however, replication studies did not identify any single genetic variances reaching whole-genome levels of significance.[6] Nevertheless, single nucleotide polymorphisms (SNPs) in the engulfment and cell motility 1 *(ELMO1)* gene have been associated with risk for DKD in several ethnic groups with T2D.[7-9] Gene polymorphisms with 300,000 SNPs were analyzed in a large T1D cohort (over 6000 individuals with T1D and their relatives) and recently identified the protein coding gene *ARHGAP24,* associated with focal glomerulosclerosis,[10] as linked to DKD. Gene polymorphisms also may contribute to familial clustering.

Environmental factors, especially diet, may be involved in the pathogenesis of diabetes and DKD. One of the strongest risk factors is the intake of soft drinks containing added sugars such as sucrose or high-fructose corn syrup. Fructose increases uric acid levels, a predictor for the development of T2D and potentially also DKD,[11] probably via uric acid–induced oxidative stress and endothelial dysfunction. However, a randomized study with allopurinol in patients with T1D and early to moderate DKD failed to reduce the rate of progression despite lowering uric acid levels.[12] Smoking is a strong risk factor for progression of DKD and may be related to hypoxia in the kidney. Other putative associations include sleep apnea,[13] higher caloric intake, and lower levels of exercise.

Hemodynamic Changes

Hyperfiltration is common in early diabetes but can be corrected with good glycemic control. Increased GFR involves glucose-dependent effects causing afferent arteriolar dilation mediated by a range of vasoactive mediators, including insulin-like growth factor 1 (IGF-1), transforming growth factor-β (TGF-β1), vascular endothelial growth factor (VEGF), nitric oxide (NO), prostaglandins, and glucagon (Fig. 31.1). Over time, vascular disease of the afferent arteriole may result in permanent alterations in kidney autoregulation that favor glomerular hypertension. Kidney injury in DKD is caused not only by hemodynamic disturbances (e.g., hyperfiltration, hyperperfusion) but also by disturbed glucose homeostasis, and the two pathways interact. For example, shear stress increases glucose transport into mesangial cells by upregulation of specific glucose transporters. Furthermore, shear

stress and mechanical strain resulting from altered glomerular hemodynamics trigger autocrine and paracrine release of cytokines and growth factors in the glomerulus.

DKD is also associated with tubular abnormalities in which angiotensin II (Ang II) causes hypertrophic proximal tubular growth and increased sodium reabsorption.[14] Specific inhibition of the sodium glucose cotransporter-2 (SGLT2) in proximal tubular cells slowed progression of DKD, highlighting the role of tubuloglomerular feedback and glomerular hyperfiltration in DKD (see Chapter 32).[15] shiftenterInsulin itself stimulated matrix production in proximal tubular epithelial cells (TECs), and deficiency of the insulin receptor specifically in proximal TECs protected against obesity-induced kidney disease,[16] implicating a key role of elevated insulin levels in kidney disease progression.

Glomerular Changes

Kidney growth occurs early after the onset of diabetes. Glomerular enlargement is associated with increased mesangial cell number, hypertrophy, and increase of capillary loops, thus enhancing the filtration surface area. Renal tubular hypertrophy is primarily the result of TEC proliferation and hypertrophy.

Experimentally, avoidance of hyperglycemia prevents kidney hypertrophy. Hyperglycemia causes hypertrophy by stimulating growth factors in the kidney, including IGF-1, epidermal growth factor (EGF), platelet-derived growth factor (PDGF), VEGF, TGF-β, and Ang II. Hyperglycemia also induces thrombospondin, a potent activator of latent TGF-β. Antagonizing TGF-β in diabetic patients, however, did not confer beneficial effects on kidney function or proteinuria.[17] Similarly, inhibition of VEGF prevented glomerular hypertrophy in models of DKD and reduced albuminuria.[18] Urine EGF levels are linked to progression of chronic kidney disease (CKD) of multiple etiologies, including DKD.[19]

The pathologic hallmarks of diabetic nephropathy (DN) are mesangial expansion, nodular diabetic glomerulosclerosis (the acellular Kimmelstiel-Wilson lesion), and diffuse glomerulosclerosis. Mesangiolysis likely plays a key role in cell loss and nodule formation. Increasing evidence suggests that local NO deficiency contributes to these histologic lesions, in particular nodule formation.

The mechanisms underlying the emergence of albuminuria start with widening of the glomerular basement membrane (GBM) with accumulation of type IV collagen and net reduction in negatively charged heparin sulfate proteoglycan (see the section Kidney

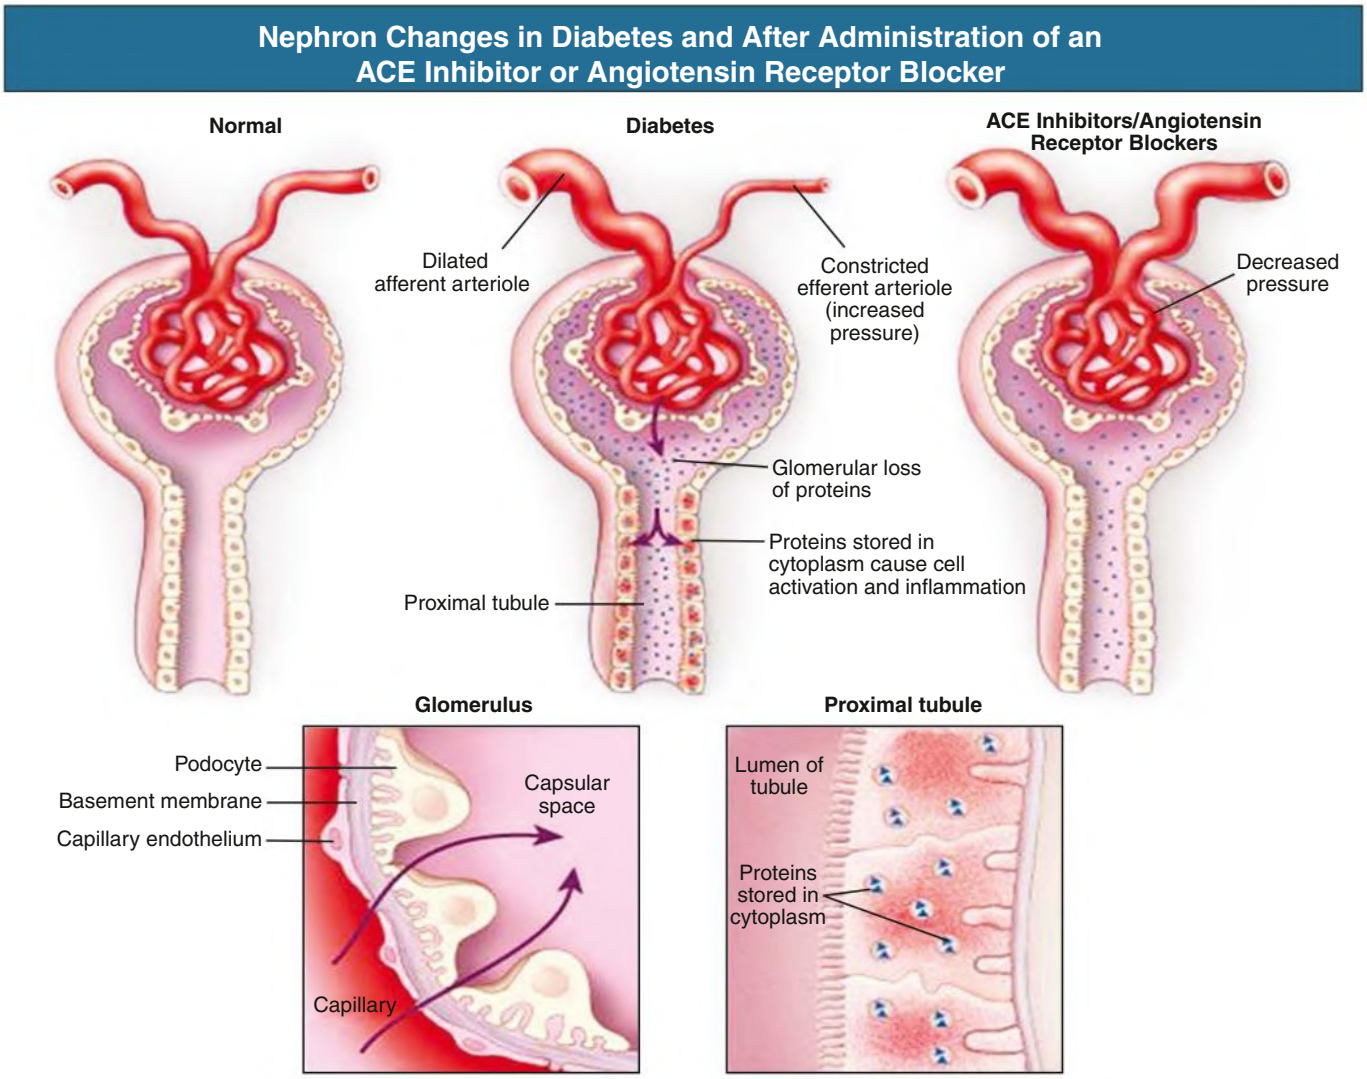

Fig. 31.1 Comparison of normal nephron, nephron in diabetic kidney disease (DKD), and nephron in DKD after angiotensin-converting enzyme (ACE) inhibitor/angiotensin receptor blocker (ARB) administration. Note afferent vasodilation and efferent angiotensin II–mediated vasoconstriction in DKD causing glomerular hypertension, which is relieved by an ACE inhibitor and ARB therapy. Note also protein leakage into the filtrate and tubular loading, with endocytosed protein causing an inflammatory reaction that promotes interstitial fibrosis. This is reversed by ACE inhibitor/ARB treatment.

Pathology). The expression of one permeability-controlling protein, nephrin, is abnormally low in DKD.[18] Its transcription is suppressed by Ang II and restored by renin-angiotensin system (RAS) blockers. Apoptosis of podocytes is triggered by various factors, including Ang II and TGF-β, and adhesion of podocytes to the GBM is reduced by advanced glycation end products (AGEs)-induced suppression of neuropilin-1. Podocyte loss also follows hyperglycemia-induced reactive oxygen species (ROS) generation, causing podocyte apoptosis or detachment. ROS generation in podocytes may be largely mediated by Nox4,[20,21] although other contributors of ROS have also been implicated. Migration of podocytes is also attenuated by the reduction of neuropilin-1, thereby preventing surviving podocytes from covering denuded areas of GBM, which promotes development of focal segmental glomerulosclerosis (FSGS).

Crosstalk between glomerular endothelial cells and podocytes involves activated protein C (APC), the formation of which is regulated by endothelial thrombomodulin and is reduced in diabetic mice.[22] In DKD, thrombomodulin-dependent APC formation inhibits podocyte apoptosis.[23] In cultured podocytes, administration of the adipocyte-specific hormone adiponectin prevented high glucose–induced podocyte dysfunction. Endothelial cell dysfunction associated with altered fenestrations and glycocalyx may contribute to enhanced permeability. Adiponectin levels are low in patients with the metabolic syndrome or T2D, which may contribute to the development of albuminuria[20]; however, once diabetes is established, elevated adiponectin levels correlate with faster progression of disease. In advanced DKD, albuminuria evolves into nonselective proteinuria with high-molecular-weight serum proteins escaping the GBM with disrupted texture, gaps, and holes.

Tubular and Inflammatory Changes

Tubulointerstitial injury ultimately determines the rate of attrition of kidney function. In vitro studies demonstrate the pathogenic role of various diabetic substrates in promoting tubule hypertrophy, extracellular matrix (ECM) production, and inflammation,[18] which is a complex process with a large number of interacting pathways that lead to a chronic inflammatory infiltrate, which includes macrophages and other immune cells that release cytokines and profibrotic factors and interact with intrinsic kidney cells to create a profibrotic microenvironment. Chemokines and their receptors, in particular monocyte chemotactic protein-1 (MCP-1/CCL2), RANTES/CCL5, IL-6, and tumor necrosis factor (TNF) receptors, as well as adhesion molecules (e.g., ICAM-1), contribute to persistent inflammation that triggers a profibrotic cascade in the kidney (Fig. 31.2).[18,24] Glomerular cells, TECs, macrophages/lymphocytes, and fibroblasts/myofibroblasts all contribute to matrix accumulation along the glomerular and tubular basement membranes and within the interstitium. Myofibroblasts promote progression of fibrosis in DKD by facilitating deposition of interstitial ECM (Fig. 31.3). Soluble TNF receptors appear to be a robust biomarker for progressive kidney disease in both T1D and T2D. Th17 immune cells and their effector cytokine IL-17A take part in diabetes-mediated kidney damage and could be a promising therapeutic target.[25]

Bardoxolone methyl, as an inducer of the KEAP1-Nrf2 pathway, exhibits antiinflammatory effects. Although the BEACON trial was terminated due to safety concerns about early heart failure, a post hoc analysis[26] revealed reduction in albuminuria coupled to estimated glomerular filtration rate (eGFR) reduction. The Japanese TSUBAKI study trial showed that bardoxolone methyl increased GFR among 65 patients with T2D and stage 3 or 4 CKD versus placebo.[27] The oral CCR2 inhibitor CCX140-B for 52 weeks reduced residual albuminuria in subjects with T2D.[28] The FIDELIO-DKD study[29] found that finerenone, a nonsteroidal blocker of the mineralocorticoid receptor (half-life ~2 hours and without metabolites), reduced the rate of progression of DKD in T2D without causing hyperkalemia. Any beneficial effects of finerenone may be mediated by reductions in inflammation, as its blood pressure lowering effects were minimal.

Clinical studies showed that even mild anemia (hemoglobin level <12.5 g/dL for men, <11.5 g/dL for women) increases the risk for progression of DKD. Anemia presumably causes kidney hypoxia. Moreover, hypoxia is exacerbated by the progressive hyalinosis of the afferent and efferent arterioles and loss of peritubular capillaries. In experimental chronic kidney injury, hypoxia is an important factor aggravating interstitial fibrosis. The transition of TECs into fibroblasts is stimulated by cellular hypoxia.[30] The induction of growth factors and cytokines is mediated by hypoxia-inducible factor-1 (HIF-1), which can be amplified by Ang II. However, the TREAT trial[31] showed that anemia treatment with darbepoetin-alfa initiated at a hemoglobin level of around 10.5 g/dL does not slow the rate of GFR loss in both diabetic and nondiabetic CKD.

Hyperglycemia

Role of Glucose Control

The following clinical evidence sheds light on the role of tight glycemic control in slowing the development of DKD:

- In the Diabetes Control and Complications Trial (DCCT), there was a remarkable reduction in progression from normoalbuminuria to moderately increased albuminuria and other microvascular complications, specifically retinopathy, in patients with T1D with tight glycemic control.[32]
- Euglycemia that followed isolated pancreatic transplantation was associated with regression of diabetic glomerulosclerosis after 10 years.[33]
- In the United Kingdom Prospective Diabetes Study (UKPDS), reducing the hemoglobin A_{1c} (HbA_{1c}) level by approximately 0.9% in patients with T2D reduced the risk for microvascular complications, including nephropathy.[34]
- In the ADVANCE study, intensive glucose control with a target HbA_{1c} level of 6.5% was associated with a long-term reduction in kidney failure, without evidence of any increased risk for cardiovascular events or death.[35]
- In the EMPA-REG study, individuals with type 2 diabetes treated with empagliflozin with lower glycated hemoglobin levels had significant reduction in cardiovascular and kidney events, though the protective effects of the SGLT2 inhibitor are likely beyond simply glycemic control.[15]
- In the CREDENCE trial,[36] canagliflozin reduced the risk of kidney failure and cardiovascular events among 4401 individuals with type 2 diabetes with an eGFR of 30 to 90 mL/min per 1.73 m^2 and albuminuria 300 to 5000 mg/g after a median follow up of 2.62 years. These benefits were consistent across eGFR subgroups, including those initiating treatment at eGFR 30 to 45 mL/min per 1.73 m^2.[37]
- In the DAPA-CKD trial,[38] dapagliflozin conferred kidney and cardiovascular protection among patients with diabetic and nondiabetic CKD with eGFR 25 to 75 mL/min per 1.73 m^2 and albuminuria 200 to 5000 mg/g, suggesting that the clinical benefits of SGLT2i are a class effect that extends to people with CKD. The larger EMPA-KIDNEY trial (NCT03594110), which recruited patients with eGFR down to 20 mL/min/1.73 m^2 will further address the latter possibility.

A unifying theory was that hyperglycemia leads to diabetic complications through an accumulation of mitochondrial superoxide production and oxidative sequelae.[39] As the kidneys are highly active metabolically and require vast amounts of adenosine triphosphate (ATP) for their normal function, they are

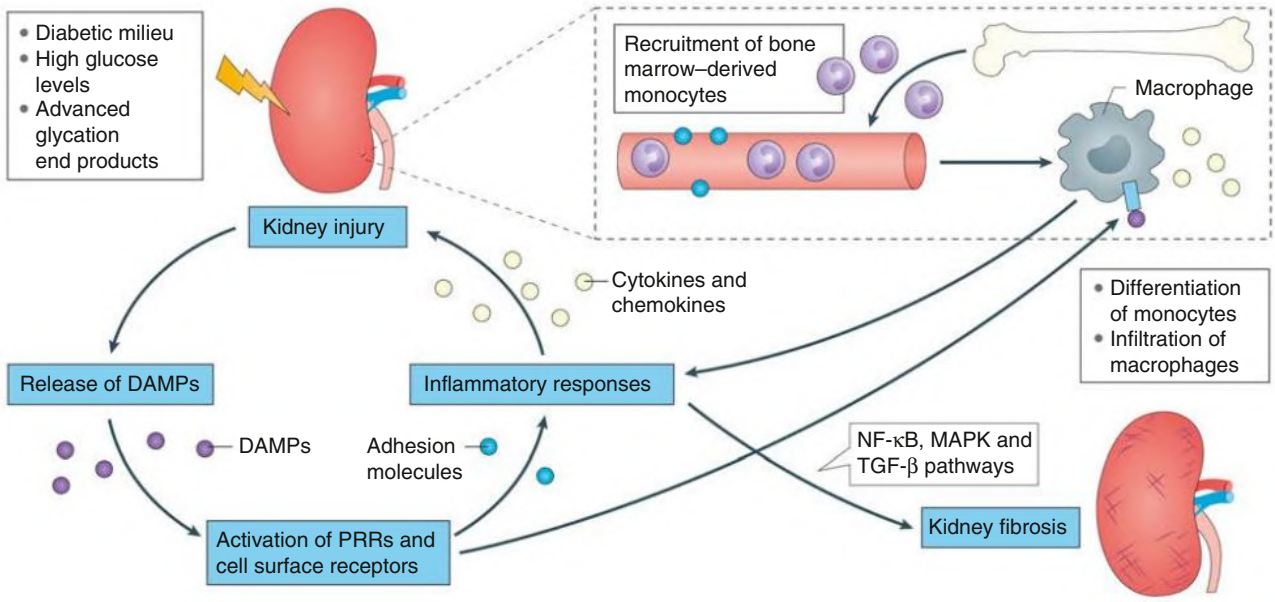

Fig. 31.2 Crosstalk Between Endothelial Cells and Podocytes Involving Protein C. Under physiologic conditions, protein C is activated by the binding of thrombin to its cofactor, thrombomodulin, on glomerular endothelial cells. The formed complex catalyzes the conversion of protein C to its catalytically activated form, which has potent anticoagulant, profibrinolytic, antiinflammatory, and cytoprotective effects. In DKD, the production of activated protein C (APC) in the glomerulus is reduced because of suppression of thrombomodulin expression. Decreased functional activity of APC affects the permeability of the glomerular capillary wall and enhances apoptosis of glomerular endothelial cells and podocytes. (From Gilbert RE, Marsden PA. Activated protein C and diabetic nephropathy. *N Engl J Med.* 2008;358:1628–1630.)

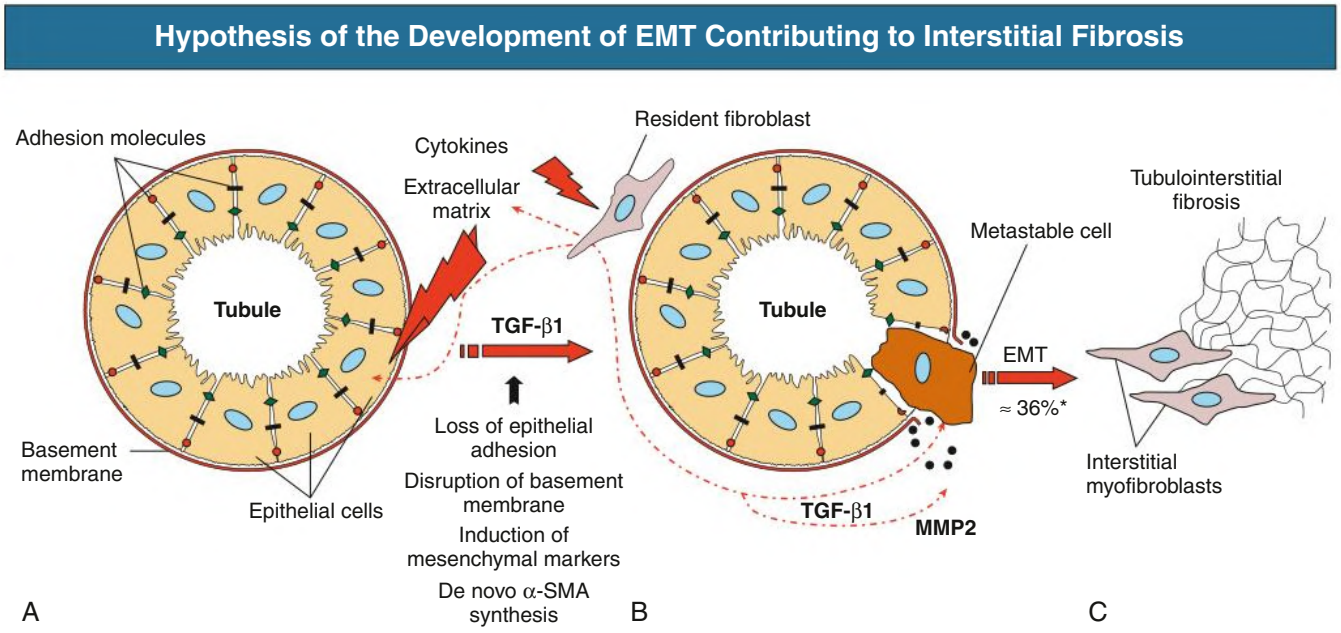

Fig. 31.3 Hypothesis of the Development of Epithelial-Mesenchymal Transition (EMT) Contributing to Interstitial Fibrosis. Initiated by external stimuli (e.g., cytokines), tubular cells lose their cell-cell contacts (e.g., E-cadherin) (A) and start to express mesenchymal markers (e.g., α-SMA, vimentin) (B). After disruption of tubular basement membrane (by MMP2), metastable cells disengage themselves from cell connective and transdifferentiate to interstitial myofibroblasts that synthesize extracellular matrix and contribute to fibrosis (C). *MMP,* Matrix metalloproteinase; *SMA,* smooth muscle actin; *TGF-β1,* transforming growth factor-β1. *Up to 36% of all interstitial myofibroblasts in diabetic kidney disease are thought to derive from EMT. (Modified from Loffler I. Pathophysiology of diabetic nephropathy. In: Wolf G, ed. *Diabetes and Kidney Disease.* Wiley-Blackwell; 2013.)

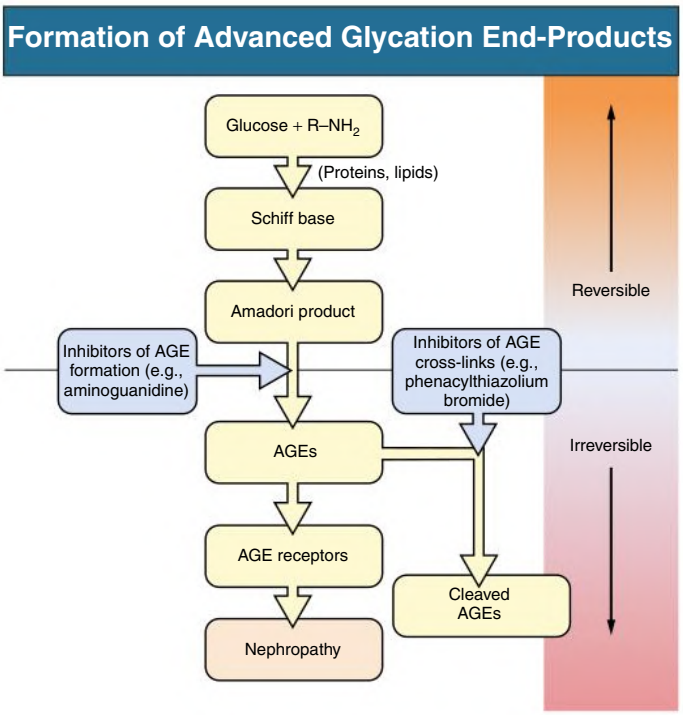

Fig. 31.4 Mechanism of formation of advanced glycation end-products (AGEs).

mitochondrially rich. Diabetes alters the delivery of substrates and oxygen to the kidneys, and changes in metabolic fuel sources to meet ATP demands result in increased oxygen consumption, which contributes to kidney hypoxia. Mitochondrial fission and fusion events enable energy demands to be met and provide mitochondrial quality control. Disruption of these events in diabetes reduces mitochondrial biogenesis, as reflected by a deficiency of the master regulator of mitochondrial biogenesis peroxisome proliferator-activated receptor γ coactivator 1α.[40] Restoring mitochondrial biogenesis and mitochondrial superoxide levels is associated with reduced inflammation, albuminuria, and fibrosis in experimental DKD.[41] The protective effect of SGLT2 inhibitors may be mediated by normalizing mitochondrial function,[42] and enhancing SIRT1 and hypoxia inducible factor 2α (HIF-2α) signaling[43] that can explain the biologic consequences of ketonemia and erythrocytosis. Recent studies using urine metabolomics have identified that mitochondrial dysfunction plays a role in progression of DKD,[44-46] and one recent clinical study[47] demonstrated that SGLT2 inhibitors have beneficial effects on markers of mitochondrial function. There is likely an important role for hepatic ketone generation in response to SGLT2 inhibition, which may be a preferential fuel for kidney proximal TECs and cardiac myocytes.

Pathways Related to Glucose Metabolism

Protein kinase C (PKC) is a family of serine-threonine kinases that regulate diverse vascular functions. PKC-α mediates diabetic podocyte injury via phosphorylation of p66SHC and its inhibition by Klotho overexpression attenuated podocyte injury and proteinuria in streptozocin-treated mice.[48] Protein kinase C–η mediates advanced oxidation protein product–induced mitochondrial dysfunction and oxidative stress in kidney tubular cells.[49]

Chronic hyperglycemia leads to nonenzymatic glycation of amino acids and proteins (Maillard or Browning reaction)[50] (Fig. 31.4).

AGEs are increased in the serum, glomeruli, and tubules of DKD patients. They bind to macrophages, mesangial cells, and tubular cells and mediate cellular actions, including expression of adhesion molecules, cell hypertrophy, ECM synthesis, epithelial-mesenchymal transition (EMT), and inhibition of NO synthetase (NOS). AGEs injected in vivo induce albuminuria and glomerulosclerosis.[50] AGEs induce podocyte hypertrophy, followed by apoptosis and suppression of nephrin synthesis. Among several binding sites, the most important is RAGE (receptor for advanced glycation end product), which is present in tubular cells and podocytes. Ang II stimulates upregulation of RAGE on podocytes.[51] This effect is mediated by Ang II (AT_2) receptors not blocked by sartanes.[51] One of the actions of RAGE is activation of nuclear factor-κB (NF-κB). The soluble extracellular domain of RAGE (sRAGE) acts as a decoy receptor and experimentally ameliorates kidney lesions in diabetes.[50] In T1D, sRAGE is associated with progression from severely increased albuminuria to kidney failure, though causality could not be established.[52] In T2D, sRAGE is an early predictor of renovascular complications.[53]

Blocking the binding of AGEs to its receptor using a RAGE-aptamer could inhibit tubular injury in diabetic mice partly by suppressing the AGE-RAGE-oxidative stress axis and improving insulin resistance independent of glycemic control.[54] A selective RAGE inhibitor, FPS-ZM1, combined with valsartan alleviated podocyte injury in streptozocin-treated rats by restoring nephrin and synaptopodin expression and lowering albuminuria and serum cystatin C.[55]

The AGE/RAGE interaction upregulated myo-inositol oxygenase (MIOX), a tubule-specific enzyme modulating redox balance, to induce ROS generation and NF-κB activation to cause tubulointerstitial injury.[56] Dietary supplementation of d-glucarate in diabetic mice decreased MIOX expression, attenuated tubular damage, and improved kidney function by attenuating mitochondrial fragmentation, oxidative stress, and apoptosis and restoring autophagy/mitophagy in tubular cells.[57] In transgenic models, MIOX overexpression accentuated, whereas its knockdown protected the diabetic kidney in mice from tubulointerstitial injury.[58]

Finally, some fructose-6-phosphate is diverted into the hexosamine pathway, increasing the concentrations of *N*-acetylglucosamine, which modifies certain transcription factors, such as Sp1 activity. In turn, Sp1 upregulates key fibrotic mediators, such as TGF-β1 and plasminogen activator inhibitor 1.

Adenosine Monophosphate Kinase

The energy-sensing enzyme 5′-adenosine monophosphate kinase (AMPK) shiftenterpathway may contribute to DKD. Inhibition of 5′-AMP-activated protein kinase in caloric-excess states has been linked to inflammation (NF-κB, nicotinamide adenine dinucleotide phosphate [NADPH] oxidase, monocyte chemotactic protein-1 [MCP-1] stimulation), vascular dysfunction (endothelial NOS inhibition), stimulation of hypertrophy (mammalian target of rapamycin complex [activation]), and profibrotic pathways (TGF-β signaling).[59-61] Stimulation of AMPK is beneficial in both type 1 and type 2 models of DKD. Key regulators of mitochondrial health-adenosine monophosphate kinase, sirtuins, and PCG1α (peroxisome proliferator-activated receptor γ coactivator-1α) have all been shown to play significant roles in the resilience of the kidney against disease.[62]

Activation of Innate Immunity

Diabetes can be considered a metabolic danger signal that is effected via toll-like receptors (TLRs), a conserved family of pattern recognition

receptors that play a fundamental role in innate immunity.[24] In particular, TLR-4 is overexpressed in the kidney tubules of human DN biopsies.[63,64] In vitro, silencing TLR-4 ameliorated high glucose–induced tubular cell inflammation. In experimental DKD, either systemic deletion or the application of a TLR-4 antagonist conferred renoprotection.[64] In addition, TLRs are also expressed in other resident kidney cell types such as podocytes and mesangial cells, as well as infiltrating macrophages, that could act in concert to bring about an inflammatory phenotype observed in DKD (Fig. 31.5). The NLRP3 inflammasome links sensing of metabolic stress in the diabetic kidney to activation of proinflammatory cascades via the induction of IL-1β and IL-18. The kallikrein-kinin system promotes inflammatory processes via the generation of bradykinins and the activation of bradykinin receptors, and activation of protease-activated receptors on kidney cells by coagulation enzymes contributes to kidney inflammation and fibrosis in DKD.

A key component of innate immunity includes the NADPH oxidase pathway, expressed primarily in the lysosomes of phagocytic cells, but also in the kidney. Enhanced Nox4 in podocytes may contribute to glomerular disease involving a pathway linking Nox to the citric acid cycle.[65]

Complement has been increasingly implicated in DKD. Increased levels of C5a were detected in kidney tubules from patients with biopsy confirmed DN and its intensity correlated with the progression of the disease.[66] In experimental DKD, genetic deletion of C5aR1 in mice conferred protection against diabetes-induced kidney injury and in vitro, C5a/C5aR propagated injury during DKD by disrupting mitochondrial agility.[67]

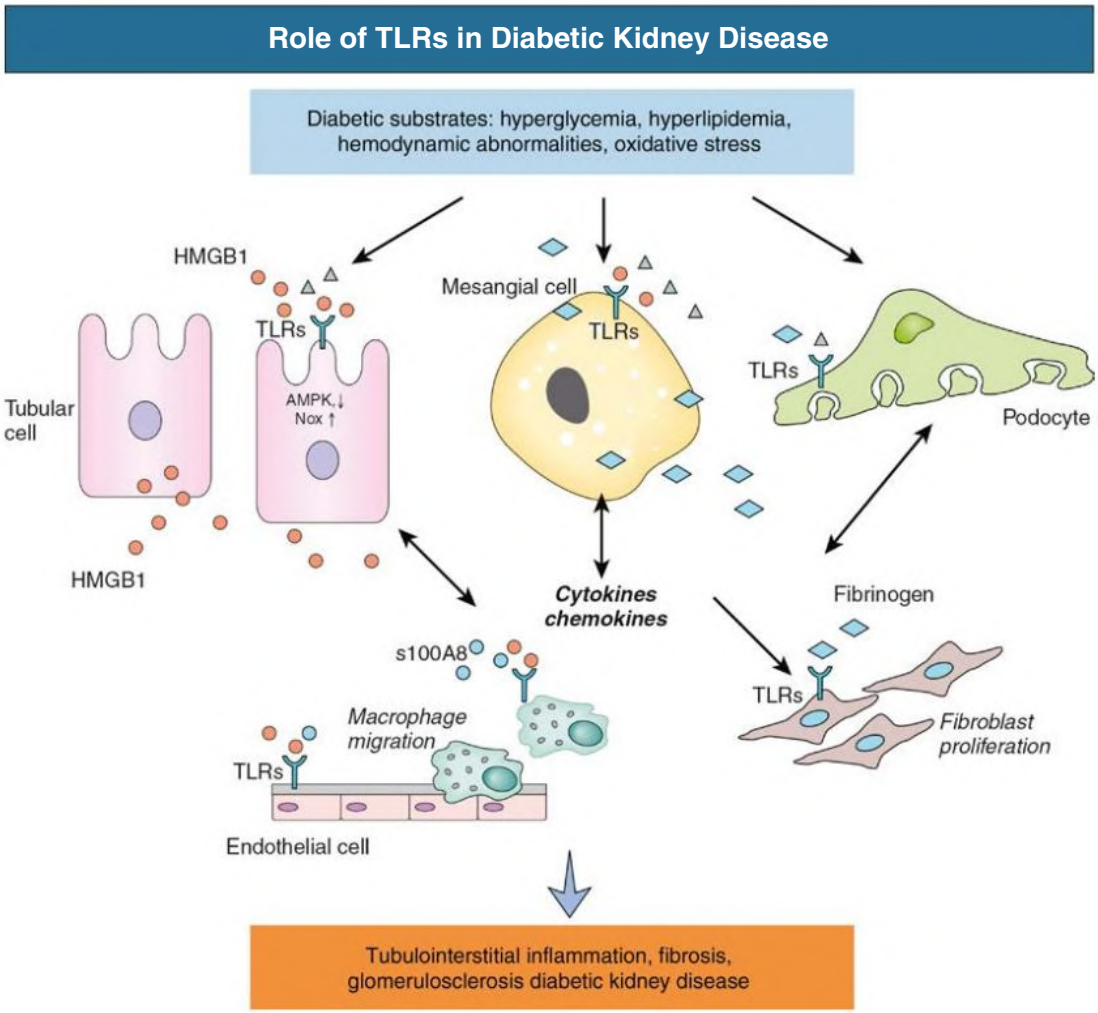

Fig. 31.5 Role of Toll-like Receptors (TLRs) in Diabetic Kidney Disease. Toll-like receptors in resident kidney cells could recognize and respond to the metabolic stress of diabetes or endogenous ligands activated during the diabetic state, inducing downstream signaling events to propagate the synthesis of proinflammatory cytokines and chemokines, which act as effectors to further facilitate macrophage recruitment and fibroblast proliferation, leading to a self-perpetuating cycle of kidney inflammation and subsequent tubulointerstitial fibrosis and glomerulosclerosis. *AMPK,* 5′-Adenosine monophosphate kinase; *HMGB1,* high-mobility group box-1 protein; *S100A8,* S100 calcium binding protein A8. (Modified from Lin M, Yiu WH, Wu HJ, et al. Toll-like receptor 4 promotes tubular inflammation in diabetic nephropathy. *J Am Soc Nephrol.* 2012;23:86–102.)

Lipotoxicity

Lipotoxicity is increasingly implicated in the pathogenesis of DKD. In obesity, a myriad of metabolic disturbances including chronic systemic low-grade inflammation and insulin resistance are directly or indirectly associated with not only obesity, but also other metabolic diseases like metabolic syndrome, obesity-related T2D, nonalcoholic fatty liver disease, and cardiovascular disease. Animal and in vitro studies have identified saturated fatty acids as the dominant nonesterified fatty acids in the circulation of obese subjects that act as nonmicrobial agonists to trigger the inflammatory response via activating TLR4 signaling.[68] Increased lipogenesis predicted DKD in T2D.[69] In experimental DKD, kidney VEGF-B expression correlates with the severity of disease and inhibiting its signaling reduces kidney lipotoxicity, resensitizes podocytes to insulin signaling, inhibits the development of diabetic pathologies, and prevents kidney dysfunction.[70]

Epigenetics and Epigenomics

Epigenetic mechanisms involve chromatin histone modifications, DNA methylation, and noncoding RNAs.[71] The first miRNA shown to have a functional role in DKD was miR-192, which acts by targeting key repressors to promote the expression of ECM and collagen and to augment the profibrotic effects of TGF-β1. Numerous miRNAs are now thought to regulate key features of DKD, such as podocyte apoptosis, ECM accumulation, glomerular and tubular hypertrophy, and fibrosis.

LncRNAs are long transcripts (>200 nucleotides and up to ~100 kb in length) that have many similarities with mRNAs but lack protein-coding (translation) potential. They have distinct cellular roles that affect various biologic mechanisms and processes. These mechanisms can respond to changes in the environment and mediate persistent expression of DKD-related genes and phenotypes induced by prior exposure to the diabetic milieu despite subsequent glycemic control, a phenomenon called metabolic memory. A number of lncRNAs could play a pivotal role in development and progression of DKD either via direct involvement or as indirect mediators of nephropathic pathways, such as TGF-β1, NF-κB, STAT3, and GSK-3β signaling. Some lncRNAs may therefore become biomarkers for early diagnosis or prognosis of DKD or as therapeutic targets for DKD.

Gut Microbiome

Among patients with T2D with normoalbuminuria or moderately or severely increased albuminuria, the levels of phenyl sulfate, a gut microbiota–derived metabolite, significantly correlated with basal and predicted 2-year progression of albuminuria in patients with moderately increased albuminuria.[72] In experimental diabetes, phenyl sulfate administration induced albuminuria and podocyte damage, and inhibition of tyrosine phenol-lyase, a bacterial enzyme responsible for the synthesis of phenol from dietary tyrosine before it is metabolized into phenyl sulfate in the liver, reduces albuminuria. Applying broad-spectrum oral antibiotics or fecal microbiota transplantation from healthy donors to diabetic rats decreased serum acetate levels and alleviated tubulointerstitial injury,[73] suggesting that gut microbiota reprogramming might become a new strategy for DKD.

Renin-Angiotensin-Aldosterone System and Diabetic Kidney Disease

Angiotensin-converting enzyme (ACE) inhibitors or angiotensin receptor blockers (ARBs) slow progression of DKD (see Chapter 32). Although plasma renin activity is low in DKD, it is inappropriate in relation to increased extracellular volume and exchangeable sodium, suggesting activation of the RAS.[74] In experimental diabetes, sites of local RAS activation have been identified in glomeruli and TECs.[74] High glucose and AGEs stimulate angiotensinogen and renin expression in various kidney cells, mainly through ROS.[74] Proteinuria further activates the local RAS of tubular cells.

Ang II has many nonhemodynamic effects and mediates cell proliferation, hypertrophy, ECM expansion, and cytokine (TGF-β, VEGF) synthesis.[74] Therefore, ACE inhibitors and ARBs presumably act via hemodynamic and nonhemodynamic actions.

Aldosterone accelerates progression in kidney damage models independently of Ang II. In DKD, aldosterone escape has been linked to progression of proteinuria (see Chapter 32). Aldosterone synthesis is stimulated in DKD, and this steroid hormone stimulates the synthesis of other proinflammatory and profibrogenic cytokines (MCP-1, shiftenterTGF-β).[75] The beneficial effects of the mineralocorticoid receptor blocker finerenone is likely mediated via its antiinflammatory action.

Other vasoactive agents involved in the pathogenesis of DKD include endothelin, NO, the kallikrein-kinin system, and natriuretic peptides. The SONAR trial[76] showed that the selective endothelin-A receptor antagonist atrasentan, administered to 1325 T2D patients with eGFR 25 to 75 mL/min/1.73 m^2 and albuminuria 300 to 5000 mg/g creatinine versus 1323 placebo control subjects reduced the risk of kidney events after a median follow-up of 2.2 years, though at an increased risk of fluid retention and anemia.

Uric Acid and Fructose

An elevated uric acid level can predict the development of DKD. Uric acid is generated during the metabolism of fructose when it induces mitochondrial oxidative stress. In addition to dietary fructose from added sugars, there is increasing evidence that in diabetes, fructose is generated in the kidney, where it is metabolized to uric acid that may mediate kidney injury. Thus, both dietary and endogenous production of fructose may be involved in the development of diabetes and its complications.[77] Lowering of serum urate levels with allopurinol among 267 individuals with T1D with DKD versus 263 placebo control subjects in the PERL[12] (Preventing Early Renal Function Loss) trial, however, did not affect kidney outcomes.

EPIDEMIOLOGY

The US Renal Data System 2020 Annual Report (www.USRDS.org) revealed in 2018 that DKD was the most frequent primary diagnosis accounting for 47.1% of incident patients being started on kidney replacement therapy. The China Kidney Disease Network (CKD-NET) 2016 Annual Data Report[78] published in 2020 revealed DKD to be the top cause of CKD, accounting for 26.7% of CKD. The proportion of diabetes among patients with kidney failure varies considerably among countries, but in many countries DKD is the leading cause of kidney failure.[79] Classic features of DKD were observed in about 60% of diabetic patients (i.e., normal kidney size despite kidney failure; proteinuria >1 g/2 h with or without retinopathy); 13% had an atypical presentation with ischemic nephropathy, and in 27% a known primary kidney disease coexisted with diabetes. An important mode of presentation has become irreversible acute kidney injury (AKI), for example, after administration of nonsteroidal antiinflammatory drugs (NSAIDs), cardiac events, and septicemia. Many patients also lose the clinical manifestations

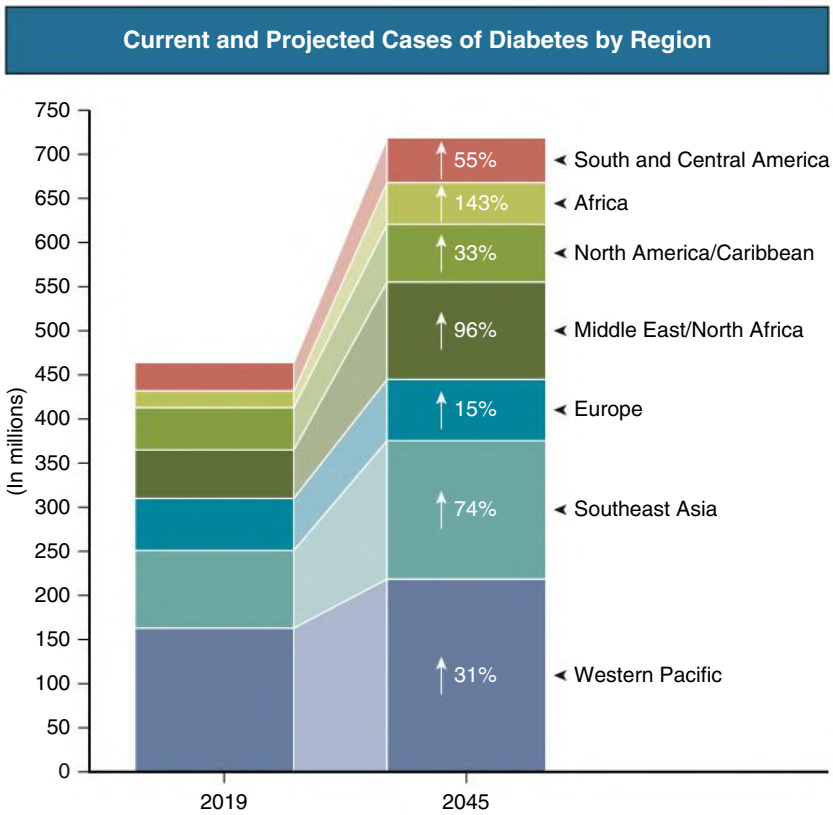

Fig. 31.6 Predicted Increase in Diabetes Prevalence by Geographic Region Over the Next Two Decades. The rate of increase is greatest in the developing world. (Modified from Saeedi P, Petersohn I, Salpea P, et al.; IDF Diabetes Atlas Committee. Global and regional diabetes prevalence estimates for 2019 and projections for 2030 and 2045: results from the International Diabetes Federation Diabetes Atlas, 9th edition. *Diabetes Res Clin Pract*. 2019;157:107843.)

of overt diabetes (e.g., hyperglycemia) because of CKD-associated weight loss, impaired kidney gluconeogenesis, or increased insulin half-life in CKD.

The proportion of patients with T1D and T2D who develop proteinuria and elevated serum creatinine concentration is related to the duration of diabetes. Diabetes and its complications caused an estimated 4.2 million deaths worldwide in 2019, of which half occurred in patients below the age of 60, and more than half were caused by increased risks for cardiovascular and other diseases. There is a more rapid increase in the prevalence of T2D in lower-income versus higher-income regions: 4 out of 5 people with diabetes live in low- and middle-income countries, and these countries are predicted to experience the greatest surge in diabetes over the next 25 years (Fig. 31.6).[80] For example, the prevalence of diabetes from 2019 is predicted to increase by 143% in Africa, 74% in Southeast Asia, and 55% in South and Central America by 2045 versus 33% in North America, 15% in Europe, and 31% in the Western Pacific. In Africa and the Middle East/North Africa, 75% and 50% of deaths due to diabetes were in people younger than 60 years, respectively. In Asia, high mortality from diabetes is most prominent in patients aged 50 to 60 years, which translates to a reduction in life expectancy of more than a decade. Up to 60% of Asian patients with diabetes have elevated albuminuria, compared with 30% to 40% reported in Western diabetic populations in cross-sectional surveys.[81]

CLINICAL MANIFESTATIONS AND NATURAL HISTORY

Diabetic kidney disease is part of a generalized microvascular and macrovascular disease.

Obesity, Metabolic Syndrome, and Kidney Disease

The metabolic syndrome—defined by the presence of three or more of certain factors (increased waist circumference, elevated triglycerides, decreased high-density lipoprotein, elevated blood pressure [BP], and elevated fasting blood glucose concentration)—is increasingly recognized as a major contributor to cardiovascular diseases with a negative impact on kidney function.[82,83] Obesity is often defined as body mass index greater than 30, although different values define obesity in other countries (e.g., China, India, Japan). Obese individuals have large kidneys and glomerulomegaly, with increased kidney blood flow, increased filtration fraction, and glomerular hyperfiltration.[84] Obese patients have moderate albuminuria even in the absence of hypertension. The resemblance of obesity-related kidney disease to early DKD is striking. In addition, sleep apnea, which is common in obese individuals, leading to hypoxic episodes, may contribute to kidney impairment. Visceral adipocytes are a potent source of deleterious factors[85] and could have an impact on kidney function (Ang II, leptin, TNF-α). By contrast, the secretion and

plasma concentration of adiponectin, an adipokine with cardiovascular protective, antidiabetic, and antiinflammatory properties, are markedly decreased in obesity and its related pathologies (see the section Glomerular Changes). Thus, kidney changes may occur years before the manifestation of T2D during obesity and the development of the metabolic syndrome.

Evolution of Diabetic Kidney Disease

One of the earliest changes of kidney function in patients with T1D and many with T2D is an increase in GFR, or hyperfiltration, which is accompanied by an increase in kidney size. The next observable change is the development from normal (<30 mg albumin/24 h) to *moderately increased albuminuria* (30-300 mg albumin/24 h or 30 to 300 mg/g or 3 to 30 mg/mmol creatinine, graded as A2 by the Kidney Disease: Improving Global Outcomes [KDIGO] nomenclature[86]), previously termed *microalbuminuria*. This may progress to severely increased albuminuria (>300 mg albumin/24 h or >300 mg/g or >30 mg/mmol creatinine; graded as A3 by KDIGO), previously termed *macroalbuminuria* (Table 31.1). Williams[87] proposed a scheme of the natural history and pathophysiology of nephropathy typically observed in T2D over a period of 20 years (Fig. 31.7).

TABLE 31.1 Classification of Albuminuria Categories

	URINE ALBUMIN EXCRETION			
	24-hr Urine	SPOT URINE		
Condition	(mg/day)	(mg/g Cr)	(mg/mmol Cr)	Category
Normoalbuminuria	<30	<30	<3	A1
Moderately increased albuminuria	30–300	30–300	3–30	A2
Severely increased albuminuria	>300	>300	>30	A3

Mogensen[88] proposed a scheme of the different stages of DKD that is largely valid in T1D but less reliable in T2D. In the latter, CKD may occur in the absence of albuminuria, possibly as a result of macrovascular disease. Of note, with improved glycemic and BP control there is a growing population of patients with T1D with normoalbuminuria who have progressive DKD.[87] In this cohort, progressive kidney function decline, not albuminuria, is the predominant clinical feature. The putative mechanisms that initiate and sustain progressive kidney function decline in T1D are not well known. In clinical practice, annual eGFR decline is expected to be within 5 mL/min/1.73 m^2 while on a RAS blocker, and further investigation and more frequent monitoring are warranted for attrition rates above this level.

Hypertension and Diabetic Kidney Disease

In patients with T2D, hypertension often precedes the onset of diabetes by years. At diagnosis of T2D, an abnormal BP and an abnormal circadian BP profile are found in 80% of patients. Prediabetic hypertension increases the risk for onset and progression of DKD. The onset of DKD in T2D further increases BP, though this relationship is generally much less than in T1D. The pathogenesis of hypertension in T2D is complex and involves RAS activation, direct sympathetic nerve activation, and macrovascular changes.[89] Furthermore, genetic factors defining primary hypertension as well as diabetes are clustered (Fig. 31.8).

In DKD, nocturnal BP decrease is frequently attenuated, and this nondipping phenomenon may precede the onset of moderately increased albuminuria.[89] Furthermore, BP responses to exercise tend to be exaggerated. Stiffening of the aorta increases the peak systolic pressure and decreases the diastolic pressure, resulting in increased BP amplitude, which explains why isolated systolic hypertension is so common in patients with T2D.[90] Low diastolic pressure increases

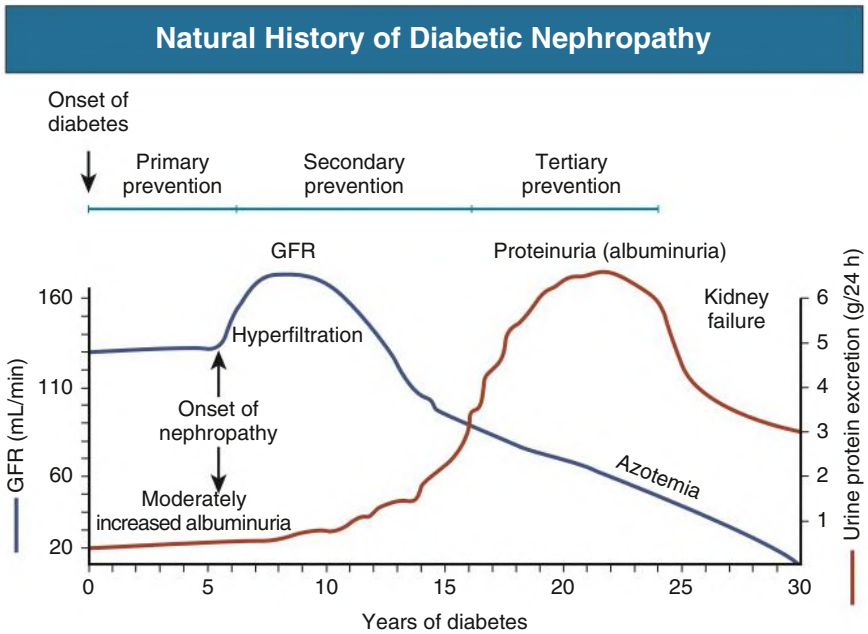

Fig. 31.7 Natural History of Diabetic Nephropathy. Changes in glomerular filtration and proteinuria over time from the onset of diabetes. Proteinuria reduction is shown as a tertiary prevention. *GFR,* Glomerular filtration rate. (From Krolewski AS. Progressive renal decline: the new paradigm of diabetic nephropathy in type 1 diabetes. *Diabetes Care.* 2015;38[6]:954–962.)

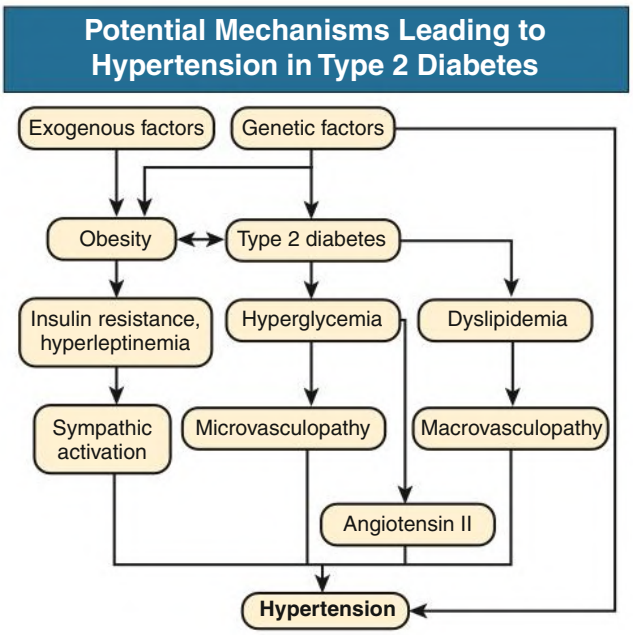

Fig. 31.8 Overview of Potential Mechanisms Leading to Hypertension in Patients With Type 2 Diabetes. Genetic susceptibility factors for primary hypertension and diabetes may be clustered so that an individual patient may have a higher incidence of both diseases. Obesity and metabolic syndrome lead to insulin resistance and hyperleptinemia associated with sympathetic nerve activation. Hyperglycemia directly activates the renin-angiotensin system and, in addition, stimulates development of hypertension through kidney microvasculopathy. Dyslipidemia leads to stiffness of vessels and hypertension through macrovasculopathic alteration.

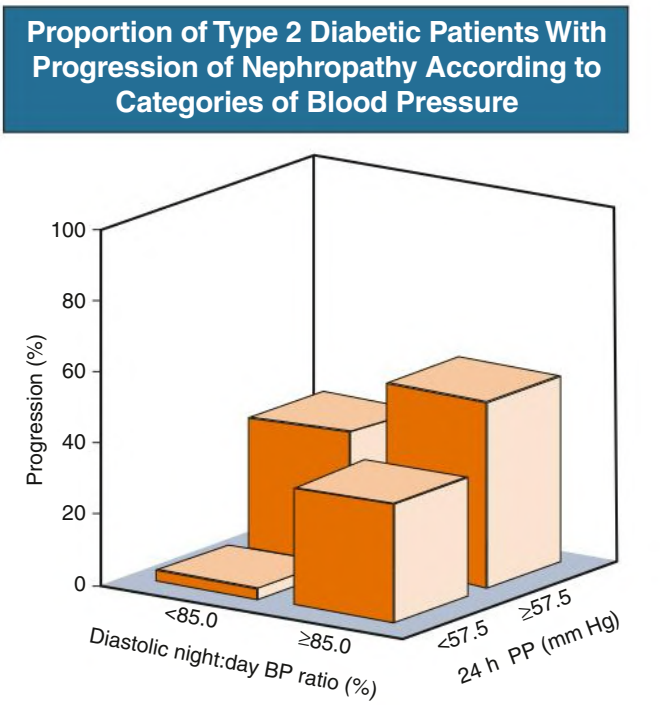

Fig. 31.9 Proportion of Patients With Type 2 Diabetes With Progression of Nephropathy According to Categories of Blood Pressure (BP). Progression risk according to categories of nighttime to daytime diastolic BP (median value <85% or ≥85%) and 24-hour ambulatory pulse pressure (PP) (median value <57.5% or ≥57.5%). (From Knudsen ST, Laugesen E, Hansen KW, et al. Ambulatory pulse pressure, decreased nocturnal blood pressure reduction and progression of nephropathy in type 2 diabetic patients. *Diabetologia.* 2009;52:698–704.)

the risk for coronary events because coronary perfusion occurs during diastole only.[91] Augmented pulse pressure and impaired nocturnal BP decline are independent predictors of nephropathy progression in T2D (Fig. 31.9). The increased prevalence of sleep apnea in DKD also contributes to hypertension.[92]

Associated Extrarenal Microvascular and Macrovascular Complications

Diabetic retinopathy is present in virtually all patients with T1D and albuminuria from DN. In contrast, only 50% to 60% of proteinuric patients with T2D have retinopathy.[93,94] Consequently, the absence of retinopathy does not exclude the diagnosis of DN in patients with T2D.[94] In patients with DN, retinopathy tends to progress more rapidly, hence more frequent ophthalmologic monitoring is needed.

Many patients with DN also have polyneuropathy. Sensory polyneuropathy is an important cause of the diabetic foot, which correlates with loss of kidney function. Because cardiac innervation is defective, pain and angina are frequently absent when the patient has coronary heart disease and myocardial infarction. Further consequences of autonomic polyneuropathy are gastroparesis and diarrhea or constipation (see Chapter 89). Erectile impotence and detrusor paresis with delayed and incomplete emptying of the bladder are common urologic problems.

The major macrovascular complications associated with DKD are stroke, coronary heart disease, and peripheral vascular disease,[95,96] with a fivefold higher frequency than diabetic patients without DKD.

Survival in Patients With Diabetic Kidney Disease

The presence of DKD greatly increases mortality in patients with both T1D and T2D. Compared with the general population, mortality in patients with T1D and no proteinuria is elevated by two- to threefold, which increased to 20-fold to 200-fold with proteinuria.[97,98]

The major increase in risks occurs not only with the onset of albuminuria (Fig. 31.10) but also in the upper normal range of albuminuria (Fig. 31.11). Urinary albumin excretion is a good predictor of cardiovascular events.[98] Albuminuria likely reflects generalized endothelial cell dysfunction with an increased risk for atherosclerosis[98] and other associated cardiovascular risk factors, such as elevated BP, dyslipoproteinemia, increased platelet aggregation, and increased C-reactive protein concentration. Other biomarkers for progressive DKD have been described including soluble TNFR1 or TNFR2,[99] and other urine metabolites such as aconitic acid and 3-hydroxyisobutyrate.[45]

KIDNEY PATHOLOGY

After the onset of diabetes, kidney weight increases by an average of 15%. Kidney size remains increased until overt nephropathy is established. Most patients with T1D have a sustained increase in glomerular volume and glomerular capillary luminal volume. These changes are accompanied by hypertrophy of the interstitium.[100]

In patients having diabetes for more than 10 years, regardless of whether nephropathy is present, GBM thickening up to three times the normal range of 270 to 359 nm is common (Fig. 31.12). In advancing DKD, there is a consistent correlation between GBM thickness and fractional mesangial volumes with albuminuria.

Nodular glomerular intercapillary lesions in advanced DKD were described in 1936 by Kimmelstiel and Wilson (Fig. 31.13C).[101] The nodules are located in the central regions of peripheral glomerular lobules as well-demarcated eosinophilic and periodic acid–Schiff–positive masses (see Fig. 31.13C–D). When they are not acellular, nodules contain pyknotic nuclei. It is suggested that nodules result from microaneurysmal dilation of the associated capillary followed by mesangiolysis and laminar organization of the mesangial debris with lysis of the center of the lobule. Foam cells often surround the nodules. These appearances, reported in only 10% to 50% of biopsy specimens in both T1D and T2D, are also seen in diseases with a membranoproliferative glomerulonephritis pattern (see Chapter 22), in amyloidosis and light-chain deposition disease (see Chapter 28), and specific stains and immunofluorescence findings, respectively, will clarify the diagnosis.

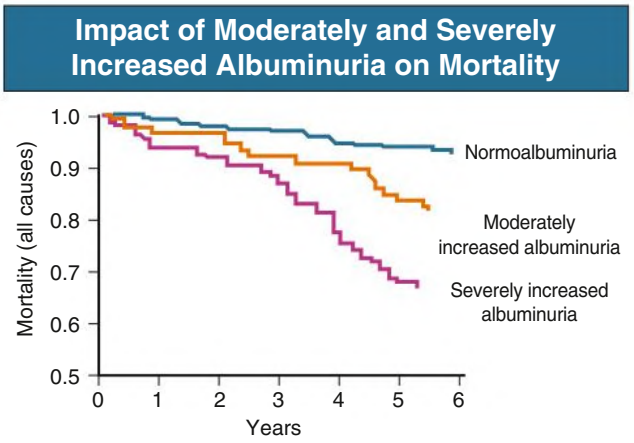

Fig. 31.10 Influence of Microalbuminuria and Macroalbuminuria on Mortality. The influence of microalbuminuria and macroalbuminuria on mortality was evaluated prospectively in 328 White patients with non–insulin-dependent diabetes mellitus observed for 5 years. Microalbuminuria and macroalbuminuria led to a significant increase in total mortality compared with that in patients who remained normoalbuminuric. (From Gall MA, Borch-Johnsen K, Hougaard P, et al. Albuminuria and poor glycemic control predict mortality in NIDDM. *Diabetes.* 1995;44:1303–1309.)

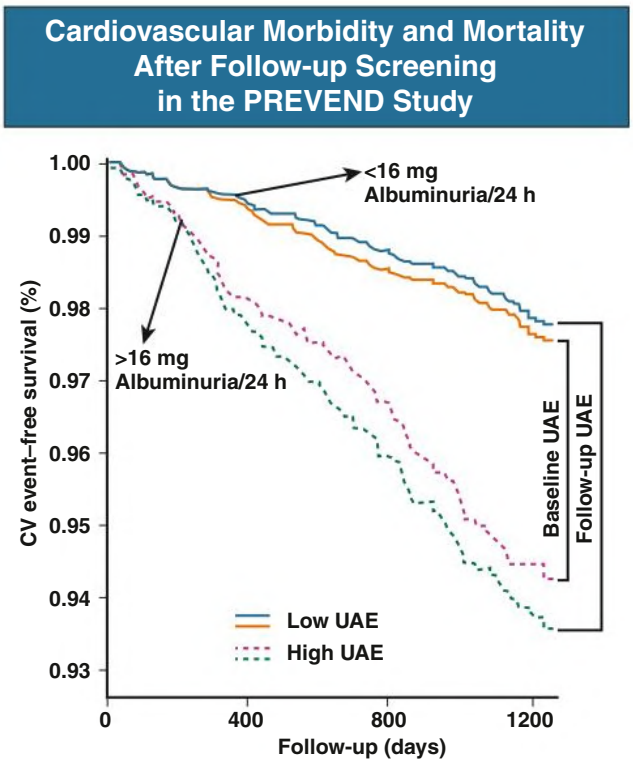

Fig. 31.11 Event-Free Survival for Cardiovascular (CV) Morbidity and Mortality After Follow-up Screening in the PREVEND Study. Individuals are stratified according to the presence of a high or low urinary albumin excretion (UAE). High and low UAE are defined by either the UAE measurement from the baseline screening *(orange and purple lines)* of approximately 4.2 years before follow-up screening or the repeated UAE measurement at time of the follow-up screening *(blue and green lines)*. To allow comparison, the survival curves for the 6800 individuals with either the baseline or follow-up measurement of UAE are plotted in the same graph. A high UAE *(dashed lines)* is defined as a UAE ≥16.2 mg/24 h, being the 75th percentile of UAE with use of the UAE measurement of the baseline screening. (From Brantsma AH, Bakker SJ, de Zeeuw D, et al; PREVEND Study Group. Extended prognostic value of urinary albumin excretion for cardiovascular events. *J Am Soc Nephrol.* 2008;19:1785–1791.)

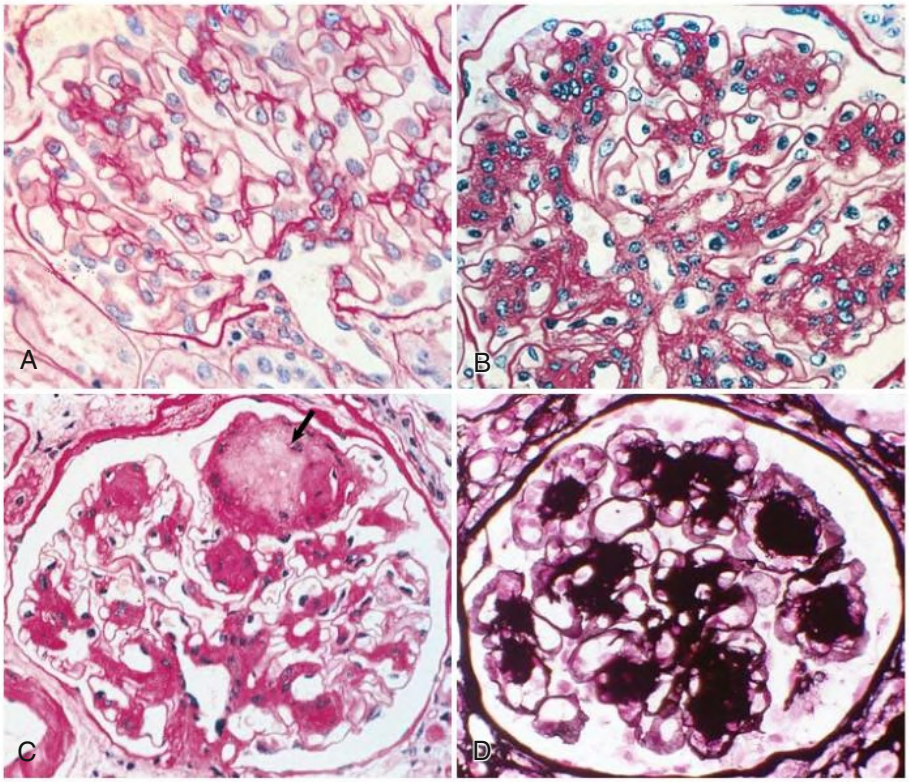

Fig. 31.13 Light Microscopy of Glomerular Changes in Diabetic Kidney Disease. (A) Normal glomerulus. (B) Diffuse glomerular lesion. Widespread mesangial expansion. (C) Nodular lesion and mesangial expansion. There is a typical Kimmelstiel-Wilson nodule at the top of the glomerulus *(arrow).* (D) Nodular lesion. Methenamine silver staining shows the marked nodular expansion of mesangial matrix. (A–C, Periodic acid–Schiff reaction.)

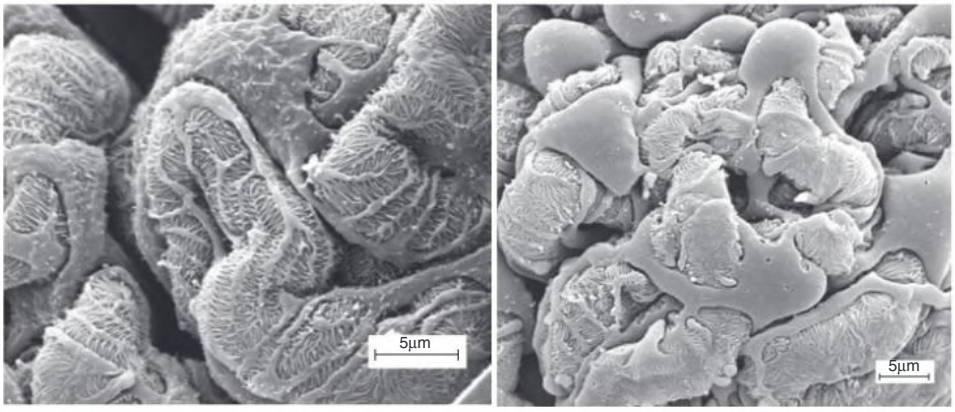

Fig. 31.14 Electron Micrograph of External Surface of Glomerular Tufts From Rats After Removal of Bowman's Capsule by Freeze Fracture. *Left,* Normal rat kidney with podocyte cell body; the primary processes and terminal foot processes resting on the glomerular capillary basement membrane are seen clearly. *Right,* In the diabetic rat kidney, the decrease in the density of foot processes and the denuded glomerular capillary basement membrane are apparent. (From Marshall SM. The podocyte: a major player in the development of diabetic nephropathy? *Horm Metab Res.* 2005;37[suppl 1]:9–16.)

Diffuse glomerular lesions occur more often than nodular lesions, seen in 90% of patients with T1D greater than 10 years and in 25% to 50% of T2D patients. They consist of an increase of mesangial matrix extending to involve the capillary loops (see Fig. 31.13B). In contrast to nodular lesions, which are of little functional significance, the degree of diffuse glomerulosclerosis and in particular mesangial matric expansion correlates with worsening kidney function.[102] In more severe disease, capillary wall thickening and mesangial expansion lead to capillary narrowing (see Fig. 31.12B) and hyalinization, with accompanying periglomerular fibrosis.

Podocytes are involved early in the course of DKD in T1D and T2D (Fig. 31.14), and an increase in foot process width is already observed with only slight increases in albuminuria.[103,104] Longitudinal studies demonstrated a reduction in podocyte number that closely correlated with proteinuria.[103]

Arteriolar lesions are prominent in diabetes. Hyaline material progressively replaces the entire wall structure and involves both the afferent and efferent vessels, which is highly specific for diabetes.

A new classification of DN was introduced in 2007. This classification considers not only glomerular changes (Fig. 31.15) but also pathologic alterations of the tubulointerstitium and vasculature.[105] Immunohistologic examination is usually negative, but linear immunoglobulin G (IgG) can be seen occasionally because of passive trapping in the GBM (Fig. 31.16).

Tubulointerstitial fibrosis and tubular atrophy may be the best pathologic correlates for progressive decline in GFR. Tubulointerstitial fibrosis and renal arteriolosclerosis are more prevalent in T2D than

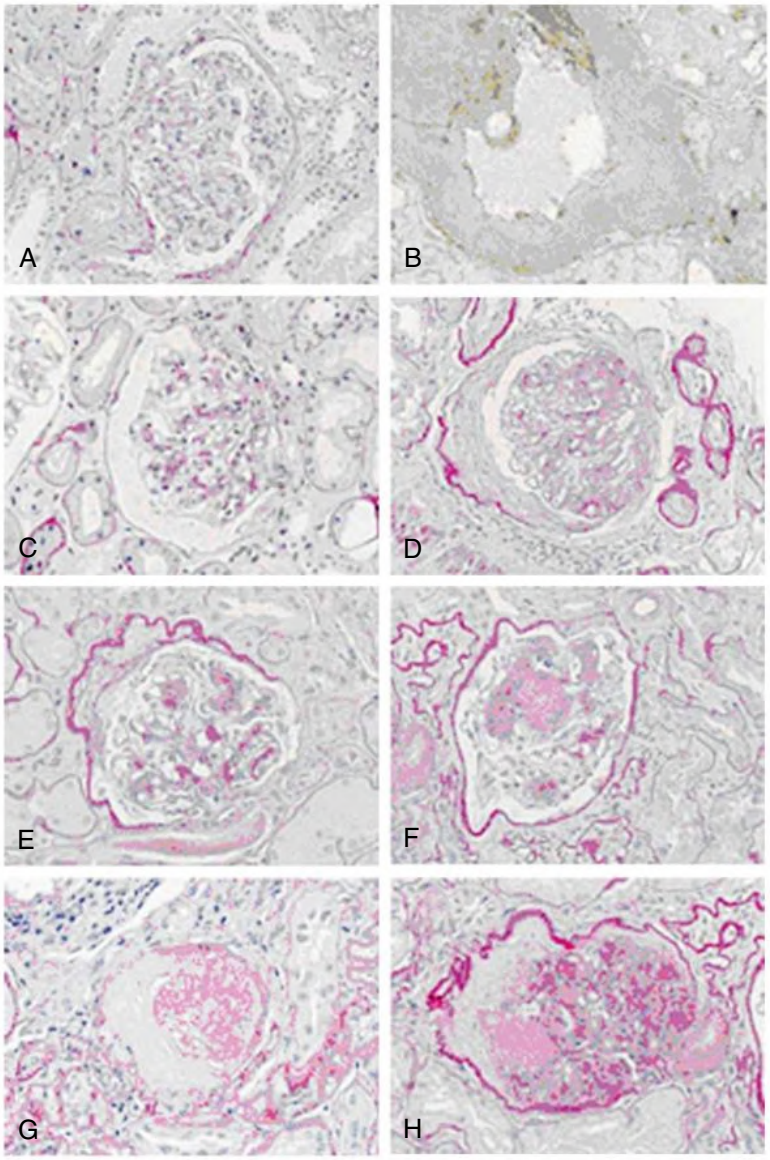

Fig. 31.15 Pathologic Classification of Diabetic Kidney Disease (DKD). Representative examples of the morphologic lesions in DKD. (A) Glomerulus showing only mild ischemic changes, with splitting of Bowman's capsule. No clear mesangial alteration. (B) Electron micrograph of this glomerulus. The mean width of the glomerular basement membrane was 671 nm (mean taken over 55 random measurements). Electron microscopy provides the evidence for classifying the biopsy with only mild light microscopy changes into class I. (C–D) Class II glomeruli with mild and moderate mesangial expansion, respectively. In part C, the mesangial expansion does not exceed the mean area of a capillary lumen (IIa), whereas in part D it does (IIb). (E–F) A class III Kimmelstiel-Wilson lesion is seen in part F. The lesion in part E is not a convincing Kimmelstiel-Wilson lesion; therefore, on the basis of the findings in this glomerulus, the finding is consistent with class IIb. For the purpose of the classification, at least one convincing Kimmelstiel-Wilson lesion (as in F) needs to be present. (G) Example of glomerulosclerosis that does not reveal its cause (glomerulus from same biopsy as H). (H) Signs of class IV DKD consist of hyalinosis of the glomerular vascular pole and a remnant of a Kimmelstiel-Wilson lesion on the opposite site of the pole. For the purpose of the classification, signs of DKD should be histopathologically or clinically present to classify a biopsy with global glomerulosclerosis in more than 50% of glomeruli as class IV. (From Tervaert TW, Mooyaart AL, Amann K, et al. Pathologic classification of diabetic nephropathy. *J Am Soc Nephrol.* 2010;21:556–563.)

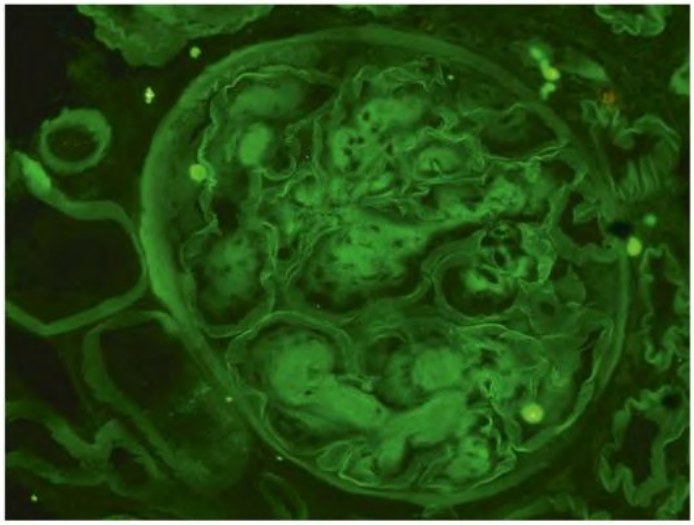

Fig. 31.16 Immunofluorescence for Glomerular Immunoglobulin G (IgG) in Diabetic Nephropathy. Faint staining of the glomerular basement membrane (GBM) for IgG results from passive trapping of IgG in the expanded GBM. (Courtesy Prof. Peter Furness, Leicester, UK.)

T1D. In fact, kidney structure is heterogeneous in patients with T2D; only a subset of patients with T2D have typical diabetic glomerulopathy, whereas others have more advanced tubulointerstitial and vascular rather than glomerular lesions or have normal or near-normal kidney structure,[105] or even features suggestive of glomerular ischemia.

DIAGNOSIS AND DIFFERENTIAL DIAGNOSIS

The diagnosis of DKD is based on the detection of proteinuria. In addition, most patients also have hypertension and retinopathy. The main evaluation procedures in the patient with suspected DKD include:

- Measurement of urinary albumin or protein
- Measurement of serum creatinine concentration and estimation of GFR
- Measurement of BP
- Ophthalmologic examination

Measurement of Albuminuria or Proteinuria

There is substantial individual day-to-day variation in albumin excretion (coefficient of variation, 30%–50%) and day and night differences (Fig. 31.17). Even in the upper quantiles of so-called normoalbuminuria, the risk for progression and cardiovascular events is elevated. At concentrations of 30 to 300 mg/24 h, albumin is normally not detected by conventional dipsticks for proteinuria. Albumin can be detected by special dipsticks for moderately increased albuminuria or by a suitable laboratory assay. A first-void morning urine sample is preferred. The normal range is less than 20 μg/mL.

The detection of urinary albumin is a specific indicator of DN only if confounding factors such as fever, physical exercise, urinary tract infection, nondiabetic kidney disease, hematuria from other causes, heart failure, uncontrolled hypertension, and uncontrolled hyperglycemia have been excluded.[106]

The main advantage of testing for moderately increased albuminuria early is that it predicts a high kidney and cardiovascular risk and thus allows targeted intervention. The American Diabetes Association, KDIGO, and others recommend annual testing of albumin-to-creatinine ratio (more costly) or protein-to-creatinine ratio.

By definition, there is clinically overt DKD (or severely increased albuminuria) if the rate of albumin excretion exceeds 300 mg/day. At this point, serum proteins other than albumin are usually excreted in the urine as well (nonselective proteinuria).

Measurement of Blood Pressure

The following points should be noted:

- In overweight T2D patients, the size of the cuff should be adapted to the upper arm circumference. When this exceeds 32 cm, cuffs of 18 cm width are indicated.
- Patients with severe autonomic neuropathy tend to develop orthostatic hypotension, defined as a decrease of systolic BP by more than 20 mm Hg in the upright position.
- The circadian BP profile tends to be abnormal in the early stages, and even a paradoxical increase in nocturnal BP is not rare. In DKD patients, increase in nocturnal BP is independently associated with a 20-fold higher mortality and a higher risk for kidney failure. Ambulatory BP recordings are useful to assess the efficacy of antihypertensive treatment.
- In diabetic patients with sclerosis or calcification of the radial and brachial arteries, there may be pseudohypertension characterized by spuriously elevated BP despite normotension upon intraarterial BP measurements with a discrepancy between mild target organ damage (e.g., left ventricular hypertrophy) and very high measured BP values. Such patients tend to develop marked hypotension even with modest antihypertensive therapy.

Measurement of Serum Creatinine and Estimation of Glomerular Filtration Rate

Serum creatinine concentration may be inaccurate in cachexic patients with low muscle mass. This problem is particularly frequent in elderly patients with T2D. KDIGO recommends reporting estimated GFR in adults using the 2009 CKD-EPI (Chronic Kidney Disease Epidemiology Collaboration) creatinine equation.

Differential Diagnosis

Although hematuria is one of the atypical features indicating the presence of nondiabetic kidney disease in patients with diabetes, it may be present in DKD. Moreover, a study identified hematuric patients with pathologically defined DKD, who had significantly lower kidney function than nonhematuric patients with DKD.[107] The prevalence of nephrotic

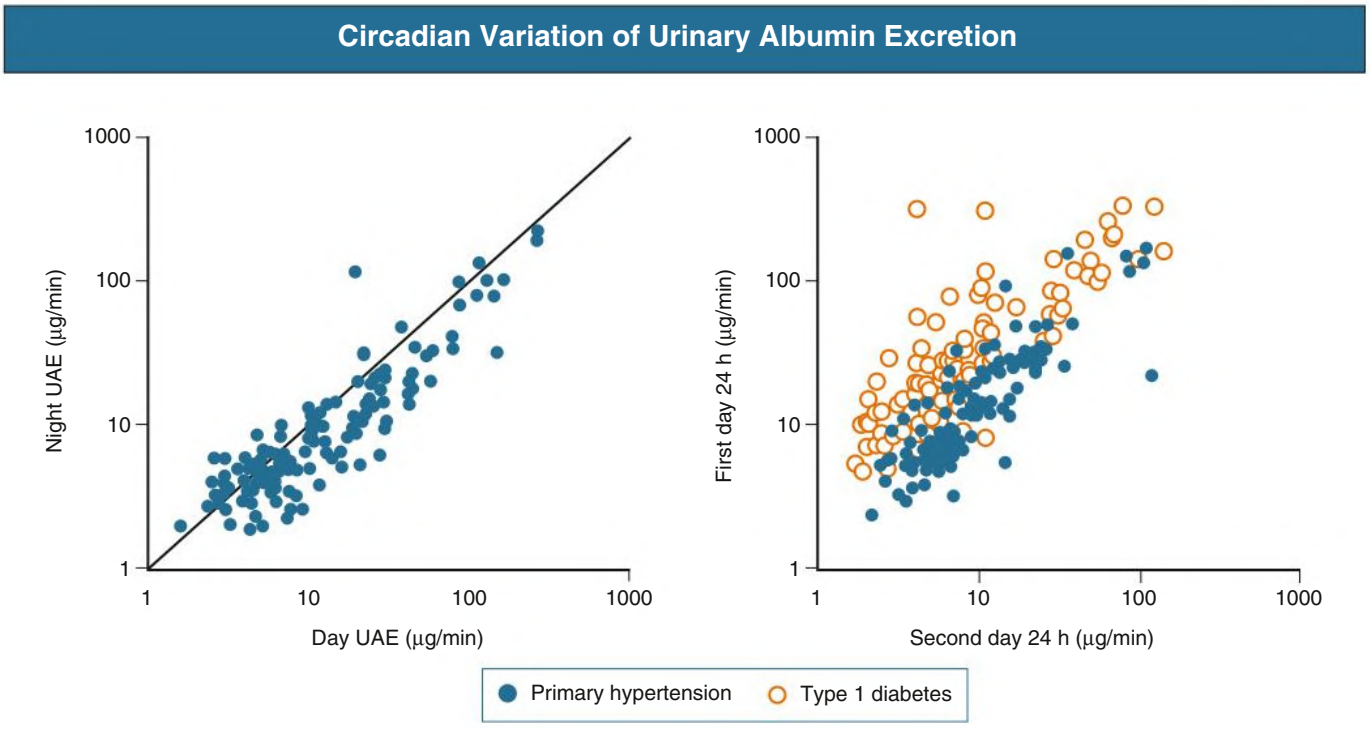

Fig. 31.17 Circadian Variation of Urinary Albumin Excretion (UAE). UAE is lower in resting conditions at night *(left)* than during daytime activity *(right).* Relationship between UAE assessed on two different days 1 week apart in patients with type 1 diabetes *(open circles)* and primary hypertension *(closed circles).* There is substantial individual day-to-day variation of albumin excretion and also between day and night collections. (From Redon J. Measurement of microalbuminuria: what the nephrologist should know. *Nephrol Dial Transplant.* 2006;21:573–576.)

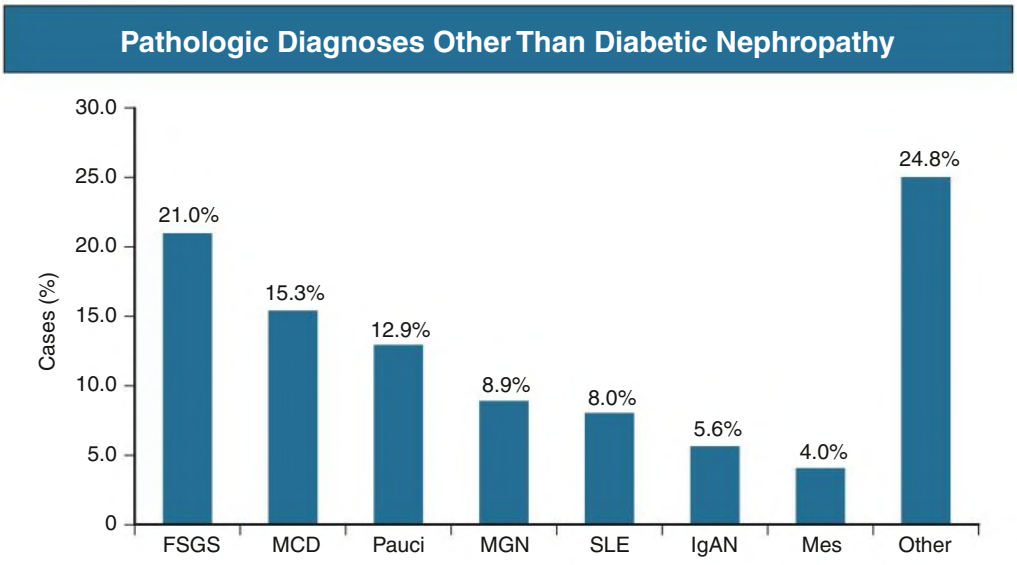

Fig. 31.18 Pathologic Diagnoses Other Than Diabetic Nephropathy Are Found in More Than Half of Patients With Type 2 Diabetes With Proteinuria. A total of 233 patients were studied; 53.2% (124 patients) had a diagnosis of nondiabetic kidney disease. *FSGS,* Focal segmental glomerulosclerosis; *IgAN,* immunoglobulin A nephropathy; *MCD,* minimal change disease; *Mes,* mesangial immune complex glomerulonephritis; *MGN,* membranous nephropathy; *Pauci,* ANCA-positive pauci-immune glomerulonephritis; *SLE,* systemic lupus erythematosus. (From Pham TT, Sim JJ, Kujubu DA, et al. Prevalence of nondiabetic renal disease in diabetic patients. *Am J Nephrol.* 2007;27:322–328.)

syndrome and retinopathy was significantly higher in hematuric patients than in nonhematuric patients with diabetic glomerulosclerosis.

On the other hand, other forms of kidney disease may be found in patients with T2D. Younger patients with diabetes, shorter duration of diabetes, and proteinuria without retinopathy may suggest nondiabetic kidney disease.[108] Membranous nephropathy, FSGS, acute interstitial nephritis, postinfectious GN, and IgA nephropathy have all been described in patients with T2D in whom DKD was clinically suspected (Fig. 31.18).

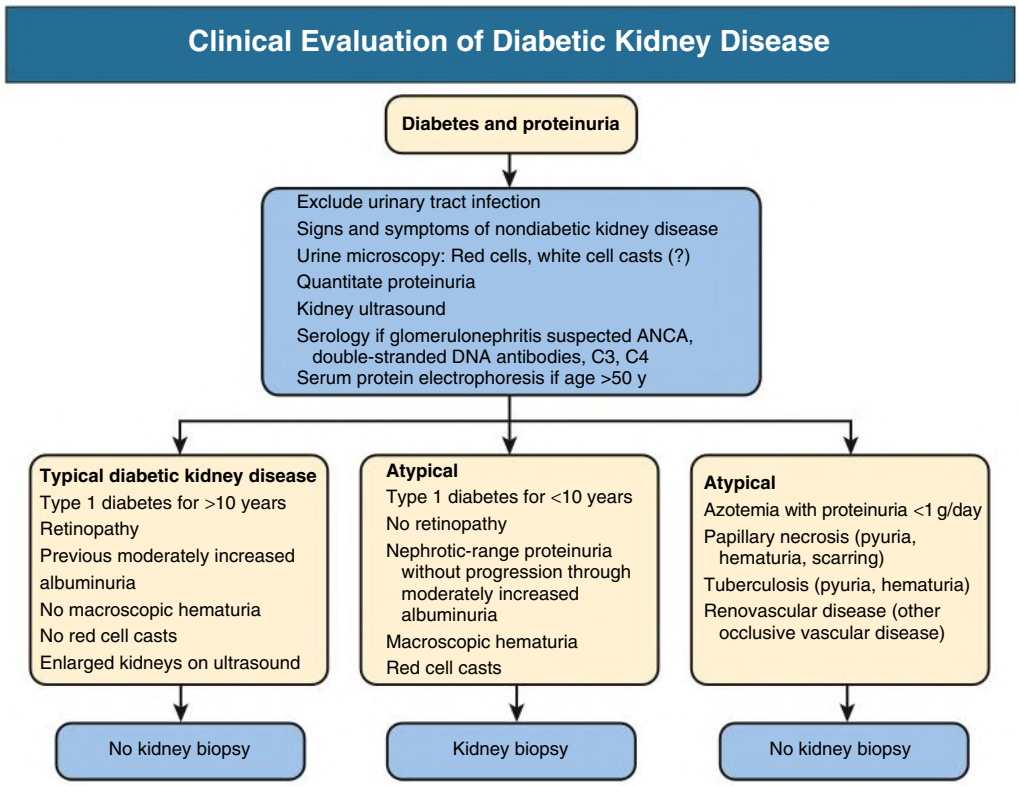

Fig. 31.19 Clinical evaluation of diabetic kidney disease. *ANCA,* Antineutrophil cytoplasmic antibody.

Indications for Kidney Biopsy

Further investigation, including kidney biopsy, should be considered in the following situations[109] (Fig. 31.19):

- If retinopathy is not present in T1D with proteinuria or moderately impaired kidney function (absence of retinopathy does not exclude DKD in T2D).
- If the onset of proteinuria has been sudden and rapid, and the duration of T1D less than 5 years. Alternatively, if the evolution has been atypical, for example, without transition through the usual stages, particularly the development of nephrotic syndrome without previous moderately increased albuminuria.
- If there is macrohematuria or an active nephritic urinary sediment including acanthocytes or red blood cell casts; the sediment in DKD typically is not more than occasional erythrocytes.
- If the decline in kidney function is exceptionally rapid after excluding reversible causes of AKI such as infection, drugs, and obstruction, or if kidney dysfunction is found without significant proteinuria (first, renovascular disease must be excluded) (Fig. 31.20).
- If there are signs and symptoms suggestive of a nondiabetic cause for kidney disease.

If kidney ultrasound reveals small kidneys or a significant size difference, it is prudent not to perform a kidney biopsy. Recent initiatives by the National Institutes of Health (NIH)-funded Kidney Precision Medicine Project are assessing biopsies from patients with DN to determine whether a multiomic approach with single cell transcriptomics, proteomics, and spatial metabolomics could provide new insights in humans.

Approach to the Diabetic Patient With Impaired Kidney Function

When seeing a diabetic patient with CKD, the nephrologist should:

- Assess the cause of CKD (acute vs. chronic kidney impairment; DKD vs. alternative causes of kidney damage).

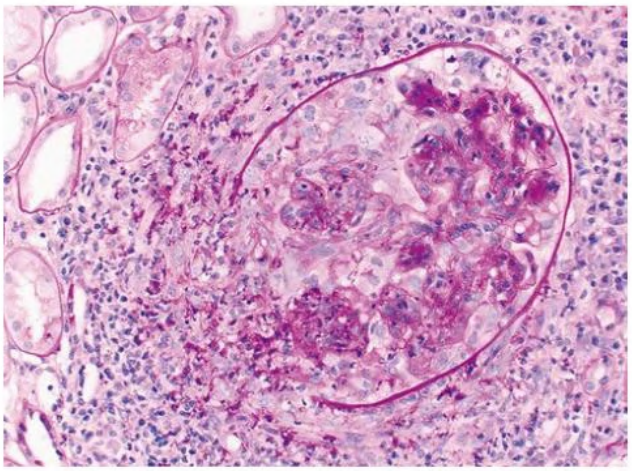

Fig. 31.20 Glomerulonephritis Superimposed on Diabetic Kidney Disease (DKD). A glomerulus showing a cellular crescent with rupture of the Bowman's capsule superimposed on nodular DKD. The patient, known to have diabetic nephropathy, presented with rapidly deteriorating kidney function and red cell casts in the urine.

- Assess the magnitude of proteinuria and the rate of progression.
- Search for typical extrarenal microvascular and macrovascular complications of diabetes.

The majority of diabetic patients with heavy proteinuria or kidney failure have DKD. Kidney ischemia (atherosclerotic kidney artery stenosis or cholesterol embolism) is common in diabetic patients, and many patients with T2D have small kidneys and low GFR without albuminuria, possibly from macrovascular disease.

If urinary tract infection occurs, it is more severe in the diabetic than the nondiabetic patient. Purulent papillary necrosis and intrarenal abscess formation have now become rare.

Diabetic patients with nephropathy are particularly prone to development of AKI after administration of NSAIDs or radiocontrast media or after cardiovascular events or septicemia. Preventive measures for AKI are discussed in Chapter 74. AKI superimposed on preexisting DKD carries a poor kidney prognosis.

SELF-ASSESSMENT QUESTIONS

1. Which of the following statements about diabetic nephropathy is *correct?*
   - **A.** The pathophysiology for diabetic nephropathy is different in T1D and T2D.
   - **B.** Glomerulosclerosis, tubular atrophy, and tubulointerstitial lesions are typical pathologic findings in diabetic nephropathy.
   - **C.** Development of diabetic nephropathy is always associated with microalbuminuria.
   - **D.** Development of diabetic nephropathy is always associated with hypertension.
2. Which of the following is *not* a risk factor for the development of diabetic kidney disease?
   - **A.** Genetic background
   - **B.** Hyperglycemia
   - **C.** Smoking
   - **D.** Anemia
   - **E.** Type of diabetes
3. Which of the following findings *may* suggest a nondiabetic origin of the kidney disease?
   - **A.** Proteinuria greater than 2 g/day
   - **B.** Large kidneys on ultrasound
   - **C.** Increased serum creatinine
   - **D.** Acanthocytes in urine sediment
4. Which of the following observations suggests inflammation is a feature in diabetic kidney disease?
   - **A.** Increased transforming growth factor-β levels
   - **B.** Inflammasome activation in the diabetic kidney
   - **C.** Markedly elevated C-reactive protein and ferritin levels
   - **D.** Peripheral leukocytosis
   - **E.** Presence of urinary red and white cell casts

Prevention and Treatment of Diabetic Kidney Disease

Li-Li Tong, Sharon Adler, Christoph Wanner

INTRODUCTION

The development of diabetic kidney disease (DKD) signifies a generalized microvascular syndrome that is frequently accompanied by macrovascular disease (see Chapter 31). We use the terms DKD (and formerly diabetic nephropathy) to encompass the spectrum of vascular, glomerular, and tubulointerstitial components of chronic kidney disease (CKD) attributed to diabetes. Classically, DKD evolves through several stages based on urine albumin excretion and measured as urine albumin-to-creatinine ratio in a spot urine sample (UACR): normoalbuminuria (<30 mg/g), moderately increased albuminuria (previously called microalbuminuria, 30–300 mg/g), and severely increased albuminuria (previously called macroalbuminuria or overt nephropathy, >300 mg/g).[1] Furthermore, a substantial proportion of patients with diabetes mellitus have a nonproteinuric phenotype with progressive loss of estimated glomerular filtration rate (eGFR). DKD classification and staging are based on eGFR and degree of albuminuria, as in other causes of CKD. The level of UACR and eGFR are both independently associated with the risk of adverse kidney outcomes and cardiovascular (CV) morbidity and mortality. Normoalbuminuria is arbitrarily defined by UACR less than 30 mg/g, a threshold far above the normal albumin excretion in most healthy individuals. Thus, even in individuals with normoalbuminuria, increments in albuminuria are associated with increased cardiorenal risk.

In patients with established DKD, the goals of treatment are albuminuria regression and preservation of kidney function. Strict blood pressure (BP) and glycemic control early in the disease course are vital. Aggressive lipid-lowering and lifestyle modifications, including adherence to a low-protein and low-sodium diet, exercise, weight loss, and smoking cessation all are beneficial and likely to improve kidney and CV outcomes. Such multifactorial therapy lowered the risk for cardiovascular disease (CVD), nephropathy, retinopathy, and autonomic polyneuropathy in the Steno 2 trial in patients with type 2 diabetes (T2D), and even delayed mortality.[2] Most patients with advanced-stage DKD, however, are likely to die of CVD or progress to end-stage kidney disease (ESKD), even though treatment may slow progression.

This chapter reviews the management of patients with type 1 diabetes and kidney disease and focuses on strategies that promote kidney protection and cardioprotection in patients with T2D. The recent introduction of highly effective medications to ameliorate CV and kidney outcomes in patients with T2D and DKD has revolutionized the approach to clinical care, and management strategies are rapidly changing as new pharmaceuticals become available and as their indications and use in the lower eGFR ranges widen. Fig. 32.1 is from the Kidney Disease: Improving Global Outcomes (KDIGO) DKD 2022 Guideline.[2a] In general, the pyramidal peak describes the overall treatment goals, which are to optimize glycemic, blood pressure, and lipid control in patients with T2D. Treatment approaches begin with the foundational goals of smoking cessation and encouraging exercise. In addition, patients should be encouraged to eat a healthy diet, especially targeting lipid, sodium, and modest protein restriction, encouraging fruits and vegetables, and achieving an optimal body weight. For patients with hypertension, hyperlipidemia, and CV disease complicating T2D, the KDIGO guidelines recommend first-line therapy to control glycemia with metformin (for patients with eGFR > 30 mL/min/1.73 m^2); a sodium-glucose transporter inhibitor (SGLT2i, for patients with underlying CV and/or kidney involvement and eGFR > 20 mL/min/1.73 m^2); blood pressure and proteinuria modulation with renin-angiotensin system (RAS) inhibition or angiotensin receptor blockade; and control of hyperlipidemia with a statin. For those in need of additional or alternative medication approaches to achieve glycemic, blood pressure, proteinuria, CV, and/or lipid goals, second-line therapies including glucagon-like peptide 1 (GLP-1) receptor agonists may be used to address hyperglycemia, proteinuria, renal function decline, and CV complications. A nonsteroidal aldosterone antagonist may be added to further reduce proteinuria, slow the rate of loss of eGFR, and reduce CV complications. Finally, antiplatelet agents may be used to address atherosclerotic CV disease.

One obstacle to achieving adherence is the complexity of these regimens. Therefore, prevention and treatment of patients with DKD must be individualized and require consideration of the cost, side effects, and convenience of the drug regimen measured against the anticipated benefits. A comprehensive approach incorporating multidisciplinary teams, along with patient participation in shared decision-making, is best for managing patients with DKD. Special considerations are indicated in the management of the diabetic patient with advanced CKD (see Chapter 33). Many therapeutic issues discussed here are not specific for DKD and may be relevant for CKD in general (see Chapter 82). The paragraphs below expand on specific considerations in using particular medications or medication classes.

DIABETIC KIDNEY DISEASE IN TYPE 1 DIABETES

In patients with T1D, strict glycemic control decreases the risk for developing DKD. The Diabetes Control and Complications Trial (DCCT) compared the effects of intensive glucose control with conventional treatment on the long-term complications of T1D (Fig. 32.2). Over 9 years, patients with mean hemoglobin A1c (HbA1c) of 7% who received intensive therapy had a 35% to 45% lower risk for development of moderately increased albuminuria compared with the control group (mean HbA1c, 9%).[3] In the DCCT follow-up, the Epidemiology of Diabetes Interventions and Complications (EDIC) trial, the long-term risk for developing impaired glomerular filtration rate (GFR) was 50% lower in patients assigned to tight control compared with those treated with conventional therapy. This effect was not evident until more than 10 years after randomization.[4]

The appearance of moderately increased albuminuria typically precedes hypertension in patients with T1D. When hypertension occurs, control is imperative. Higher BP is associated with increasing

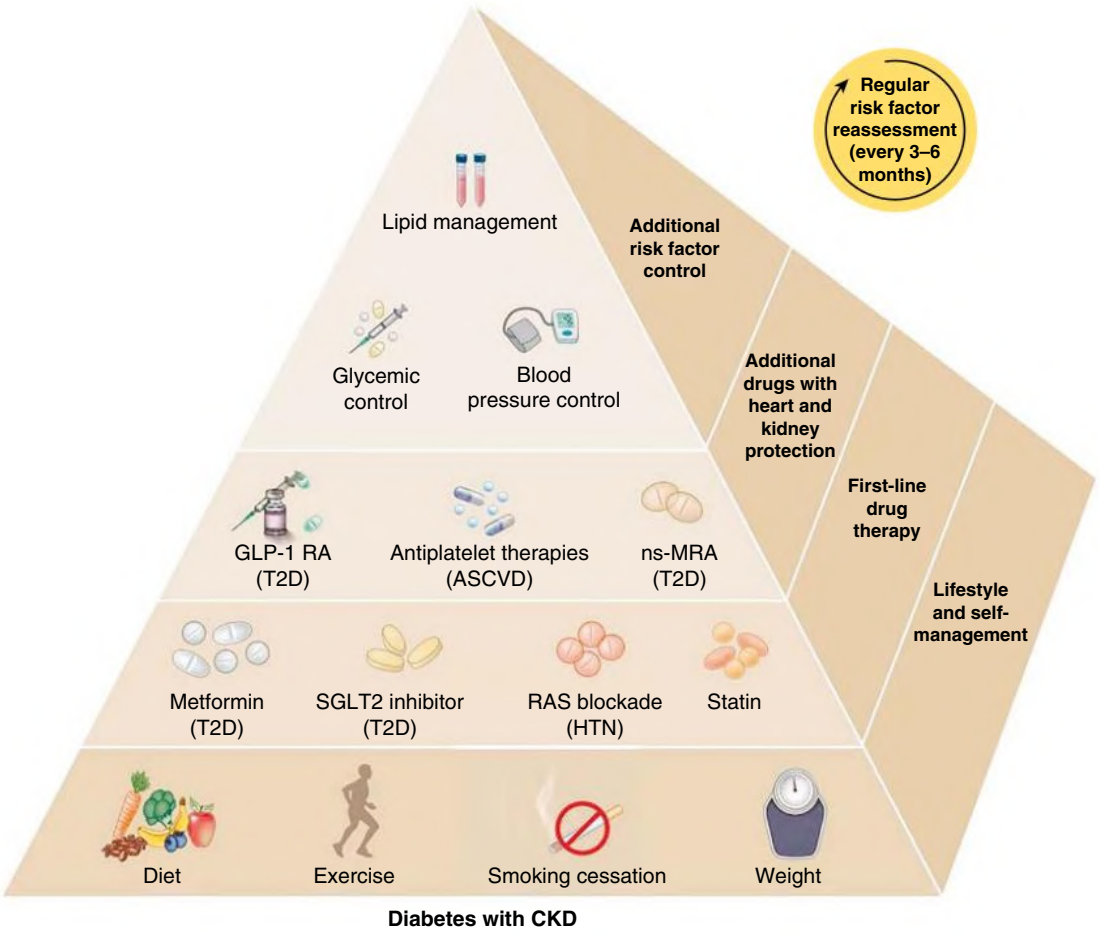

Fig. 32.1 Treatment Algorithm for Diabetic Kidney Disease (DKD) in Patients With Type 2 Diabetes (T2D). The Kidney Disease: Improving Global Outcomes (KDIGO) Executive Summary describes a recommended approach for the management of DKD, beginning with foundational lifestyle recommendations. Built upon these are the sequential incorporation of first- and second-line glycemic lowering medications, with preferential consideration of each drug's potential for cardioprotection and renoprotection above and beyond their capacity to improve glycemic control. At the top of the pyramid are overarching goals of risk factor modification, including optimization of glycemic, hypertensive, and lipid management. *ASCVD*, Atherosclerotic cardiovascular disease; *HTN*, hypertension; *SGLT2*, sodium-glucose transporter 2. (From Rossing P, Caramori ML, Chan JCN, et al. Kidney Disease: Improving Global Outcomes [KDIGO] Executive Summary of the KDIGO 2022 Clinical Practice Guideline for diabetes management in chronic kidney disease. An update based on rapidly emerging new evidence. *Kidney Int.* 2022;102:990–999.)

albuminuria, more rapid progression, and increased risk for kidney failure, as well as increased risk for fatal and nonfatal CV events.[5] Thus, effective treatment of hypertension is arguably the single most important strategy in the treatment of established DKD (Fig. 32.3). Antihypertensive therapies, regardless of the agent used, reduce UACR, delay progression of nephropathy, postpone loss of GFR, and improve survival.

Lower rates of ESKD among patients with T1D attributable to BP and tight glycemic control, along with antiproteinuric strategies (see section on RAAS blockade), are now reported from many countries around the world, and ESKD, when it does occur, occurs at an older age.[6] These encouraging data underscore the need for early glycemic and BP control in T1D.

DIABETIC KIDNEY DISEASE IN TYPE 2 DIABETES

Glycemic Control

Several major studies demonstrate a lower risk for nephropathy with stricter glycemic control in patients with T2D. In a design similar to the DCCT, the Kumamoto study found a 60% reduction in moderately increased albuminuria in relatively young, nonobese patients with T2D receiving intensive glycemic treatment (HbA1c 7.1%) compared with conventional treatment (HbA1c 9.4%).[7] In the United Kingdom Prospective Diabetes Study (UKPDS) trial, newly diagnosed patients with T2D were assigned to intensive management (HbA1c 7.0%) with a sulfonylurea or insulin or to conventional management (HbA1c 7.9%) with diet alone. After 9 years of intensive therapy, the risk of developing moderately increased albuminuria was reduced by 24%.[8] After termination of the study, patients were observed for a further 10 years. The differences in HbA1c were lost within 1 year, but a 24% lower relative risk of microvascular disease and myocardial infarction (−15%) persisted. All-cause mortality was also reduced by 13%. This phenomenon of ongoing beneficial effects on diabetic complications after a period of improved glycemic control even if followed by a return to less intensive metabolic control has been termed *metabolic memory* or *legacy effect*. It emphasizes the importance of early glycemic control in the primary prevention of microvascular and macrovascular complications in diabetic patients.

Most of the evidence favoring strict glycemic control comes from studies of patients with normoalbuminuria or early stages of DKD. Fewer studies addressed intensive glycemic control in patients with more advanced DKD stages, in whom it may be difficult to show

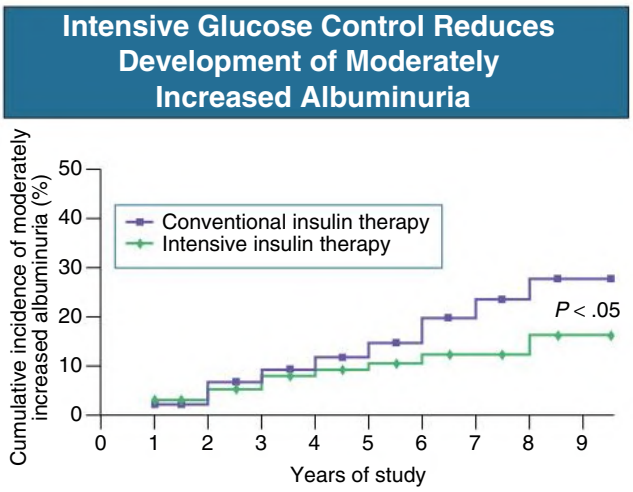

Fig. 32.2 Moderately Increased Albuminuria Risk Reduction With Intensive Versus Conventional Insulin Therapy. Intensive glucose control was associated with a decreased risk for the subsequent development of moderately increased albuminuria in patients with type 1 diabetes. (Modified from Diabetes Control and Complications Trial Research Group. The effect of intensive treatment of diabetes on the development and progression of long-term complications in insulin-dependent diabetes mellitus. *N Engl J Med.* 1993;329:977–986.)

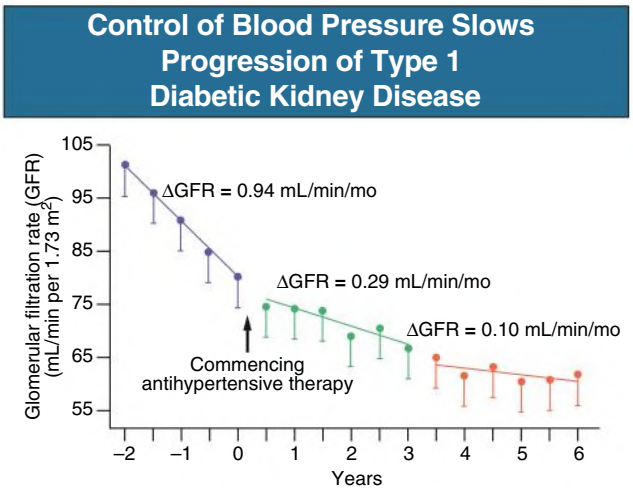

Fig. 32.3 Control of blood pressure reduces the risk for progression in type 1 diabetes and diabetic kidney disease. (Modified from Parving HH, Andersen AR, Smidt VM, et al. Effect of antihypertensive treatment on kidney function in diabetic nephropathy. *Br Med J (Clin Res Ed).* 1987;294[6585]:1443–1447.)

benefit because the results are confounded by the effects of concomitant hypertension and CVD. Even so, there is evidence to support glycemic control in reducing the risk for worsening albuminuria and kidney functional decline.

Glycemic Targets

HbA1c is widely used to monitor glycemic control, and testing should be performed routinely in all patients with diabetes as part of continuing care, combined with patient self-monitoring of blood glucose or continuous glucose monitoring in selected patients. The HbA1c assay has limitations in patients with advanced CKD, as the result can be influenced by conditions that affect red cell turnover (see Chapter 33).

Several major trials tested whether strict glycemic targets reduced CVD risk in patients with T2D. The Action in Diabetes and Vascular Disease, Perindopril and Indapamide Controlled Evaluation (ADVANCE) study showed that intensive glycemic control (HbA1c 6.5% vs. 7.3%) yielded a 10% relative reduction in major macro- and microvascular events, in particular a 21% relative reduction in nephropathy.[9] However, in the Action to Control Cardiovascular Risk in Diabetes (ACCORD) trial, very tight glycemic control (lowering HbA1c to a median of 6.4% vs. 7.5% with conventional control) led to a 22% increase in mortality from any cause and did not significantly reduce major CV events.[10] A third major study of tight glucose control in patients with T2D, the Veterans Affairs Diabetes Trial (VADT), found no significant reduction in CV deaths or events over 7.5 years in high-risk patients treated aggressively for glycemic control (median HbA1c 6.9%) compared with standard therapy (median HbA1c 8.4%).[11] A meta-analysis showed that tight glycemic control reduced microvascular complications, including kidney and eye events.[12]

We interpret the data to suggest that glycemic control must be individualized, considering the patient's age, duration of diabetes, presence of CVD, presence of CKD, and microvascular risks and complications, as well as previous glycemic control and susceptibility to and awareness of hypoglycemia. In younger patients with short diabetes duration, longer life expectancy, low hypoglycemia risk, and no prior CV events, strict glycemic control can reduce DKD risk and other microvascular complications. A more cautious approach to glycemic control is recommended in the frail or elderly patient with long-standing diabetes or preexisting CV problems or in patients who are susceptible to hypoglycemic episodes. In these patients, the HbA1c goal may be set higher. The Kidney Disease: Improving Global Outcomes (KDIGO) 2020 clinical practice guidelines recommend lowering HbA1c to a goal ranging from less than 6.5% to less than 8.0%.[13] The American Diabetes Association (ADA) and the European Association for the Study of Diabetes (EASD) similarly endorse tight glycemic control at the onset of diabetes in patients with few comorbidities as a preventive strategy and less stringent control in patients with more advanced comorbidities.[14]

Antihyperglycemic Therapeutic Options in Type 2 Diabetes and Kidney Disease

Options for antihyperglycemic treatment in patients with T2D have expanded over the past decade, and several confer CV and kidney protection substantially beyond their glycemic effects. Despite specific indications and relative contraindications for some newer drug classes discussed below, most patients can safely be prescribed at least one, if not more, classes of the newer antiglycemic agents as needed. These newer agents have been shown to confer a level of CV and kidney protection that far surpasses the protection conferred by RAS inhibition alone. Importantly, the severity of CKD has implications for the efficacy and safety of glycemic treatments. Dosing adjustments and careful monitoring for adverse effects are required for patients with advanced CKD or with kidney failure (see Chapter 33). Fig. 32.4 represents a treatment strategy combining lifestyle recommendations and a hierarchical medication prescribing approach recommended in the KDIGO DKD Guideline[2a] to address glycemic control and CV and renoprotection in patients with T2D. The following paragraphs expand on the particular pharmacologic considerations of medication use in each of the drug classes.

Metformin

Metformin is a biguanide which has been used for over 60 years and is the preferred initial antihyperglycemic drug for T2D because of its low cost, high efficacy, and low risk for hypoglycemia. Metformin also has weight- and lipid-lowering properties, and beneficial effects on CV and all-cause mortality.[15] It is primarily eliminated by the kidney, and the risk of lactic acidosis in patients with kidney impairment or acute illness is a concern. However, the lowest eGFR safety threshold for metformin has been reconsidered in recent years, as data demonstrating an increased risk of lactic acidosis in CKD is limited. Currently, it is

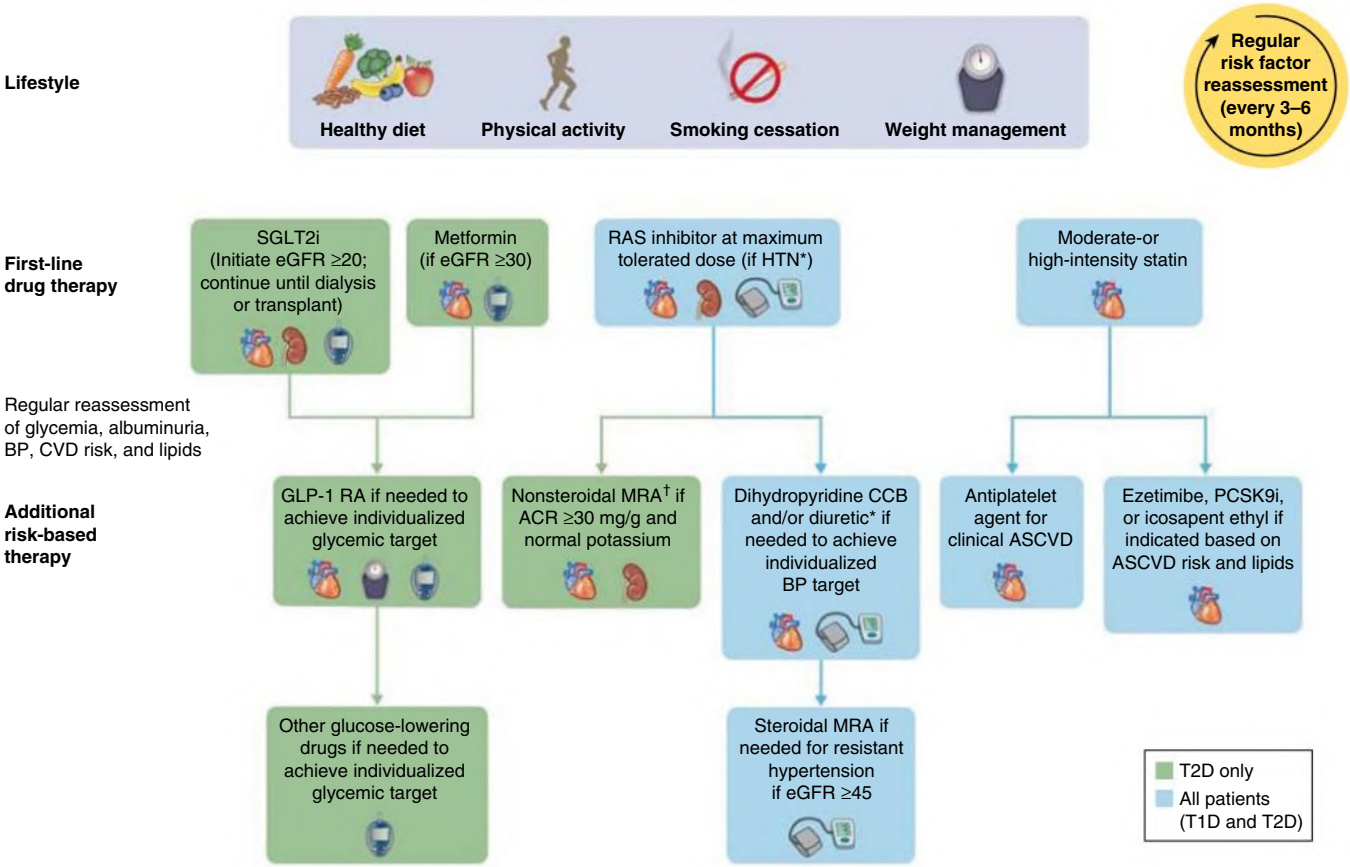

Fig. 32.4 Treatment algorithm for glycemic control in patients with type 2 diabetes and diabetic kidney disease. *ACR,* Albumin/creatinine ratio; *ASCVD,* atherosclerotic cardiovascular disease; *BP,* blood pressure;*CCB,* calcium channel blocker; *CVD,* cardiovascular disease; *eGFR,* estimated glomerular filtration rate; *GLP-1,* glucagon-like peptide-1; *HTN,* hypertension; *MRA,* mineralocorticoid receptor antagonist; *PCSK9i,* proprotein convertase subtilisin/kexin type 9 inhibitor; *RA,* receptor agonist; *RAS,* renin-angiotensin system; *SGLT2i,* sodium-glucose cotransporter-2 inhibitor; *T2D,* type 2 diabetes. (From Rossing P, Caramori ML, Chan JCN, et al. Executive summary of the KDIGO 2022 Clinical Practice Guideline for Diabetes Management in Chronic Kidney Disease: an update based on rapidly emerging new evidence. *Kidney Int.* 2022;102:990-999.)

recommended to decrease the dose of metformin to 500 mg twice daily at eGFR less than 45 mL/min/1.73 m^2 and discontinue use at eGFR less than 30 ml/min/1.73 m^2.[2a]

Sodium Glucose Cotransporter-2 Inhibitors

The magnitude of the effect size of SGLT2i for kidney protection in T2D is approximately 2.5 times the protective effect of RAS inhibitor when added to a maximally tolerated dose of RAS inhibitor. No drug class currently exists with this degree of renoprotection. Empagliflozin, dapagliflozin, canagliflozin, and ertugliflozin are now widely approved antihyperglycemic therapies with kidney benefits conferred at least in part via glycosuric and tubuloglomerular feedback mechanisms. They induce osmotic diuresis, which in turn confers natriuretic effects contributing to plasma volume contraction, have decreased weight, and have decreased systolic BP by 4 to 6 mm Hg and diastolic BP by 1 to 2 mm Hg. SGLT2 inhibition is associated with an acute reduction of more than 10% in eGFR in about a third of all individuals with T2D and CVD. However, this initial decline is fully reversible after stopping SGLT inhibition. Albuminuria is reduced by 30% to 40%. These effects mirror preclinical observations suggesting that proximal tubular natriuresis activates renal tubuloglomerular feedback through increased macula densa sodium and chloride delivery, leading to afferent vasoconstriction. Glycosuric effects are attenuated in patients with eGFR less than 60 mL/min/1.73 m^2, but BP, eGFR, and albuminuria lowering effects are preserved.

There is solid evidence for CV and kidney protection of SGLT2 inhibitors in patients with T2D. The Empagliflozin Cardiovascular Outcome Event (EMPA-REG OUTCOME) trial in patients with T2D and established CVD reported a 14% reduction in the primary composite outcome of CV death, nonfatal myocardial infarction, nonfatal stroke, and more than 30% reductions in CV mortality, overall mortality, and heart failure hospitalizations.[16] The Canagliflozin Cardiovascular Assessment Study (CANVAS) showed a similar magnitude of CV event reduction using canagliflozin in patients with T2D and a high risk of CVD. In terms of kidney protection, the EMPA-REG OUTCOME study reported a 39% reduction in incident or worsening kidney disease that included doubling of serum creatinine (relative risk reduction, 44%) and kidney-replacement therapy (relative risk reduction, 55%) in the empagliflozin group, whereas the CANVAS-Renal trial similarly reported an impressive 40% reduction in the composite kidney outcome (defined as a sustained 40% reduction in the rate of eGFR decline, need for kidney replacement therapy, or death from kidney causes).[17,18] The Canagliflozin and Renal Events in Diabetes with Established Nephropathy Clinical Evaluation (CREDENCE) trial was halted early after a planned interim analysis indicated significant 30% reduction in composite outcome (ESKD, doubling of the serum creatinine, or death from kidney or CV causes) in the canagliflozin group

compared with the placebo group.[19] Similarly, dapagliflozin was shown to reduce heart failure and fatal myocardial outcomes in patients with T2D and CV risk factors in the DECLARE study.[19a] and the DAPA-HF study[19b] Of great significance, the DAPA-CKD study showed that treatment with dapagliflozin improved all of the components of the composite kidney endpoint of sustained eGFR decline, ESKD, and CV or renal death in patients with and without DKD with a relative risk reduction of 39%.[20] In 2022, similar findings of CV and renoprotection were reported for empagliflozin[20a] in patients with and without T2D. Corroborating all of the results of these individual studies, a meta-analysis[20b] reported that SGLT2 inhibitors reduced the risk of kidney disease progression by 37%, the risk of acute kidney injury by 23%, and the risk of cardiovascular death or hospitalization for heart failure by 23%, with similar effects in those with and without diabetes. SGLT2 inhibitors also reduced the CV death risk but did not reduce the risk of non-CV death. The authors concluded that the absolute effects of SGLT2 inhibitors outweighed the small risks of ketoacidosis or amputation, the latter having been observed in only one trial with canagliflozin. The risk for genital and urinary tract infections, especially with *Candida* species, is generally increased, and hygiene measures are recommended.[20]

Collective evidence from clinical studies demonstrated that SGLT2 inhibitor use does not predispose to clinically significant AKI.

GLP-1 Receptor Agonists

GLP-1 receptor agonists are a newer class of antihyperglycemic treatment with demonstrated CV and kidney benefits in patients with T2D. They lower glucose levels and reduce body weight and BP. The Liraglutide Effect and Action in Diabetes: Evaluation of Cardiovascular Outcome Results (LEADER) trial showed that fewer patients in the liraglutide group died from CV causes (relative risk reduction, 22%), and the rate of death from any cause was also lower (15%). Fewer patients reached a kidney endpoint (23%), which consisted mainly of a lower frequency of heavy albuminuria.[21] Similarly impressive CV benefits were demonstrated for semaglutide in the SUSTAIN-6 and PIONEER-6 studies.[22] Both the 2020 ADA guideline and the 2022 KDIGO guideline now recommend the use of GLP-1 receptor agonists with proven CV benefits in patients with T2D who have established CVD or are at high risk. Notably, the 2020 ADA guidelines recommend using these agents for the reduction of CV risk independent of glycemic control,[14] and the 2022 KDIGO guidelines recommend these as adjunctive therapies after consideration of metformin and SGLT2 inhibitors.[2a] Cost concerns and the need for injection remain barriers to using GLP-1 receptor agonists. Additional research is needed to fully characterize subgroups among patients with T2D who will particularly benefit from GLP-1 receptor agonists and to determine if the CV and kidney benefits extend to patients with T1D.

Dipeptidyl Peptidase-4Inhibitors

Like the GLP-1RA, the dipeptidyl peptidase-4 (DPP-4) inhibitors (i.e., gliptins) are incretin-based antihyperglycemic agents effective in lowering blood glucose in patients with T2D. By inhibiting DPP-4, a regulator of GLP-1 degradation, these agents increase GLP-1 levels. Thus, combined use of DPP-4 inhibitors and GLP-1 RA is not recommended. As a class, DPP-4 inhibitors are generally well tolerated and can be used even in patients with advanced CKD. Treatment with DPP-4 inhibitors reduces albuminuria. So far, clinical trials of DPP-4 inhibitors have demonstrated no additional CV outcome benefit compared with placebo.[23]

Blood Pressure Control

As many as 40% of patients with T2D have known hypertension before the diagnosis of DKD. Once severely increased albuminuria develops, hypertension is almost universal and is associated with volume expansion and salt sensitivity. The absence of hypertension in an untreated patient with T2D and DKD should raise suspicion for underlying cardiac disease.

The optimal BP target in DKD remains unclear. Guidelines published before the Action to Control Cardiovascular Risk in Diabetes Blood Pressure (ACCORD BP) trial suggested a BP target in diabetic patients of less than 130/80 mm Hg. However, this BP target was challenged by the ACCORD BP trial. Among patients with T2D and high CV risk, randomized to goal systolic BP of under 120 mm Hg or standard therapy aiming for under 140 mm Hg, there was no difference in the risks for composite major CV events. The risks for hyperkalemia and kidney dysfunction were increased at lower BP goals in ACCORD.[24] In contrast, the large Systolic Blood Pressure Intervention Trial (SPRINT) showed that for nondiabetic patients, lowering systolic BP below 120 mm Hg, compared with the standard goal below 140 mm Hg, significantly lowered event rates and mortality without a significant increase in adverse events.[25] Unfortunately, data are more limited in patients with diabetes or advanced stage CKD. In the Irbesartan Diabetic Nephropathy Trial (IDNT), progressive lowering of systolic BP to 120 mm Hg was associated with improved kidney and patient survival, an effect independent of baseline kidney function.[26] Mortality increased with systolic BP below 120 mm Hg, although a cause-and-effect relationship could not be inferred. Low diastolic BP is poorly tolerated, and the incidence of myocardial infarction and mortality increases at values less than 70 mm Hg, at least in patients with coronary heart disease, presumably because coronary perfusion occurs during diastole. Indeed, in the IDNT study, CV mortality increased not only with higher systolic BP but also with low diastolic BP.

The KDIGO 2021 Hypertension Guideline remained somewhat agnostic about the blood pressure target in patients with diabetes. Citing SPRINT, the workgroup report stated "The working group feels that cardiovascular benefits of intensive BP lowering cannot be excluded in patients with concomitant diabetes and CKD and that a large randomized trial addressing this issue is warranted."[27] Thus, a solid evidence-based recommendation for a BP target in patients with diabetes remains elusive, but based on KDIGO 2021, it appears appropriate to target a BP less than 140/90 mm Hg for all diabetic patients and less than 130/80 mm Hg as tolerated for patients with CKD and/or UACR greater than 30 mg/g.[27] The American College of Cardiology/American Heart Association (ACC/AHA) 2017 hypertension guideline similarly set a BP target below 130/80 mm Hg for individuals with CKD and others at elevated CV risk. For diabetic patients at highest risk for cerebrovascular accidents, lower systolic BP goals (i.e., <120 mm Hg) may provide greater protection against stroke, but the potential risks for adverse events and the burden of antihypertensive therapy must be considered.

RAAS BLOCKADE

Renin-Angiotensin-Aldosterone System Inhibition in the Prevention of Diabetic Kidney Disease

We do not recommend the use of renin-angiotensin system (RAS) inhibition in normotensive, normoalbuminuric diabetic patients for the primary prevention of DKD. Most patients with diabetes do not develop DKD, even after long periods of uncontrolled hyperglycemia, and there are hazards using RAS inhibitors, including their potential teratogenicity. In a post hoc analysis of the multicenter Diabetic Retinopathy Candesartan Trials (DIRECT) program, which included patients with normotensive and normoalbuminuric T1D and normoalbuminuric T2D with or without hypertension, candesartan had no effect on the development of moderately increased albuminuria.[28]

In hypertensive, normoalbuminuric patients, an angiotensin-converting enzyme (ACE) inhibitor or angiotensin receptor blocker (ARB) are both effective as first-line antihypertensive agents. The

Bergamo Nephrologic Diabetes Complications Trial (BENEDICT), which randomized patients with hypertension, normoalbuminuria, and T2D to placebo, verapamil, trandolapril, or a combination of verapamil plus trandolapril, showed less progression to moderately increased albuminuria in those receiving trandolapril either alone or with verapamil.[29] Results with verapamil alone were similar to placebo. There were similar findings in smaller studies with other RAS inhibitors, implicating a class effect. Longer-term studies would be required to demonstrate the effects of RAS inhibitors on the clinically important outcomes of death, dialysis, and doubling of serum creatinine level in normoalbuminuric patients.

Renin-Angiotensin System Inhibition in the Treatment of Diabetic Kidney Disease

In patients with established DKD, RAS inhibition confers kidney protection that is independent of BP reduction. The mitigation of intraglomerular hemodynamic and nonhemodynamic kidney effects of angiotensin II best explain the observed protection. Supporting this hypothesis, in vitro models of DKD show cellular effects of RAS inhibition that are consistent with benefits independent of BP effects (see Chapter 31).

Type 1 Diabetes

In patients with T1D with moderately increased albuminuria, ACE inhibitors reduce the risk for progression to overt nephropathy. In a meta-analysis in normotensive patients with T1D and moderately increased albuminuria treated with ACE inhibitors, the majority for more than 2 years, treatment was associated with a 60% reduction in progression to severely increased albuminuria and a threefold increase in regression to normoalbuminuria.[30] Changes in BP do not entirely explain the antiproteinuric effect of ACE inhibition.

In patients with severely increased albuminuria or overt nephropathy, captopril reduced albuminuria, slowed loss of GFR, and delayed the onset of kidney failure compared with placebo.[31] The beneficial effect of captopril was greater in patients with reduced GFR at baseline largely because one of the components of the composite endpoint, a doubling of baseline serum creatinine level, was achieved more quickly in these patients.

Data are insufficient to demonstrate the efficacy of ARBs in T1D and DKD. Nevertheless, based on the shared properties of ACE inhibitors and ARBs in inhibiting the RAS, ARBs are probably effective in the treatment of T1D and DKD.

Type 2 Diabetes

In patients with T2D, more data are available on the kidney-protective effect of ARBs compared with ACE inhibitors. In the stage of moderately increased albuminuria, the IRMA 2 study showed that irbesartan reduced progression to overt nephropathy by 70% in patients with hypertension and T2D during a 2-year follow-up period.[32] In the MARVAL trial, valsartan produced a greater reduction in UACR than did amlodipine (44% vs. 8%), with the same degree of BP reduction, suggesting that the antiproteinuric effect of ARBs is BP independent.

In patients with T2D with severely increased albuminuria and decreased GFR, the large randomized controlled trials (RCTs) IDNT and RENAAL showed that ARBs are effective in lowering proteinuria and decreasing the relative risk for reaching the composite endpoint of death, dialysis, and doubling of serum creatinine level.[33,34] However, the risk reduction for reaching the composite endpoint was only 18% to 20% in these studies in patients with T2D and nephropathy, compared with the more robust risk reduction of about 50% in patients with T1D receiving captopril. ARBs did not decrease CV death in these trials but did decrease the incidence of heart failure.

Compared with ARBs, data on the efficacy of ACE inhibitors in T2D and DKD are less strong, largely because of small sample size or short follow-up. In general, ACE inhibitors and ARBs have similar effects on patient outcomes. In a small RCT of patients with T2D with early DKD and 5-year follow-up, telmisartan was not inferior to enalapril in providing long-term kidney protection.[35]

Aldosterone Blockade in Diabetic Kidney Disease

The beneficial effect of ACE inhibitors and ARBs in slowing progressive kidney disease did not differentiate between the relative contributions of the RAS inhibition versus aldosterone system blockade (see Chapter 82). In fact, plasma aldosterone levels are elevated in a subset of patients despite ACE inhibitor and ARB therapy (also known as aldosterone breakthrough; see Chapter 82). In studies that defined aldosterone breakthrough as any increase from an individual's baseline serum aldosterone level (i.e., before RAS inhibition), the incidence ranged from 40% over 10 months to 53% over 12 months.[36] In addition to its classic effects of promoting sodium retention and enhancing potassium and magnesium excretion, aldosterone promotes tissue inflammation and fibrosis. Small studies demonstrated faster decline in GFR in patients who experienced aldosterone breakthrough (median, −5.0 mL/min/y) than in those who did not (median, −2.4 mL/min/y). However, current evidence is not strong enough to support widespread testing for aldosterone breakthrough. In selected patients, the addition of a mineralocorticoid receptor antagonist (MRA) may represent optimal therapy for patients who no longer show maximal antiproteinuric effects with RAS inhibitors.

The steroidal MRAs spironolactone and eplerenone reduce proteinuria when used alone. They have an additive effect on proteinuria when combined with an ACE inhibitor or ARB.[37] However, the risk for hyperkalemia, AKI, and other adverse effects, including gynecomastia, erectile dysfunction, and dysmenorrhea, frequently limit the use of combined MRA with ACE inhibitors or ARBs, especially in patients with reduced eGFR. Finerenone, a new nonsteroidal MRA, has greater receptor selectivity and affinity compared with steroidal MRAs (e.g., spironolactone and eplerenone) and has been approved by the US Food and Drug Administration and the European Medicines Agency for the treatment of patients with T2D to reduce CV morbidity and mortality and slow the rate of progressive renal functional decline. Recently published results from the two phase III finerenone studies, FIGARO and FIDELIO, demonstrated that finerenone reduced the relative risks of CKD progression and CV morbidity and mortality in patients with T2D CV risk and CKD.[38,38a]Adverse events were similar between the finerenone and placebo group. Hyperkalemia leading to finerenone discontinuation was uncommon (2.3%) compared with placebo (0.9%). The success of. finerenone to confer CV and kidney benefits and a low incidence of underlies the recommendation in the KDIGO DKD Guidelines to consider utilizing finerenone in a triple combination drug therapy strategy of ACE inhibitors or ARBs, SGLT2 inhibitors, and the nonsteroidal MRAs to provide optimal CV and kidney protection for most patients with T2D and DKD. Trials of several additional novel MRAs (esaxerenone, apararenone, KBP-5074) are underway. Recently, a phase III study of esaxerenone in patients with T2D showed albuminuria reduction compared to placebo.[53] Esaxerone is approved in Japan for the treatment of hypertension.

Combination Therapy With Renin-Angiotensin System Inhibitors

Combination therapy with an ACE inhibitor and an ARB is not recommended for DKD based on the results of several large trials in which the combination failed to improve clinical outcomes but which did

engender hyperkalemia and/or AKI.[39] Similar untoward events were observed when an ACE inhibitor or ARB was combined with the direct renin inhibitor aliskerin.[40]

Dosing and Adverse Effects Associated With ACE Inhibitors and ARBs

In individual patients, proteinuria may respond to ACE inhibitor or ARB dose escalations beyond those recommended for BP control.[41] Unfortunately, maximal dosing of ACE inhibitors or ARBs may be limited by side effects, including hyperkalemia, hypotension, and AKI. In women of reproductive age, counseling about pregnancy prevention and contraceptive use should begin before a RAS inhibitor is started.

Serum creatinine concentration may increase up to 30% in proteinuric patients with kidney impairment after starting a RAS inhibitor. This rise in creatinine is associated with long-term kidney protection, and therapy should not necessarily be stopped in these patients. Increases in serum creatinine concentration above 30% after initiation of a RAS inhibitor should raise the suspicion of renal artery stenosis. Aggressive dose increments of ACE inhibitors or ARBs, especially in conjunction with diuresis, can precipitate AKI, so caution is appropriate. Interestingly, a retrospective cohort study showed that discontinuing RAS inhibition in patients with eGFR less than 30 mL/min/1.73 m^2 was associated with 39% and 37% higher risks for all-cause mortality and major adverse cardiovascular events (MACE), respectively, over 5 years of follow-up compared with continuation.[42] No significant difference in the risk of progression to ESKD was found. A randomized clinical trial of RAS inhibition withdrawal in patients with advanced kidney disease (STOP-ACE) is currently underway. In practice, the addition of diuretic therapy and potassium binders can reduce the incidence of hyperkalemia in patients with severe CKD and offer the potential to enhance the therapeutic effects of RAS inhibitors.

TREATMENT OF DYSLIPIDEMIA

Most patients with DKD have dyslipidemia characterized by low levels of high-density lipoprotein (HDL) cholesterol, high triglyceride (TG) levels, and a shift from larger toward smaller low-density lipoprotein (LDL) cholesterol. Dyslipidemia in diabetic patients may contribute to the development of glomerulosclerosis and progressive kidney disease.[43] In the Diabetes Atherosclerosis Intervention Study (DAIS), patients with T2D taking fenofibrate had a significantly lower rate of progression from normoalbuminuria to moderately increased albuminuria at 3 years compared with the placebo group.[44]

Statins have the strongest evidence for reducing atherosclerotic CVD risk and are the first-choice hypolipidemic agent. Treatment emphasis is placed on assessing a patient's global risk for CVD and using maximum tolerated statin intensity for primary and secondary prevention of CVD. For diabetic patients ages 40 to 75 years without atherosclerotic CVD, the ACC/AHA guidelines recommend moderate-intensity statin therapy. Younger patients with elevated CVD risk factors may reasonably be treated with a statin as well. In diabetic patients with atherosclerotic CVD, maximally tolerated dose of high-intensity statin is recommended, aiming to lower LDL cholesterol by 50% or more.[45] Follow up fasting lipid measurements should be done 4 to 12 weeks after starting a statin and should be repeated every 3 to 12 months as needed. The addition of a nonstatin hypolipidemic agent (e.g., ezetimibe) may be considered in high-risk patients who have not achieved a LDL cholesterol reduction goal on statin therapy. Once a patient has ESKD and is placed on dialysis, statin therapy may not improve CV outcomes (see Chapter 33).[46]

In patients with T2D, LDL cholesterol is not the sole lipoprotein that defines CV risk. As major statin trials have demonstrated, lowering of LDL cholesterol does not prevent the majority of adverse CV events and does not bring the CV risk in T2D down to the level of nondiabetic patients (referred to as residual CV risk). Atherogenic dyslipidemias, specifically elevated TG, low HDL cholesterol, elevated apolipoprotein B, and elevated apolipoprotein C III, are thought to be key factors associated with residual CV risk in diabetic patients.[47] In the UKPDS, elevated TG was independently associated with albuminuria in patients with T2D. Thus, interventions aimed at improving all lipid targets are recommended. However, it is not clear whether this is best achieved by intensification of statin therapy or supplementation of statin therapy with other hypolipidemic therapeutics or omega-3 fatty acids. In the ACCORD Lipid trial, routine use of combination therapy with a statin plus a fibrate did not reduce CV risk in patients with T2D.[48]

NONPHARMACOLOGIC INTERVENTIONS

For all patients with diabetes mellitus, emphasis should be placed on lifestyle modification to lower the risk for DKD and CV events, including dietary restriction of salt and saturated fat, weight reduction and exercise as appropriate, and smoking cessation.

Dietary protein restriction may alleviate uremic symptoms in patients at or approaching ESKD. Small trials have shown low-protein diets (≤0.8 g/kg/day) reduce proteinuria significantly with increased plasma albumin in patients with T2D with severely increased albuminuria. A recent meta-analysis concluded that a low-protein diet (≤0.8 g/kg/day) slows the decline in eGFR and improves proteinuria in patients with DKD.[49] Even patients with mild DKD appear to benefit from dietary protein restriction with decreased proteinuria. However, nutritional counseling is advised for all patients to avoid protein-energy malnutrition and to receive education on salt, potassium, and phosphate restriction, as well as choice of carbohydrates and fats (see Chapter 90). The efficacy of low-protein diets in reducing the rate of kidney function loss in patients taking SGLT2 inhibitors has not been systematically studied.

Smoking cessation and weight reduction can provide additive kidney benefits and lower the risk for CV events in patients with DKD. Smoking is an independent risk factor for the development of nephropathy in T2D and is associated with accelerated loss of kidney function. Smoking cessation attenuates albuminuria and improves kidney prognosis.[50] Weight reduction also may improve kidney outcome. The Look-AHEAD trial found intensive lifestyle interventions consisting of diet and exercise plans achieved greater weight loss compared with diabetes support and education (mean 1-year weight loss of 8.6% vs. 0.7%) and reduced the incidence of CKD (0.63% vs. 0.91%) in obese patients with T2D.[51] Furthermore, results of prospective cohort studies and emerging evidence from randomized clinical trials show bariatric surgery may prevent or slow the progression of DKD over medical intervention in obese patients with T2D.[52]

EMERGING TREATMENTS FOR DIABETIC KIDNEY DISEASE

Genetic and epigenetic factors, glomerular hypertension and hyperfiltration, overactive RAS, accumulation of advanced glycation end products, oxidative stress, kidney inflammation, and fibrosis contribute to DKD and are potential therapeutic targets.

A number of treatments, some experimental and others in clinical use for other indications, have been tried to prevent or treat DKD. Unfortunately, many investigational drugs failed to meet primary clinical endpoints, had unacceptable side effects, or were abandoned by pharmaceutical companies for financial reasons. Bardoxolone methyl

TABLE 32.1 Selected Investigational Drugs for Diabetic Kidney Disease

Drug	Mechanism of Action	Clinical Trials and Comments
Finerenone, esaxerenone, apararenone, KBP-5074	Selective nonsteroidal MRAs	In FIDELIO-DKD, finerenone reduced kidney progression and CV events in T2D with advanced CKD.[38] A phase III trial of esaxerenone in T2D with moderately elevated albuminuria showed that it is effective in reducing albuminuria. Esaxerenone is approved in Japan for the treatment of hypertension.
Atrasentan, avosentan	Endothelin A receptor blocker	In a phase III trial (SONAR), atrasentan reduced kidney endpoints by 35% in patients with T2D; significant risk for fluid retention and anemia occurred in the atrasentan group.[55] A phase III trial of avosentan (ASCEND) showed a reduction in albuminuria in the short term, but the trial was terminated early due to fluid retention in the avosentan group.[54]
Paricalcitol	Vitamin D receptor activators	An RCT ($n = 281$) found addition of paricalcitol to RAS inhibition nonsignificantly lowered albuminuria in patients with T2D and DKD.[57]
Allopurinol, febuxostat, topiroxostat	Purine analog and inhibitor of xanthine oxidase that decreases uric acid formation	The PERL and CKD-FIX trials concluded that allopurinol did not reduce the progression of DKD.[58,59]
Pentoxifylline, CTP-499	Nonselective phosphodiesterase inhibitors	In a small trial ($n = 169$) of patients with T2D, the addition of pentoxifylline to a RAS inhibitor had additive antiproteinuric effect and slowed kidney disease progression after the first year of treatment and maintained statistical significance with placebo after 24 months.[60]
CCX-140, NOX-E36	C-C chemokine receptor 2 antagonist and chemokine ligand 2 inhibitor	Phase II trials of several chemokine inhibitors have shown kidney protective effects of chemokine inhibitors in T2D with DKD.
Selonsertib (GS-4997)	Selective ASK1 inhibitor	A phase II trial of selonsertib showed no effect on albuminuria compared with placebo, though post hoc analyses suggest that it may slow DKD progression.[56]
ASP-8232	Vascular adhesion protein 1 inhibitor	Ongoing phase II trial to evaluate the efficacy and safety of ASP-8232 in patients with T2D and DKD.
Bardoxolone methyl (RTA-402)	Inducer of Nrf2 pathway	A phase III trial of bardoxolone methyl in DKD was halted because of excess serious adverse events in the treated group. A separate phase II study in Japan showed significant improvement in eGFR, with an associated increase in UACR, in the bardoxolone methyl group compared with placebo. There is an ongoing phase III trial in Japanese patients with T2D and CKD.

ASCEND, Avosentan on Doubling of Serum Creatinine, ESKD and Death; *ASK1,* apoptosis signal-regulating kinase 1; *CKD,* chronic kidney disease; *CV,* cardiovascular; *DKD,* diabetic kidney disease; *eGFR,* estimated glomerular filtration rate; *FIDELIO-DKD,* Finerenone in Reducing Kidney Failure and Disease Progression in Diabetic Kidney Disease; *MRA,* mineralocorticoid receptor antagonist; *RAS,* renin-angiotensin system; *RCT,* randomized controlled trial; *SONAR,* Atrasentan and Renal Events in Patients with Type 2 Diabetes and Chronic Kidney Disease; *T1D,* type 1 diabetes; *T2D,* type 2 diabetes; *UACR,* urine albumin-to-creatinine ratio.

(an inducer of the Nrf2 pathway), ruboxistaurin (a protein kinase C inhibitor), pirfenidone (an antifibrotic agent), pimagedine/aminoguanidine/pyridoxamine (advanced glycation end product formation inhibitors), baricitinib (janus kinase inhibitor), palosuran (a vasopeptidase inhibitor), probucol (an antioxidant), and sulodexide (a glycosaminoglycan) are examples. Ongoing trials exploring new DKD treatments include endothelin receptor antagonists, drugs that target oxidative stress, xanthine oxidase inhibitors, and other antiinflammatory and antifibrotic agents (Table 32.1).

ENDOTHELIN RECEPTOR ANTAGONISTS

The kidney endothelin system is activated in experimental and clinical DKD. The antiproteinuric effect of an endothelin A receptor blocker was shown in the Avosentan on Doubling of Serum Creatinine, ESKD and Death (ASCEND) phase III clinical trial. However, fluid retention led to early termination of the ASCEND trial.[54] Another endothelin A receptor blocker, atrasentan, is more selective than avosentan and was shown in the Atrasentan and Renal Events in Patients with Type 2 Diabetes and Chronic Kidney Disease (SONAR) trial to reduce the incidence of primary composite endpoints of serum creatinine doubling or onset of ESKD. Serious adverse events included fluid retention and anemia, which occurred more frequently in the atrasentan group. There were no CV benefits.[55] Whether atrasentan will be approved for DKD treatment remains unclear.

SELECTIVE APOPTOSIS SIGNAL-REGULATING KINASE 1 INHIBITOR

Apoptosis signal-regulating kinase 1 (ASK1) activation from oxidative stress in glomerular and tubular cells has been implicated in the pathogenesis of DKD. Selonsertib is a selective ASK1 inhibitor developed as a once-daily oral agent for the treatment of DKD. In a phase II trial evaluating selonsertib's safety and efficacy, selonsertib failed to reduce UACR compared with placebo, though post hoc analyses suggest that it may slow DKD progression.[56] A phase IIb trial enrolling patients with moderate-advanced DKD is currently underway.

Vitamin D Receptor Activators

Vitamin D receptor activation reduced albuminuria in small trials of DKD. A cross-sectional analysis of the National Health and Nutrition Examination Survey (NHANES, 2001–2006) data showed that there was an independent association between vitamin D deficiency and insufficiency with the presence of nephropathy. The largest phase II RCT investigating the effect of paricalcitol (a vitamin D analog) 1 or 2 μg/day in patients with T2D failed to meet its primary endpoint

(change in albuminuria), but post hoc analysis showed lowered albuminuria compared with placebo in patients with high sodium intake and on a higher dose of paricalcitol.[57] However, only 58% of the patients assigned to 2 μg/day of paricalcitol received the full dose during the study, and the follow-up period of 24 weeks was brief. The use of vitamin D analogs in clinical applications of DKD demands further RCTs in larger patient series with adequate follow-up.

Xanthine Oxidase Inhibitors

Epidemiologic studies suggest an independent association between asymptomatic hyperuricemia and increased risk for arterial hypertension, CKD, albuminuria, CV events, and mortality. Whereas some smaller clinical trials have shown improvements in BP control and slowing of CKD progression using urate-lowering therapy, two recent RCTs did not. In one trial treating patients with CKD at high risk of progression, urate-lowering treatment with allopurinol did not slow the decline in eGFR compared with placebo.[58] Similarly, in another trial, clinically meaningful benefits of serum urate reduction with allopurinol on kidney outcomes among patients with T1D and early to moderate DKD could not be detected.[59] Although both studies had some weaknesses in design (e.g., including subjects who were not hyperuricemic), the use of allopurinol for this indication is currently unsupported.

Phosphodiesterase Inhibitors

Pentoxifylline (PTF) is a nonselective phosphodiesterase (PDE) inhibitor used for symptomatic relief of claudication. It has vasodilatory and antihypertensive effects and may have beneficial kidney hemodynamic effects. PTF also inhibits the synthesis of inflammatory cytokines. In a small trial in patients with T2D, the addition of PTF to RAS inhibition had additive antiproteinuric effects and slowed kidney disease progression after the first year of treatment. Statistical significance was maintained for 24 months.[60] A key problem for the clinical development of PTF as a DKD treatment is the low cost of the drug. A more selective PDE inhibitor, PF-489791, was discontinued despite early promising phase II results.

Novel Therapeutic Approaches

Novel investigational agents, including CCX-140, NOX-E36, DMX-200 (chemokine inhibitors), LY3016859 (an epidermal growth factor receptor inhibitor), GKT137831 (a NADPH oxidase inhibitor), ASP-8232 (a vascular adhesion protein 1 inhibitor), SER150 (a thromboxane A2 receptor antagonist), and several drugs currently in clinical use for other indications (e.g., N-acetylcysteine, colchicine), are being evaluated for treatment of proteinuric kidney disease, including DKD. A new formulation of bardoxolone methyl, RTA 402 (an inducer of Nrf2 pathway), is being tested for safety and efficacy in Japanese patients with T2D with CKD. The role of micro-RNAs in the pathogenesis of DKD is an emerging field and may also provide additional novel treatment approaches. New insights into the molecular mechanisms that underlie the origin and progression of DKD are emerging from large-scale genetic and molecular studies in experimental models and humans.

Management of Patients With Diabetes and Chronic Kidney Disease

Vikas S. Sridhar, Christine P. Limonte, David Z.I. Cherney, Ian H. de Boer

Type 2 diabetes mellitus (T2D), and to a lesser extent type 1 (T1D), are rapidly increasing in incidence and remain the leading cause of chronic kidney disease (CKD) and end-stage kidney disease (ESKD) in the Western world.[1] This chapter reviews the diagnostic and management considerations of the patient with diabetes and CKD, referred to as diabetic kidney disease (DKD), focusing on strategies with the potential to improve clinical outcomes.

DIAGNOSTIC CONSIDERATIONS

Diabetic kidney disease is usually a clinical diagnosis in patients with diabetes and CKD, with kidney biopsy reserved for atypical presentations such as frank hematuria amid negative urologic investigations, nephrotic range albuminuria in the presence of normal glomerular filtration rate (GFR), or an accelerated progression of albuminuria or decline in GFR.[2] In such populations, one-half to two-thirds of patients have nondiabetic kidney disease.[3,4] The presence of diabetic retinopathy increases the pretest probability of DKD, but its absence is less helpful in ruling it out.[4,5]

GENERAL MANAGEMENT CONSIDERATIONS

Patients with DKD are at risk of premature mortality from cardiovascular (CV) disease.[6,7] The Kidney Disease: Improving Global Outcomes (KDIGO) guideline on Diabetes Management in CKD recommends lifestyle changes, identification and treatment of kidney-heart risk factors, patient self-management, and team-based integrated care programs to complement targeted pharmacotherapy (Fig. 33.1).[8] Key lifestyle changes include smoking cessation, salt restriction to less than 5 g/day (sodium <2 g/day); adoption of diets high in fruits, vegetables, unsaturated fats, and plant-based proteins while avoiding processed meats and carbohydrates; and moderate-intensity physical activity for at least 150 minutes weekly. Self-management education programs empower patients to actively participate in this comprehensive care model, aiming to slow DKD progression, reduce CV and treatment-related complications, and improve satisfaction with and adherence to treatment plans.[9] Future aims include halting the disease process and reversing damage.

A multidisciplinary approach is pivotal. It should include nephrologists, primary care providers, endocrinologists/diabetologists, cardiologists, nephrology/diabetes nurse specialists, podiatrists, ophthalmologists, and dieticians, as needed. Regular clinical monitoring improves outcomes in CKD patients,[10] with current recommendations for follow-up ranging from yearly to quarterly depending on the level of GFR level and its rate of decline.

MONITORING DIABETIC KIDNEY DISEASE

Beyond methods for measuring glycemic control (see later), albuminuria (typically quantified by albumin-to-creatinine ratio [ACR]) and estimated GFR (eGFR) constitute the mainstay of monitoring in DKD.

Measures of Glycemic Control

Hemoglobin A1c

Hemoglobin A1c (HbA1c) arises from nonenzymatic glycation of blood hemoglobin[11] and reflects average glycemia over approximately 10 to 12 weeks. Advantages are its accessibility and low intrasubject variability.[12] Limitations include inability to provide measures of short-term serum glucose levels or glycemic variability and reduced correlation with blood glucose levels in advanced CKD stages, due largely to increased red blood cell turnover (see Chapter 86).[13] Despite this, elevated HbA1c (>8% [>64 mmol/mol]) has been associated with higher all-cause and CV mortality in people with advanced DKD, including those treated with dialysis or kidney transplantation.[14-18]

Guidelines of the KDIGO recommend an individualized HbA1c target ranging between less than 6.5% and 8.0% or less in people with nondialysis DKD. Fig. 33.2 shows factors guiding decisions on individual HbA1c targets in DKD. In dialysis patients, the optimal glycemic target is unknown.

Self-Monitoring of Blood Glucose

In contrast to HbA1c, direct glucose measurements are not affected by severe CKD. Self-monitoring of blood glucose (SMBG) using a fingerstick and glucometer may facilitate maintenance of glycemic control. Self-monitoring is especially valuable in patients receiving insulin or other agents that may cause hypoglycemia. Because SMBG is at the discretion of the patient, episodes of hypoglycemia or hyperglycemia may be missed. Additionally, glucose variability cannot be readily assessed.

Continuous Glucose Monitoring

Continuous glucose monitoring (CGM) devices measure interstitial glucose using subcutaneous sensors. Depending on the system used, glucose measurements can be programmed to be performed continuously or at specific intervals (typically every 5–15 minutes). Some models allow for visualization of glucose levels or trends in real time. Devices can generate reports that display glucose trends over time (specifying time within, above, and below the target glucose range) in addition to measures of glucose variability. A typical target range is a glucose level of 70 to 180 mg/dL (3.9–10.0 mmol/L) in more than 70% of readings.[19]

Continuous glucose monitoring facilitates meeting glycemic targets and encourages self-management, with newer models offering linkage with insulin delivery systems or smartphone integration. This type

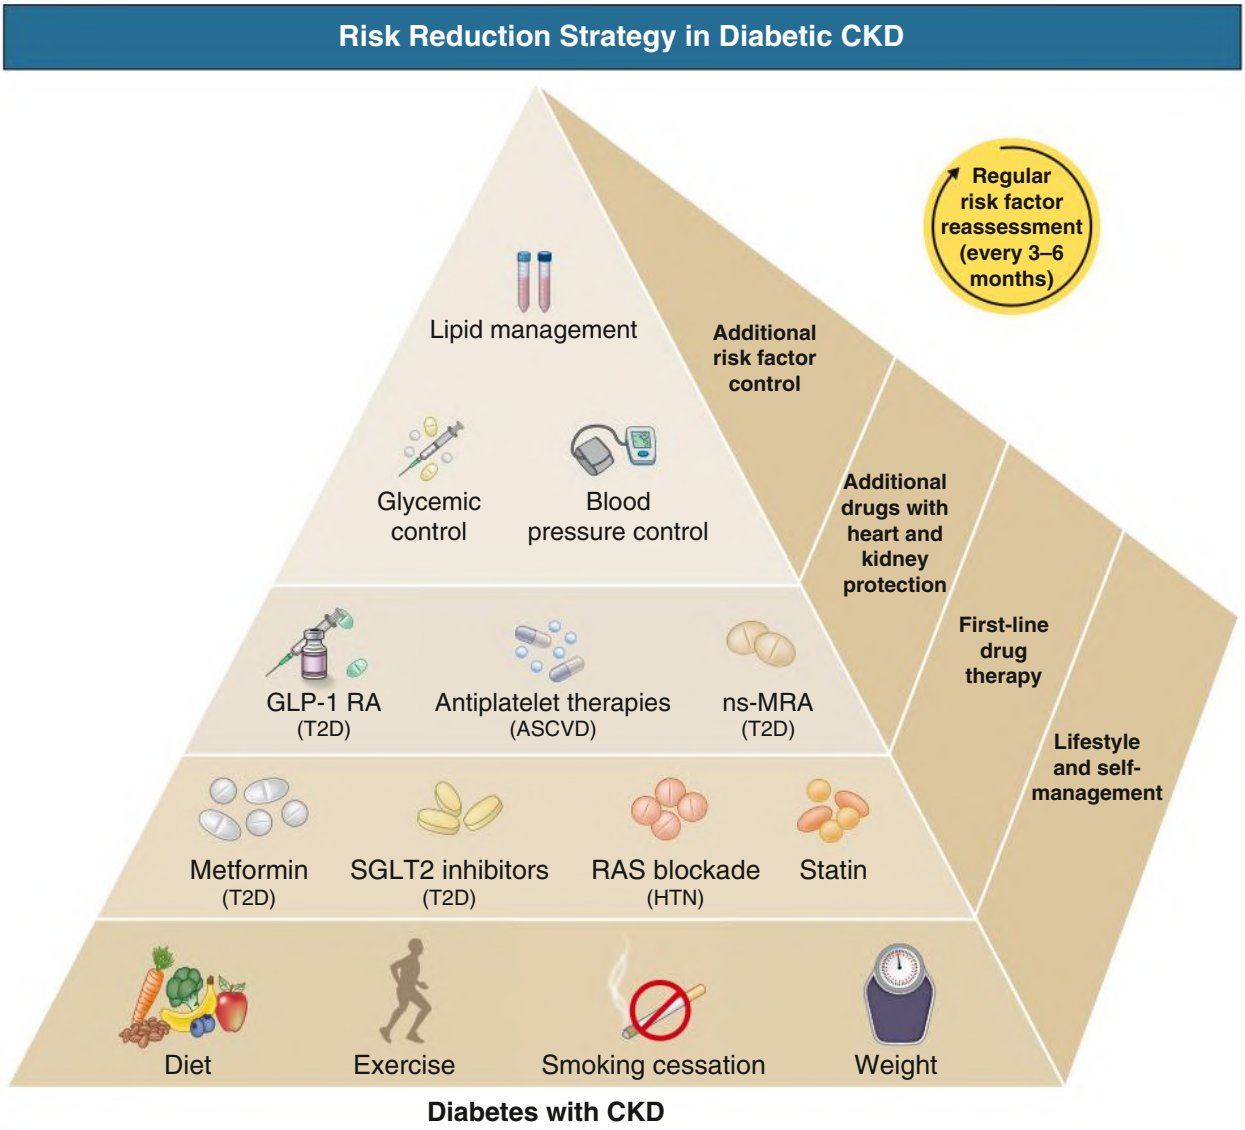

Fig. 33.1 Chronic Kidney Disease and Diabetes. Patients with diabetes and chronic kidney disease *(CKD)* Should be treated with a comprehensive strategy to reduce risks of kidney disease progression and adverse cardiovascular outcomes. Lifestyle and risk factor modification form the foundation of therapy, with pharmacotherapy targeted to appropriate patients using evidence from clinical trials. *RAS,* Renin-angiotensin system; *SGLT2,* sodium-glucose cotransporter-2. KDIGO 2022 clinical practice guidelines for diabetes management in chronic kidney disease. *Kidney Int.* 2022;102:S1-S127.)

Individualization of Glycemic Targets in Diabetic CKD

< 6.5%	HbA1c	< 8.0%
CKD G1	Severity of CKD	CKD G5
Absent/minor	Macrovascular complications	Present/severe
Few	Comorbidities	Many
Long	Life expectancy	Short
Present	Hypoglycemia awareness	Impaired
Available	Resources for hypoglycemia management	Scarce
Low	Propensity of treatment to cause hypoglycemia	High

Fig. 33.2 Glycemic Targets Should be Individualized for Patients with Diabetes and Chronic Kidney Disease (CKD). Clinical factors affecting benefits and risks, depicted here, should be assessed to inform shared decision making. *CKD G1,* Estimated glomerular filtration rate (eGFR) ≤90 mL/min/1.73 m^2; *CKD G5,* eGFR <15 mL/min/1.73 m^2. *HbA1c,* Hemoglobin A1c. (From Kidney Disease: Improving Global Outcomes [KDIGO] Diabetes Work Group. 2022 clinical practice guidelines for diabetes management in chronic kidney disease. *Kidney Int.* 2022;102:S1-S127.)

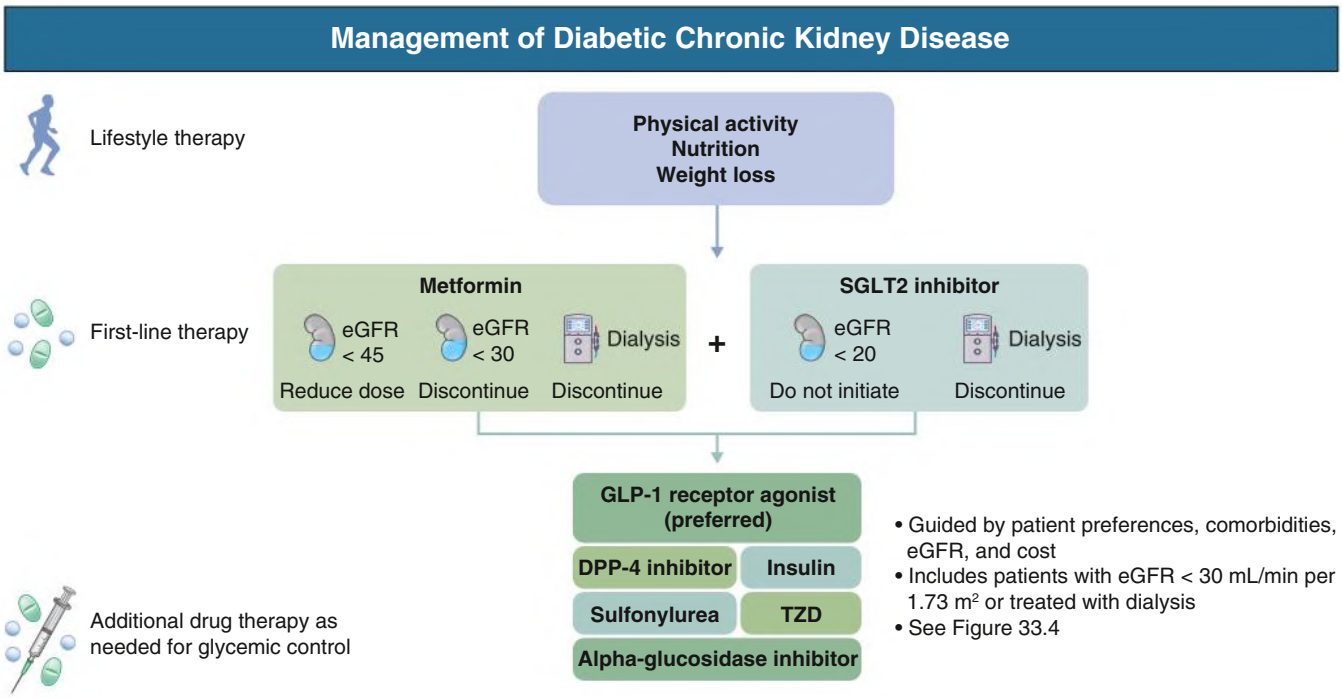

Fig. 33.3 Most patients with type 2 diabetes and chronic kidney disease should be treated with lifestyle therapy, metformin, and a sodium-glucose cotransporter-2 (SGLT2) inhibitor, depending on clinical factors and estimated glomerular filtration rate. Additional drug therapy may be needed to control glycemia if metformin and SGLT2 inhibition are not tolerated or contraindicated. *DPP-4,* Dipeptidyl peptidase-4; *eGFR,* estimated glomerular filtration rate; *GLP-1,* glucagon-like peptide 1; *TZD,* thiazolidinedione. (From Kidney Disease: Improving Global Outcomes [KDIGO] Diabetes Work Group. 2022 clinical practice guidelines for diabetes management in chronic kidney disease. *Kidney Int.* 2022;102:S1-S127.)

of monitoring is especially valuable for people who have highly variable glucose levels, are at risk for experiencing severe hypoglycemia, and those for whom HbA1c levels do not align with measured blood glucose. Disadvantages of CGM include skin irritation related to the device patch and potentially high cost.

Albuminuria

Albuminuria is classified as normoalbuminuria (<30 mg albumin/24 h), moderately increased albuminuria (30–300 mg/24 h), and severely increased albuminuria (>300 mg/24 h). The terms microalbuminuria and macroalbuminuria should be abandoned. Any albuminuria is associated with an increased risk of DKD progression and cardiovascular disease (CVD).[20,21] Moderately increased albuminuria was long viewed a first step in DKD, leading to worsening albuminuria, eGFR loss, and ESKD.[22] However, reduced GFR in the absence of albuminuria is common, particularly in T2D, with up to 57% of patients in certain CKD cohorts presenting in this manner.[23-25] These latter patients are still at increased risk of progression, albeit with slower rates of eGFR decline than albuminuric DKD.[26] Additionally, albuminuria in patients with moderately increased albuminuria may not progress to severely increased albuminuria and even undergo spontaneous remission.[27,28]

Glomerular Filtration Rate

Measured and estimated GFR are important predictors of kidney prognosis, particularly when combined with albuminuria. In healthy persons the annual age-related eGFR decline is 0.5 to 1 mL/min/1.73 m^2.[29] A large cohort of participants with T1D (mean duration of 5.5 years) had median decline in eGFR of 3 mL/min/1.73 m^2 over 3 years, with 25% experiencing a 3-year decline of 14 mL/min/1.73 m^2 or greater.[30] In more contemporary DKD cohorts, albuminuria is still associated with rapid eGFR decline even in the presence of renin-angiotensin system (RAS) inhibition. For example, the high kidney-risk CREDENCE trial participants with T2D and DKD experienced an annual eGFR decline of 4.71 ± 0.15 mL/min/1.73 m^2 per year.[31] Limitations of using GFR to monitor disease progression include nonlinear trajectories in GFR decline, including the occurrence of hyperfiltration early in the disease course and treatment-induced hemodynamic changes in kidney function, imperfect correlations between estimated and measured GFR, and potential underestimation of eGFR decline in clinical trial settings when compared with real-world clinical scenarios.

Models to Predict Kidney Failure Risk

The Kidney Failure Risk Equation (KFRE) is a widely used prediction instrument that has been validated in several cohorts and CKD etiologies, including DKD (see https://kidneyfailurerisk.com).[32] The KFRE uses patient age, sex, eGFR, and ACR to offer 2-year and 5-year risk estimates of developing ESKD. In addition to helping nephrologists quickly convey prognostic information to patients, KFRE-derived risk estimates are routinely used to anticipate and plan for the initiation of kidney-replacement therapies.

MANAGEMENT OF GLYCEMIA

Insulin is the primary treatment for T1D, with dosing schedules iteratively refined based on observed blood glucose concentrations at all levels of kidney disease. In T2D, oral antihyperglycemic agents are preferred as foundational therapy because of their lower risks of hypoglycemia and, for some drug classes, reduction in the risk of progressive CKD or CV events. For patients with T2D and CKD, lifestyle treatments, metformin, and sodium-glucose cotransporter-2 inhibitors (SGLT2i) are recommended as first-line therapy, with some restrictions according to eGFR (Fig. 33.3). Additional or alternate agents should be selected according to patient preferences, comorbidities, and other characteristics when needed to achieve glycemic goals (Fig. 33.4).

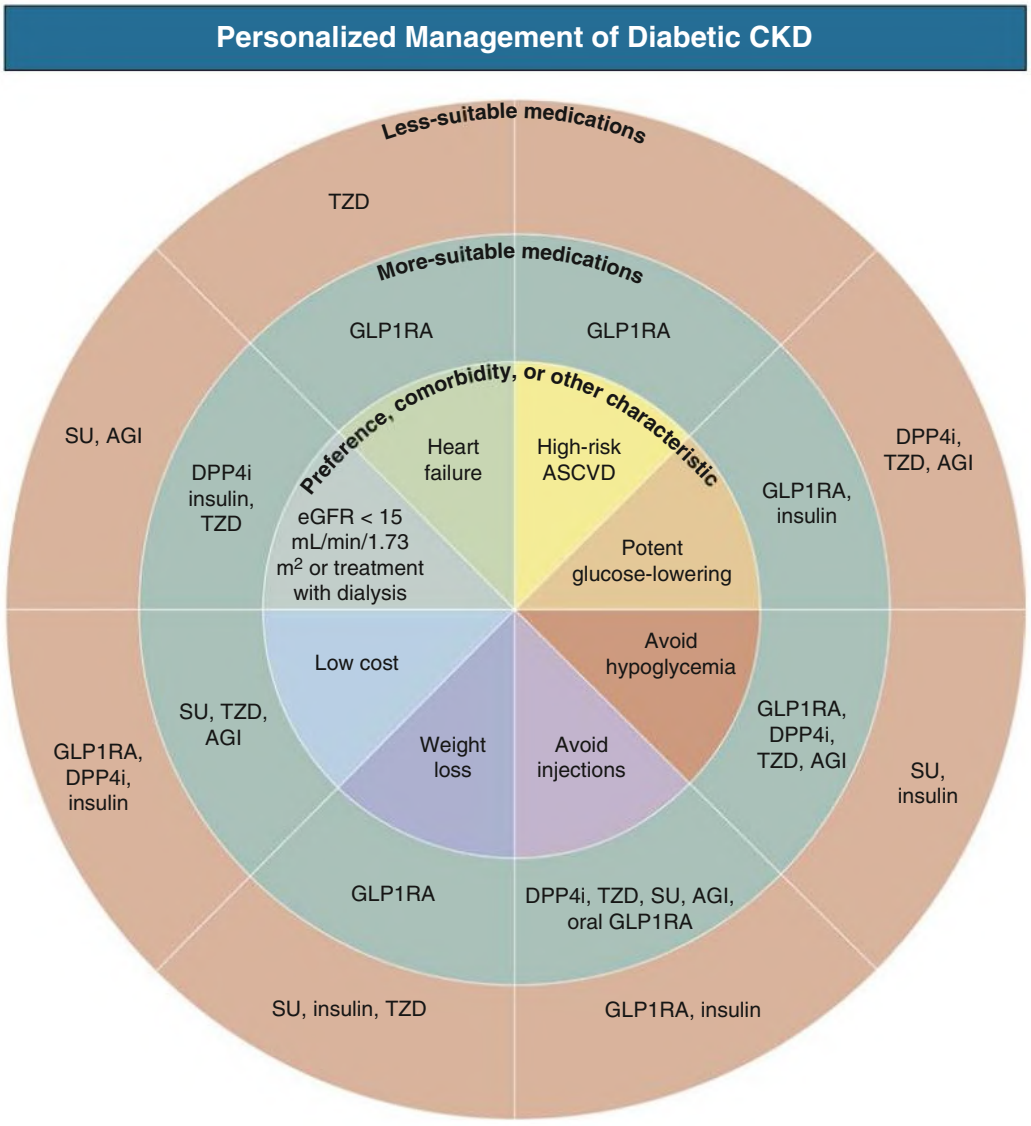

Fig. 33.4 For patients with type 2 diabetes and chronic kidney disease (CKD) who have not achieved individualized glycemic targets despite use of metformin and sodium-glucose cotransporter-2 inhibitor treatment, or who are unable to use those medications, patient preferences, comorbidities, and other characteristics should be used to select additional or alternate glucose-lowering medications. In general, glucagon-like peptide 1 receptor agonists (GLP1RA) may be preferred because of their beneficial cardiovascular effects, and possible beneficial effects on CKD progression. *AGI,* Alpha-glucosidase inhibitor; *ASCVD,* atherosclerotic cardiovascular disease; *DPP-4i,* dipeptidyl peptidase-4 inhibitor; *eGFR,* estimated glomerular filtration rate; *SU,* sulfonylurea; *TZD,* thiazolidinedione. (From Kidney Disease: Improving Global Outcomes [KDIGO] Work Group. 2022 clinical practice guidelines for diabetes management in chronic kidney disease. *Kidney Int.* 2022;102:S1-S127.)

Hypoglycemia and Hyperglycemia

Episodes of hypoglycemia are more common in patients with severe CKD or requiring dialysis due to reduced insulin clearance and impaired renal gluconeogenesis. Hypoglycemic episodes may result in increased short-term mortality, and these risks may be further elevated in patients who are elderly or have multiple comorbidities.[33] In stage III CKD, regular review of the oral antihyperglycemic regimen or insulin dosing is essential. With progression of CKD, medications that have a higher risk of inducing hypoglycemia should be dose reduced or replaced based on the following considerations.

Oral Hypoglycemic Agents

Many oral agents for the treatment of T2D require dose adjustments with reduced GFR (Table 33.1). Also, in advanced CKD, drug-drug interactions increase together with further complications of diabetes. For example, gastroparesis affects the pharmacokinetics of oral medications.

Biguanides

Metformin decreases hepatic glucose production, increases insulin sensitivity and insulin-mediated utilization of glucose in peripheral tissues, and decreases intestinal glucose absorption. Metformin is recommended as the first-line agent for management of T2D in combination with SGLT2i and lifestyle measures (Fig. 33.3).[34] In addition to effectively improving glycemic control, metformin modestly reduces the risk of CV events and death in T2D.[35] Metformin dosage should be reduced when eGFR drops below 45 mL/min/1.73 m^2, and such patients should be instructed to temporarily stop metformin in states

TABLE 33.1 Daily Dosing for Selected Oral Hypoglycemic Agents

Class	Drug	CKD1 and 2: eGFR >60 mL/min/1.73 m²	CKD3a: eGFR 45–59 mL/min/1.73 m²	CKD3b: eGFR 30–44 mL/min/1.73 m²	CKD4: eGFR 15–29 mL/min/1.73 m²	CKD5: eGFR <15 mL/min/1.73 m² or Dialysis

[a]Threshold levels of eGFR for drug initiation are based on published clinical trials. Regulatory guidance may vary by agency, over time, and according to specific indication.

CKD, Chronic kidney disease; *DPP-4,* dipeptidyl peptidase-4; *eGFR,* estimated glomerular filtration rate; *ER,* extended release; *FDA,* Food and Drug Administration; *GLP-1,* glucagon-like peptide-1; *IR,* immediate release; *SGLT-2,* sodium-glucose cotransporter-2.

Listed dosages reflect the maximum daily recommendations based on manufacturer recommendations and expert opinion. Drug initiation and uptitration should be done slowly and cautiously with declining eGFR. Available formulations and pharmacologic guidelines vary by country.

of dehydration, before the administration of radiocontrast media, and other situations where there is an increased risk for acute kidney injury (AKI). Metformin is not recommended for people with eGFR less than 30 mL/min/1.73 m² because of the risk for lactic acidosis. However, a Cochrane review[36] found no evidence that advanced CKD was associated with increased risk for lactic acidosis in patients receiving appropriate doses of metformin.[35,37]

Sodium-Glucose Cotransporter-2 Inhibitors

SGLT2i block kidney proximal tubular glucose reabsorption. Resulting reductions in blood glucose are greater with higher concentrations of blood glucose and higher GFR. Along with metformin, SGLT2i are first-line antihyperglycemic therapy in DKD, given their cardioprotective and renoprotective effects (Fig. 33.3). In the EMPA-REG OUTCOME trial in patients with T2D and eGFR above 30 mL/min/1.73 m², empagliflozin reduced the risk of CV mortality, all-cause mortality, and hospitalization for congestive heart failure with favorable effects on weight and systolic blood pressure. The EMPA-REG OUTCOME trial also reported a reduced progression of kidney failure and albuminuria.[38] The CREDENCE trial enrolled patients with T2D, eGFR 30 to 90 mL/min/1.73 m², and macroalbuminuria and demonstrated reduced CKD progression and incident kidney failure with canagliflozin.[31] Additional randomized controlled trials (RCTs; CANVAS, DECLARE-TIMI 58, VERTIS, DAPA-CKD, DAPA-HF, EMPEROR-Reduced, SCORED, SOLOIST) have consistently demonstrated substantial long-term CV and kidney benefits of SGLT2i across eGFR despite reduced antihyperglycemic effects (Table 33.2).[39-46]

The mechanisms underlying kidney benefits of SGLT2i are incompletely understood. Effects have been attributed in part to restoration of tubuloglomerular feedback and reduction of glomerular hyperfiltration via increased distal sodium delivery to the macula densa. Other mechanisms may include improvements in energy metabolism, with a shift from carbohydrate to ketone metabolism inducing an energy-efficient mitochondrial oxygen consumption that reduces kidney hypoxia.[47] Reduced glomerular hyperfiltration is thought to account for the acute decline in eGFR observed with SGLT2i initiation.

TABLE 33.2 Summary of Selected Large Clinical Trials of Recently Established and Potential New Therapeutics in Diabetic Kidney Disease

Study	Treatment Arms	Duration	Patient Cohort	Outcome
SGLT2i				
Evaluation of the Effects of Canagliflozin on Renal and Cardiovascular Outcomes in Participants with Diabetic Nephropathy (CREDENCE),[31] NCT02065791	Canagliflozin 100 mg daily vs. placebo	2.6 years	4401 T2D patients with stage 2 or 3 CKD and macroalbuminuria and on an ACE inhibitor or ARB	**Primary:** 30% reduction in ESKD, S-creatinine doubling, renal/CV death **Secondary:** 20% reduction in CV death, nonfatal MI, nonfatal stroke; 39% reduction in hospitalization for CHF; 34% reduction in composite renal endpoint (ESKD, doubling of serum Cr, renal death)
Empagliflozin, Cardiovascular Outcomes, and Mortality in Type 2 Diabetes (EMPA-REG OUTCOME),[38] NCT01131676	Empagliflozin vs. placebo	3.1 years	7020 participants with T2D at high CV risk	14% reduction in composite; death from CV causes, nonfatal MI, or nonfatal stroke
Canagliflozin and Cardiovascular and Renal Events in Type 2 Diabetes (CANVAS),[39] NCT01032629	Canagliflozin vs. placebo	3.6 years	10,142 participants with T2D and high CV risk	**Primary:** 14% reduction in composite death from CV causes, nonfatal MI, nonfatal stroke **Secondary:** 27% reduction in albuminuria progression; 40% reduction in composite sustained 40% reduction in eGFR, need for renal replacement therapy, death from renal causes
Dapagliflozin and Cardiovascular Outcomes in Type 2 Diabetes (DECLARE-TIMI 58),[40] NCT01730534	Dapagliflozin vs. placebo	4.2 years	17,160 participants with T2D at risk for atherosclerotic CVD	**Primary:** 17% reduction in CV death or hospitalization for HF; no difference with respect to MACEs **Secondary:** 24% reduction in composite renal events (>40% decrease in eGFR to <60 mL/min/1.73 m^2, new ESKD, or death from renal or CV causes); 7% reduction in death from any cause
Cardiovascular Outcomes with Ertugliflozin (VERTIS),[41] NCT01986881	Ertugliflozin vs. placebo	3.5 years	8246 participants with T2D and atherosclerotic CVD	**Primary:** noninferiority for MACEs **Secondary:** no difference in death from CV causes or hospitalization for HF; no difference in death from renal causes, renal replacement therapy, or doubling of serum Cr
Dapagliflozin in Patients with Heart Failure and Reduced Ejection Fraction (DAPA-HF),[43] NCT03036124	Dapagliflozin vs. placebo	1.5 years	4744 participants with HF and an ejection fraction ≤40%	26% reduction in composite worsening HF or CV death
Cardiovascular and Renal Outcomes with Empagliflozin in Heart Failure (EMPEROR-Reduced),[44] NCT03057977	Empagliflozin vs. placebo	1.3 years	3730 participants with HF	**Primary:** 25% reduction in composite CV death or hospitalization for worsening HF **Secondary:** slower eGFR decline, reduced renal outcomes
Sotagliflozin in Patients with Diabetes and Chronic Kidney Disease (SCORED),[45] NCT03315143	Sotagliflozin vs. placebo	1.3 years	10,584 participants with T2D and CKD at risk for CVD	26% reduction in composite death from CV causes, HF hospitalizations/urgent visits; 16% reduction in death from CV causes, nonfatal MI, or nonfatal stroke
Sotagliflozin in Patients with Diabetes and Recent Worsening Heart Failure (SOLOIST),[46] NCT03521934	Sotagliflozin vs. placebo	9 months	1222 participants with T2D and a recent HF hospitalization	33% reduction in death from CV causes, hospitalization, and urgent visits for HF
DAPA-CKD,[42] NCT02065791	Dapagliflozin vs. placebo	2.4 years	T2D with DKD or nondiabetic kidney disease with eGFR 25–75 mL/min/1.73 m^2 and UACR 200–5000 mg/g	**Primary:** 44% reduction in kidney composite endpoint (≥50% sustained decline in eGFR, ESKD, or kidney or CVD death) **Secondary:** 29% reduction in CV mortality or hospitalization for CHF; 31% reduction in all-cause mortality

TABLE 33.2 Summary of Selected Large Clinical Trials of Recently Established and Potential New Therapeutics in Diabetic Kidney Disease—cont'd

Study	Treatment Arms	Duration	Patient Cohort	Outcome
EMPA-KIDNEY (NCT03594110)	Empagliflozin vs. placebo	Ongoing	DKD (T2D or T1D) or nondiabetic kidney disease with eGFR 20–45 mL/min/1.73 m^2 *or* eGFR 45–90 mL/min/1.73 m^2 with UACR ≥200 mg/g	**Ongoing:** Composite outcome of time to first occurrence of kidney disease progression (ESKD, sustained decline in eGFR to <10 mL/min/1.73 m^2), kidney death, or a sustained decline of ≥40% in eGFR from randomization), or CV death
GLP-1 Receptor Agonists				
Liraglutide and Cardiovascular Outcomes in Type 2 Diabetes (LEADER),[48] NCT01179048	Liraglutide vs. placebo	3.8 years	9340 participants with T2D at high CV risk	Reduction in composite of death from CV causes, nonfatal MI, or nonfatal stroke
Semaglutide and Cardiovascular Outcomes in Patients with Type 2 Diabetes (SUSTAIN-6),[49] NCT01720446	Semaglutide vs. placebo	2 years	3297 participants with T2D	**Primary:** 26% reduction in composite of CV death, nonfatal MI, or nonfatal stroke **Secondary:** reduction in new or worsening kidney dysfunction
Albiglutide and Cardiovascular Outcomes in Patients with Type 2 Diabetes and Cardiovascular Disease (HARMONY),[50] NCT02465515	Albiglutide vs. placebo	1.5 years	9463 participants with T2D and CVD	22% reduction in composite of CV death, MI, or stroke
Dulaglutide and Cardiovascular Outcomes in Type 2 Diabetes (REWIND),[51] NCT01394952	Dulaglutide vs. placebo	5.4 years	9901 participants with T2D and CV risk factors	12% reduction in composite nonfatal MI, nonfatal stroke, or death from CV causes
Effect of Semaglutide Versus Placebo on the Progression of Renal Impairment in Subjects With Type 2 Diabetes and Chronic Kidney Disease (FLOW), NCT03819153	Semaglutide vs. placebo	Ongoing	T2D with eGFR ≥50 to <75 mL/min/1.73 m^2 with UACR >300 mg/g and <5000 mg/g *or* eGFR ≥25 to <50 mL/min/1.73 m^2 with UACR >100 mg/g to <5000 mg/g	**Ongoing:** Time to first occurrence of a composite primary outcome event defined as persistent eGFR decline of ≥50% from trial start, reaching ESKD, death from kidney disease, or death from CVD
A Phase IIb, Multicenter, Randomised, Double-Blind, Placebo-Controlled, and Open-Label Comparator Study of Cotadutide in Participants Who Have Chronic Kidney Disease With Type 2 Diabetes Mellitus, (NCT04515849)	Cotadutide (dual GLP1 and glucagon receptor agonist) vs. placebo	Ongoing	T2D with eGFR ≥20 to <90 mL/min/1.73 m^2 with UACR >50 mg/g	**Ongoing:** UACR, HbA1c, body weight
PKCβ Inhibitors				
Treatment of Peripheral Neuropathy in Patients with Diabetes,[109] NCT00044421	Ruboxistaurin mesylate 32 mg vs. placebo	2.7 years	707 T2D participants with diabetic neuropathy	Patients treated with ruboxistaurin had lower UACR and higher eGFR
Antiinflammatory Agents				
Canakinumab Anti-Inflammatory Thrombosis Outcome Study (CANTOS),[110] NCT01327846	Canakinumab 300 mg vs. canakinumab 150 mg vs. placebo	3.7 years	10,061 adults with a history of MI and systemic inflammation (elevated high-sensitivity CRP >2 mg/mL); 40% had T2D and 46% of those with CKD in the trial had T2D	15% reduction in 3-point MACE: nonfatal MI, any nonfatal stroke, or CV death; subsequent post hoc analyses demonstrated that the risk of MACE was reduced in people with CKD and in those with albuminuria or diabetes

Continued

TABLE 33.2 Summary of Selected Large Clinical Trials of Recently Established and Potential New Therapeutics in Diabetic Kidney Disease—cont'd

Study	Treatment Arms	Duration	Patient Cohort	Outcome
A Study to Evaluate the Safety and Efficacy of CCX140-B in Subjects With Diabetic Nephropathy,[111] NCT01447147	CCX140-B 10 mg (CCR2 inhibitor) vs CCX140-B 5 mg vs. placebo	52 weeks	332 T2D patients with proteinuria, GFR ≥25 mL/min/1.73 m^2	Albuminuria lowering
Effects of Selonsertib in Patients with Diabetic Kidney Disease,[112] NCT02177786	1:1:1:1 allocation to selonsertib (oral daily doses of 2, 6, or 18 mg) or placebo	48 weeks	333 adults with moderate to advanced DKD (eGFR of 15–60 mL/min/1.73 m^2 at screening) and albuminuria, defined as a UACR ≥600 mg/g if stage 3a CKD, UACR ≥300 mg/g if stage 3b CKD, and UACR ≥150 mg/g if stage 4 CKD	**Primary endpoint:** no difference in eGFR at 48 weeks In post hoc analyses from 4 and 48 weeks, eGFR decline was reduced by 71% for the 18-mg group vs. placebo (difference 3.11 mL/min/1.73 m^2 per year, $P = .043$) Effects on UACR did not differ between selonsertib and placebo
Mineralocorticoid Receptor Antagonists				
Mineralocorticoid Receptor Antagonist Tolerability Study–Heart Failure (ARTS-HF),[113] NCT01807221	Finerenone (multiple doses) vs. eplerenone	90 days	1066 patients with worsening HFrEF and CKD and/or T2D	Finerenone reduced a composite endpoint of death from any cause, CV hospitalizations, or emergency presentation for worsening HF; reduced albuminuria
ARTS–Diabetic Nephropathy (RTS-DN),[114] NCT1874431	Finerenone (multiple doses) vs. placebo	90 days	823 T2D patients with high or very high albuminuria on ACEs or ARBs	Reduced albuminuria
Efficacy and Safety of Finerenone in Subjects with Type 2 Diabetes Mellitus and Diabetic Kidney Disease (FIDELIO-DKD),[83] NCT02540993	Finerenone vs. placebo	2.6 years	5734 T2D patients with DKD (persistent high albuminuria or very high albuminuria)	**Primary:** 18% reduction in time to first occurrence of the composite of onset of kidney failure, sustained decrease of eGFR ≥40% from baseline over at least 4 weeks, and renal death **Secondary:** 14% reduction in death from CV causes, nonfatal MI, nonfatal stroke, or hospitalization for CHF
Efficacy and Safety of Finerenone in Subjects with Type 2 Diabetes Mellitus and a Clinical Diagnosis of Diabetic Kidney Disease (FIGARO-DKD), NCT02540993	Finerenone (10 mg vs. 20 mg vs. placebo)	3.4 years	7437 T2D patients with DKD (persistent high albuminuria or very high albuminuria)	**Primary:** 13% reduction in time to first occurence of the composite of death from CV causes, nonfatal MI, nonfatal stroke, or hospitalization for CHD.Secondary outcome: no significant difference in time to kidney failure, sustained decrease of eGFR ≥40% from baseline, or renal death.
Endothelin Receptor Antagonists				
SONAR,[115] NCT01858532	Atrasentan 0.75 mg vs. placebo	2.2 years	2,648 patients with T2D, eGFR 25–75 mL/min/1.73 m^2 and ACR 300–500 mg/g on RAS blockers	Early termination (lower number of events), 35% relative risk reduction of doubling of serum Cr or ESKD
Neprilysin Inhibitors				
Prospective Comparison of ARNI with ACEI to Determine Impact on Global Mortality and Morbidity in Heart Failure trial,[116] (PARADIGM-HF)	Sacubitril/valsartan vs. enalapril	2.25 years	8399 patients with HFrEF with and without DM	Slower rate of eGFR decline with neprilysin inhibition (–1.3 vs. –1.8 mL/min/1.73 m^2 per year; $P < .0001$); though greater increase in UACR (1.20 mg/mmol [95% CI, 1.04–1.36 mg/mmol] vs. 0.90 mg/mmol [95% CI, 0.77–1.03 mg/mmol]); greater impact in diabetes cohort

TABLE 33.2 Summary of Selected Large Clinical Trials of Recently Established and Potential New Therapeutics in Diabetic Kidney Disease—cont'd

Study	Treatment Arms	Duration	Patient Cohort	Outcome
Efficacy and Safety of LCZ696 Compared with Valsartan, on Morbidity and Mortality in Heart Failure Patients With Preserved Ejection Fraction trial,[117] (PARAGON-HF)	Sacubitril/valsartan vs. valsartan	2.9 years	4822 with HFpEF with and without DM	Nonsignificant reduction in the primary outcome of composite total hospitalizations for CHF and death from CV causes (HR, 0.87; 95% CI, 0.75–1.01; $P = .06$); renal composite outcome (time to first occurrence of either ≥50% reduction in eGFR, ESKD, or death from renal causes [HR, 0.50; 95% CI, 0.33–0.77; $P = .001$])
United Kingdom Heart and Renal Protection-III[118]	Sacubitril/valsartan vs. irbesartan	12 months	414 participants (40% with a history of DM at baseline) with eGFR 20–60 mL/min/1.73 m^2 and without CHF	Sacubitril/valsartan reduced blood pressure, NT-pro-BNP, and troponin I significantly more compared with irbesartan, but without affecting eGFR or UACR

ACE, Angiotensin-converting enzyme inhibitor; *ACR,* albumin-to-creatinine ratio; *ARB,* angiotensin receptor blocker; *CHF,* congestive heart failure; *CI,* confidence interval; *CKD,* chronic kidney disease; *Cr,* creatinine; *CRP,* C-reactive protein; *CV,* cardiovascular; *CVD,* cardiovascular disease; *DKD,* diabetic kidney disease; *DM,* diabetes mellitus; *eGFR,* estimated glomerular filtration rate; *ESKD,* end-stage kidney disease; *GLP-1,* glucagon-like peptide-1; *HbA1c,* hemoglobin A1c; *HF,* heart failure; *HFpEF,* heart failure with preserved ejection fraction; *HFrEF,* heart failure with reduced ejection fraction; *HR,* hazard ratio; *MACE,* major adverse cardiovascular event; *MI,* myocardial infarction; *PKCβ,* protein kinase Cβ; *RAS,* renin-angiotensin system; *SGLT-2i,* sodium-glucose cotransporter-2 inhibitor; *T1D,* type 1 diabetes; *T2D,* type 2 diabetes; *UACR,* urinary albumin-to-creatinine ratio.

SGLT2i are associated with increased risk of euglycemic diabetic ketoacidosis and genital mycotic infections. Patients should be advised of these adverse effects and monitored closely for their development. Additionally, the SGLT2i class is part of the routine "sick day" medication list that should be held during periods of illness.

Incretin Mimetics: Glucagon-Like Peptide-1 Receptor Agonists

Glucagon-like peptide-1 receptor agonists (GLP-1 RAs) promote glucose-mediated insulin secretion by pancreatic β-cells in response to food entering the gut and suppress glucagon secretion. These receptor agonists are potent antihyperglycemic agents and stimulate weight loss by appetite suppression, both centrally and by affecting gastric motility. Guidelines of KDIGO recommend initiation of GLP-1 RA in T2D patients who have not achieved glycemic control despite metformin and SGLT2i, in large part because of these agents' CV and kidney benefits. In RCTs, GLP-1 RA therapies reduced major adverse CV events in people with T2D at high risk for CVD (LEADER, SUSTAIN-6, HARMONY, REWIND; Table 33.2).[48-51] A subset of these studies reported a reduction in albuminuria and eGFR decline with GLP-1 RA use (detailed further later). Adverse effects associated with GLP-1 RA use include gastrointestinal symptoms and, with subcutaneously administered formulations, injection site reactions. Glucagon-like peptide-1 receptor agonists should be avoided in people with a history of medullary thyroid cancer or pancreatitis.

Sulfonylureas

Sulfonylureas are a class of insulin secretagogues that stimulate pancreatic insulin secretion by closing potassium–adenosine triphosphate channels on β-cell plasma membranes. First-generation sulfonylureas are long acting and should be avoided in people with CKD given their almost exclusive renal excretion. Second-generation agents are short acting and primarily metabolized by the liver, with most metabolites (which hold antihyperglycemic properties) undergoing kidney clearance. Their use carries the risk for hypoglycemia, especially as eGFR declines. Sulfonylureas are highly protein bound but can be displaced into the circulation by other drugs such as salicylates or β-blockers, further contributing to hypoglycemia. Sulfonylureas are therefore discouraged in patients with severe CKD.

Thiazolidinediones

Thiazolidinediones are peroxisome proliferator-activated receptor (PPAR) modulators that function by increasing insulin sensitivity. These agents do not cause hypoglycemia and come at a low cost. However, thiazolidinediones may cause weight gain and fluid retention through transcriptional upregulation of tubular amiloride-sensitive sodium channels, which may be problematic in people with CKD at risk for heart failure. Higher rates of bone fractures also have been reported in patients treated with these agents.

Meglitinides

Meglitinides are primarily metabolized in the liver and act as insulin secretagogues similar to sulfonylureas. Because of the risk of hypoglycemia, these agents should be avoided with advanced CKD. Alternatively, formulations that are not primarily excreted by the kidneys, such as repaglinide, may be used.

Gliptins: Dipeptidyl Peptidase-4 Inhibitors

Gliptins inhibit the effect of dipeptidyl peptidase-4 (DPP-4), a cellular membrane protein expressed in a variety of tissues that rapidly degrades endogenous incretin hormones (e.g., GLP-1). Agents such as linagliptin are primarily metabolized by the liver and excreted in the bile, and thus they do not require dose adjustments in CKD. Gliptins are advantageous because they do not cause weight gain or hypoglycemia. Despite their similar mechanism of action to GLP-1 RA, DPP-4 inhibitors do not have equivalent CV or kidney benefits.

α-Glucosidase Inhibitors

α-Glucosidase is an intestinal enzyme that digests carbohydrates by hydrolyzing complex starches to oligosaccharides in the lumen of the small intestine, releasing glucose. Inhibition of this enzyme maintains the integrity of complex carbohydrates, thereby allowing less glucose absorption. Thus, α-glucosidase inhibitors should be taken at the start of meals. These agents may be maintained but require dose adjustment with advancing CKD. Advantages of these agents include their low cost and low rates of hypoglycemia.

Insulin

Endogenously secreted insulin undergoes first-pass metabolism in the liver, leaving approximately 50% available to enter the systemic circulation. The kidney removes 30% to 80% of systemic insulin (endogenous insulin that escapes first-pass metabolism, or exogenous insulin given subcutaneously or parenterally).[35] Patients with severe CKD are prone to hypoglycemia due to reduced insulin clearance and decreased renal gluconeogenesis,[52] and doses may need to be reduced as GFR declines.[53]

Types of insulin. Commonly used rapid-acting analogs (e.g., aspart, lispro) and long-acting analogs (e.g., glargine, detemir) have a metabolic profile that is largely unaffected by CKD. Currently no specific insulin regimen is recommended in the setting of CKD. For T1D, the basal bolus regimen of 3 daily injections of short-acting insulin with meals combined with 1 or 2 injections of long-acting insulin, as used in the Diabetes Control and Complications Trial (DCCT), is the standard treatment regimen. Pumps administering continuous subcutaneous infusions of short-acting insulins are also common, increasingly paired with real-time glucose monitoring. For T2D patients requiring insulin, the regimen usually starts on once- or twice-daily long- or intermediate-acting insulin. Mixed formulations (fixed percentages of short- to long-acting insulins) or the basal bolus regimen as in T1D may be necessary if glycemic control is not achieved.

MANAGEMENT OF HYPERTENSION

Blood Pressure Goals

Blood pressure (BP) targets in patients with diabetes have gradually declined over the years. The 2021 KDIGO clinical practice guideline for the management of BP in CKD recommends the lowest target of a systolic BP less than 120 mm Hg in patients with hypertension and CKD (GRADE 2B).[54] This recommendation differs from CKD targets in other guidelines, including the 2017 ACC/AHA recommendation of less than 130/80 mm Hg, the ESC/ESH recommendation of less than 130 to 139 mm Hg systolic, the NICE target of 120 to 139 mm Hg systolic, the ADA target of less than 130/80 mm Hg (for patients with diabetes at high CV risk), and the Hypertension Canada target of less than 130/80 mm Hg.[55-58]

The lower BP target in CKD currently advocated for by the 2021 KDIGO BP guideline is largely based on a lack of heterogeneity in the CV and all-cause mortality outcomes of the Systolic Blood Pressure Intervention Trial (SPRINT) within the CKD subgroup.[59] However, the SPRINT trial, which compared less than 120 mm Hg to less than 140 mm Hg, excluded participants with diabetes, and KDIGO does acknowledge that benefits of intensive BP lowering is less certain in patients with DKD. The Action to Control Cardiovascular Risk in Diabetes (ACCORD) trial remains the preeminent trial comparing the less than 120 mm Hg to less than 140 mm Hg targets in an entirely diabetic population. This trial failed to show a difference in the primary CV outcome between groups, though the intensive target did significantly reduce the risk of stroke.[60] KDIGO argues that ACCORD excluded participants with a creatinine greater than 1.5 mg/dL (>132 μmol/L) and does not offer adequate evidence against intensive BP reduction in this population. This is contrasted with the large number of participants with CKD in SPRINT, as well as the 42% of SPRINT participants with prediabetes and preserved CV/mortality benefits within this group.[61] When considering a systolic target of less than 120 mm Hg for people with diabetes, it is important to acknowledge the lack of direct evidence supporting or refuting this recommendation.

The current recommendations of intensive BP control, whether a systolic BP less than 120 mm Hg or less than 130 mm Hg, are based on CV and mortality benefits as opposed to kidney protection. Intensive BP lowering in SPRINT, ACCORD, and the Secondary Prevention of Small Subcortical Strokes Trial (SPS3) was actually associated with higher overall rates of eGFR decline, and a meta-analysis of BP control trials including the African American Study of Kidney Disease and Hypertension (AASK) and Modification of Diet in Renal Disease (MDRD) demonstrated that more intensive BP control reduced kidney failure risk only in participants with baseline proteinuria.[62,63] Newer studies of intensive BP lowering on CV and kidney outcomes in patients with DKD are warranted, particularly in light of newer therapies offering cardiorenal protection including SGLT2i, GLP-1 receptor agonists, and nonsteroidal mineralocorticoid receptor antagonists (MRA).

Notwithstanding the recommendations of clinical practice guidelines, an individualized approach accounting for patients' unique clinical situation and preferences is explicitly recommended by KDIGO and ADA.[54,64,65] Standardized BP measurement techniques and validated equipment for all methods is an additional recommendation. Established techniques include ambulatory BP monitoring, home BP monitoring, and automated office BP measurements (preferable over auscultation).

Choice of Agents Including Renin-Angiotensin-Aldosterone System Blockade

Most clinical practice guidelines recommend the use of RAS inhibition with ACE inhibitors/ARBs in patients with DKD and moderately severely increased albuminuria.[8,58] Evidence for kidney protection from RAS inhibitors in macroalbuminuria is derived from the Irbesartan Diabetic Nephropathy Trial (IDNT) and Reduction of Endpoints in Noninsulin-Dependent Diabetes Mellitus With the Angiotensin II Antagonist Losartan (RENAAL) trials.[66,67] The use of ACE inhibitors in DKD with microalbuminuria was studied in the Micro-HOPE study demonstrating benefits in the composite CV outcome though without reductions in hard kidney outcomes.[68] The kidney benefits of RAS inhibitors in DKD patients without albuminuria are less clear. The HOPE, EUROPA, and PEACE studies do support the use of RAS inhibitors for CV protection in this population, however,[68-70] but other antihypertensive agents may confer similar cardioprotective effects in this population. The BENEDICT and ROADMAP trials additionally demonstrated a RAS inhibitor–associated reduction in the progression to microalbuminuria in patients with T2D without DKD.[71,72]

RAS inhibitor side effects include hyperkalemia, hemodynamic-mediated acute decline in kidney function, and ACE inhibitor–induced angioedema. Dual RAS inhibition with ACE inhibitors, ARB, or direct renin inhibitors is associated with increased harm from hyperkalemia and AKI without long-term CV or kidney benefits. Hyperkalemia, even if modest, may lead to premature and unnecessary discontinuation of RAS inhibitors. However, there are several approaches to mitigate these risks. In addition to dietary advice and use of diuretics, newer potassium binders such as patiromer and sodium zirconium cyclosilicate (SZC) safely reduce serum potassium levels. An ongoing trial is testing whether these agents confer CV and kidney benefits by controlling hyperkalemia to enable maximal RAS blockade in the treatment of heart failure and/or CKD (NCT03888066).

Patients with DKD usually will require more than one antihypertensive agent to achieve BP targets. Thiazide diuretics and dihydropyridine calcium channel blockers have been demonstrated to reduce CV events in large outcomes studies, which, however, were not dedicated CKD trials.[73-75] In patients with diabetes requiring antihypertensive therapy in addition to RAS inhibition, Hypertension Canada suggests that a dihydropyridine calcium channel blocker is preferable to a thiazide/thiazide-like diuretic,[58] based on favorable CV outcomes of the Avoiding Cardiovascular Events Through Combination Therapy

in Patients Living With Systolic Hypertension (ACCOMPLISH) trial with benazepril/amlodipine compared with benazepril/hydrochlorothiazide.[74] The ACCOMPLISH trial was not a dedicated CKD trial and used a shorter-acting thiazide diuretic, which may have been inferior to longer-acting thiazides like indapamide or chlorthalidone. Indeed, the Action in Diabetes and Vascular Disease: Preterax and Diamicron Modified Release Controlled Evaluation (ADVANCE) trial compared combination therapy with perindopril and indapamide to usual care without thiazide-type diuretic in patients with T2D. The primary outcome—a combination of macrovascular and microvascular events that included progression of DKD—was significantly reduced in the active treatment arm. A significant reduction in "all kidney events" with active treatment was also observed. Considering that both treatment groups had high rates of RAS blockade, the observed benefits in CV and kidney outcomes were attributed to greater BP lowering and/or addition of a long-acting thiazide diuretic in the active treatment arm.[75]

ADDITIONAL APPROACHES TO SLOWING CKD PROGRESSION IN DIABETES

The significant residual risk of DKD progression despite the aforementioned therapeutic strategies has led to the emergence of additional pharmacotherapies.

SGLT2 Inhibitors

The CV and kidney protective effects of SGLT2i in patients with T2D were demonstrated in several CV outcome trials with post hoc analyses of kidney outcomes.[76-78] Two dedicated kidney outcome trials have followed: CREDENCE, involving participants with T2D, eGFR of 30 to 90 mL/min/1.73 m^2, and ACR of 300 to 5000 mg/g; and DAPA-CKD, involving participants with and without diabetes, eGFR of 25 to 75 mL/min/1.73 m^2, and ACR of 200 to 5000 mg/g. Both studies demonstrated significant reductions in kidney outcomes with SGLT2 inhibition including ESKD, decline in eGFR, and death from kidney/CV causes.[31,42] Results of DAPA-CKD were consistent among subgroups of participants with and without T2D, and SGLT2i have been incorporated into most diabetes and CKD guidelines including KDIGO.

Glucagon-Like Peptide-1 Receptor Agonists

Glucagon-like peptide-1 receptor agonists also exert significant CV benefits in T2D, though kidney benefits have been variable.[79] A meta-analysis of CV outcome trials of available GLP-1 receptor agonists did not demonstrate a reduction in the risk of doubling in serum creatinine, though there was moderate heterogeneity in the included trials.[79] In the REWIND trial comparing dulaglutide to placebo, there was an 11% reduction in the incidence of a sustained decline in eGFR of 30% or greater (hazard ratio [HR], 0.89; 95% confidence interval [CI], 0.78–1.01), but further sensitivity analyses showed a 30% and 44% reduction in the incidence of a sustained decline of eGFR of 40% or greater (HR, 0.70; 95% CI, 0.57–0.85) and 50% or greater (HR, 0.56; 95% CI, 0.41–0.76), respectively.[80] The ongoing FLOW trial (NCT03819153) involving semaglutide in participants with DKD assesses the composite outcome of persistent eGFR decline of 50% or greater, progression to ESKD, or death from kidney/CVD.

Mineralocorticoid Receptor Antagonists

Mineralocorticoid receptors are widely expressed in kidney and cardiac tissue, and their activation by aldosterone leads to hemodynamic and nonhemodynamic effects culminating in inflammation, fibrosis, and progression of cardiac and kidney disease.[81] However, clinical studies of MRA in DKD had not studied "hard" kidney outcomes and suffered from hyperkalemia events.[82,83] FIDELIO-DKD was a phase III trial of the nonsteroidal MRA finerenone, in addition to standard of care, in participants with T2D, most in CKD stage III and with a median urinary albumin-to-creatinine ratio (UACR) of 852 mg/g. Finerenone was safe and reduced rates of the primary composite of kidney failure, sustained 40% decline or greater in eGFR, or death from renal causes by 18% as well as the secondary composite CV outcome.[84] The FIGARO-DKD trial demonstrated a 13% reduction in the same composite CV outcome with finerenone compared with placebo, establishing finerenone as another treatment option to improve clinical outcomes in DKD.[84a]

Implementation of Newer Agents to Slow DKD Progression

It is expected that SGLT2i, GLP-1 receptor agonists, and nonsteroidal MRAs increasingly will be used together in the setting of DKD on a background of single-agent RAS blockade. The 28-week, phase III, DURATION-8 trial demonstrated that dual therapy with dapagliflozin and exenatide had additive effects on lowering weight and blood pressure, though with a less than additive effect on HbA1c. Additive effects on weight loss were similarly demonstrated in the SUSTAIN-9 and AWARD-10 trials.[85,86] The effect of combination therapy on heart and kidney outcomes in DKD is unknown. A propensity-matched cohort from the EXSCEL trial demonstrated that the addition of exenatide in patients on a background of SGLT2 inhibition resulted in modest improvements in major adverse cardiovascular events (MACE), all-cause mortality, and slower rates of kidney function decline compared with patients not on an SGLT2i.[87] Only 4% to 11% of FIDELIO-DKD participants were on an SGLT2i over the course of the study, and CREDENCE did not enroll participants taking an MRA at baseline, so there is limited evidence for the combined use of these two agents.

Emerging Therapies in DKD

New agents continue to be developed to prevent patients with diabetes developing CKD and progressing to ESKD (see Table 33.2). Alongside these treatment avenues is the development of more sensitive biomarkers that may aid the decision of when to commence new therapies.

Cardiovascular Complications

Diabetes is associated with increased risk for CV complications, including coronary artery disease (CAD) and heart failure. This risk is further compounded by the presence of CKD.[88-90]

Coronary Artery Disease

Although the risk of ischemic CV events is high in people with DKD, there is no established consensus about how best to detect subclinical CAD in this population. Chronic kidney disease increases CAD risk through mechanisms distinct from increased atherosclerotic disease burden. Additionally, people with CKD and CAD may present with atypical anginal symptoms. For these reasons, the usefulness of traditional CAD risk-prediction tools in people with CKD is limited.

Patients with severe CKD and stable CAD experience no benefit with coronary revascularization compared with medical therapy based on the Management of Coronary Disease in Patients with Advanced Kidney Disease (ISCHEMIA-CKD) trial, which included 57% of patients with diabetes at baseline[91] (see Chapter 85). In cases where revascularization may be indicated, patients with diabetes and severe CKD should undergo intervention irrespective of the radiocontrast agent risk in view of improved cardiac outcomes. Coronary artery bypass grafting (CABG) is superior to percutaneous coronary intervention (PCI) in patients with multivessel or complex CAD. Additionally,

observational studies suggest that CABG reduces the risk from cardiac death more than PCI in DKD, including in patients on dialysis.

Treatment with SGLT2i and/or GLP1-RA should be considered in patients with T2D, CKD, and increased CVD risk, as both of these agents have been demonstrated to reduce rates of major adverse cardiac events (a composite endpoint including myocardial infarction, stroke, and CV death). In patients with severe atherosclerotic CVD, GLP1-RA may be particularly useful.

Heart Failure

People with diabetes and CKD are at increased risk for developing heart failure and related mortality and hospitalization. Factors contributing to this increased risk include higher rates of CAD, hypertension, and impaired natriuresis.

In people with heart failure with reduced ejection fraction (HFrEF), treatment with β-blockers, RAS inhibitors, MRAs, and neprilysin inhibitors reduce CV risk (see Chapter 85). Though these agents do not have proven benefits for the treatment of heart failure with preserved ejection fraction (HFpEF), they are commonly used in this population as well.

SGLT2i should be considered in subjects with increased CV risk or established HFrEF, as these agents reduce the risk of both heart failure hospitalization and heart failure progression (Table 33.2).[31,38-40,43,44] Notably, these benefits were observed even in subjects without diabetes, suggesting glycemic control is not the primary underlying mechanism. GLP1-RA use has also been associated with reduced heart failure hospitalizations in a meta-analysis of seven RCTs, though to a much lesser degree compared with SGLT2i.

Antiplatelet Agents

Hyperglycemia has a procoagulant effect on platelet aggregation independent of insulin levels, and hyperinsulinemia itself carries an inhibitory effect on fibrinolysis and thus significantly increases the risk for thrombosis. Daily aspirin therapy is recommended for secondary CV prevention in people with diabetes and a history of atherosclerotic disease. Randomized controlled trials investigating the use of aspirin for primary CV prevention have yielded mixed results, demonstrating little to no benefit on CV outcomes yet an increased risk of bleeding.[92-94] Furthermore, bleeding risk increases with advanced CKD due to uremic platelet dysfunction (see Chapter 87). As such, aspirin should be considered for primary prevention in people with diabetes and CKD only when risk of atherosclerotic CV events is high, and with careful consideration of bleeding risk. Use of dual antiplatelet agents is appropriate following acute coronary syndromes or revascularization procedures.

Dyslipidemia

Given the elevated risk for atherosclerotic events in DKD, it is generally recommended that hyperlipidemia be treated (Chapter 85). The KDIGO recommends that all adults aged 50 years or older with severe CKD receive treatment with a statin with or without ezetimibe, regardless of diabetes status. For adults with CKD who are between 18 to 49 years of age, statin treatment is recommended in the presence of diabetes, known coronary disease, or elevated CV risk. Patients should generally not be started on statins following dialysis initiation, but these agents may be continued in patients who had already been taking them prior to starting dialysis.

The effect of lowering low-density lipoprotein cholesterol (LDL-C) was studied in the Study of Heart and Renal Protection (SHARP), which included patients with nondialysis CKD and no history of CVD, randomized to simvastatin and ezetimibe or placebo. A 17% reduction in adverse CV outcomes was seen for every 33 mg/dL reduction in LDL-C regardless of diabetes status, with no impact on mortality.[95] However, in dialysis patients with diabetes, the SHARP, Rosuvastatin and Cardiovascular Events in Patients Undergoing Hemodialysis (AURORA), and Atorvastatin in Patients With Type 2 Diabetes Mellitus Undergoing Hemodialysis (4D) trials did not show significant reductions in CV events or mortality despite LDL-C falling by up to 42%.[96–98] Guidelines of KDIGO recommend continuation or cessation should be determined by the patients' condition and preference (see Chapter 85). Fibrates can reduce the risk for increased albuminuria and can replace statins for people with diabetes and eGFR less than 45 mL/min/1.73 m^2 patients who are intolerant of statins.[35] Dose reductions in statins are not normally required for advancing CKD.

Recently, proprotein convertase subtilisin/kexin type 9 (PSCK9) inhibitors, when added to maximally tolerated statin therapy, have demonstrated significant reduction in LDL-C and improvement in CV outcomes in people with and without diabetes in the Evolocumab and Clinical Outcomes in Patients with Cardiovascular Disease (FOURIER) and Alirocumab and Cardiovascular Outcomes After Acute Coronary Syndrome (ODYSSEY OUTCOMES) trials.[99,100]

MICROVASCULAR COMPLICATIONS OF DIABETES

Diabetic Foot Disease

Patients with diabetes and advanced CKD are at increased risk for diabetic foot ulcers and their subsequent complications, including infection and amputation. Foot ulcers typically occur in the setting of peripheral neuropathy, which increases susceptibility to foot injuries, and peripheral artery disease, which impairs wound healing. Patients should undergo foot examinations at least yearly consisting of visual inspection for ulcerations or other deformities, and assessment of pedal pulses and peripheral sensation. Additionally, patients should be regularly screened for symptoms of peripheral artery disease (e.g., leg fatigue, claudication). Concerns of peripheral artery disease should prompt further evaluation, such as with ankle-brachial index testing or vascular imaging. Education on appropriate footwear and monitoring for signs of ulceration and early infection are fundamental to prevention.

Retinopathy

Initial testing for diabetic retinopathy should take place 5 years after T1D diagnosis and at the time of T2D diagnosis. Subsequent testing should be performed every 1 to 2 years, or more frequently if retinopathy is present.

Maintenance of adequate glycemic control reduces the risk of diabetic retinopathy and slows retinopathy progression.[101] Therefore, glycemic control is an important therapeutic target even for patients with ESKD, for whom slowing CKD progression is no longer feasible. Ophthalmologic therapies for diabetic retinopathy include intravitreous antivascular endothelial growth factor injections and panretinal laser photocoagulation.

Neuropathy

Peripheral Neuropathy

Patients with diabetes should be evaluated for peripheral neuropathy at least annually. Patients should be assessed for symptoms of peripheral neuropathy (pain, numbness, or tingling of the extremities) and for signs of decreased temperature/pinprick and vibration sensation. The diagnosis of diabetic neuropathy should only be made after other potential etiologies of neuropathy are excluded.

Gabapentin is commonly used to treat neuropathic pain associated with diabetes, but dosing should be reduced as GFR declines. Dosing may require alternate days or administration after hemodialysis

sessions to avoid the known sedative and motor (myoclonus) effects of gabapentin accumulation that occur in individuals with reduced eGFR. Pregabalin is an alternative that is predominantly excreted by the kidneys and should be used cautiously with advancing CKD.

Gastroparesis

Gastroparesis occurs commonly in people with diabetes, can affect the absorption of oral medication, and can contribute to volume depletion due to poor oral intake. Pharmaceutical options for management of gastroparesis include metoclopramide, domperidone, and erythromycin. A surgically implanted gastric pacemaker may also alleviate symptoms in patients with severe symptoms. Optimizing the management of gastroparesis may be very challenging but should be considered before transplantation in view of the potential effects on immunosuppressant absorption.

Autonomic Neuropathy

Diabetic autonomic neuropathy may result in significant postural hypotension and orthostatic symptoms. As such, patients may require changes to their antihypertensive regimens in order to reduce hypotension risk. Additionally, autonomic neuropathy may contribute to hypotension during hemodialysis, necessitating the use of agents such as midodrine. Midodrine is contraindicated in patients with arrhythmias and previous cardiac events and, if used, should be done so with caution. Nonpharmaceutical approaches to managing postural hypotension include liberalizing dietary sodium and utilizing compressive leg or abdominal garments.

Erectile Dysfunction

Erectile dysfunction frequently occurs in DKD as a combination of vasculopathy and side effects of medications used to treat CAD and hypertension. Phosphodiesterase inhibitors may be used unless the patient is taking nitrates or has uncontrolled CAD.

COMPLICATIONS OF CHRONIC KIDNEY DISEASE

Anemia

Anemia occurs commonly in DKD and acts as a risk multiplier for all-cause mortality and an independent risk factor for left ventricular hypertrophy (LVH), CVD, and congestive cardiac failure (Chapter 86). Compared with nondiabetics, diabetic patients have lower hemoglobin (Hb) levels at every CKD stage. One study found the prevalence of anemia to be 41% in diabetic versus 17% in nondiabetic CKD patients, occurring before kidney function begins to decline.[102] Therefore, patients with diabetes and eGFR less than 60 mL/min/1.73 m^2 should be tested for anemia.[103] Patients with DKD have increased levels of proinflammatory cytokines from low-grade systemic inflammation, causing resistance to the effects of erythropoietin in various tissues of the body that impairs the efficient use of iron in the generation of new erythrocytes. Other factors causing resistance include autonomic neuropathy, RASi, and bone marrow microvascular injury.

The Trial to Reduce Cardiovascular Events With Aranesp Treatment (TREAT) assessed the use of erythropoiesis-stimulating agents in patients with T2D with GFR 20 to 60 mL/min/1.73 m^2 and Hb 11 g/dL or less. Patients were randomized either to darbepoetin-alfa (targeting a Hb of 13 g/dL) or control with rescue darbepoetin treatment if Hb was less than 9 g/dL. The treatment group had fewer CV revascularization procedures but significantly increased risk for fatal and nonfatal nonhemorrhagic strokes.[104] Of the TREAT cohort, 31% progressed to dialysis and death despite good BP, glycemic, and lipid control.

Long-term CV and kidney benefits of prolyl hydroxylase inhibitors (PHIs), which effectively increase Hb in DKD, have yet to be determined (see also Chapter 86).[105] In an exploratory and pooled analysis, roxadustat led to fewer CV outcomes (a composite of myocardial infarction, stroke, or all-cause mortality) than epoetin alfa in patients new to dialysis (with and without diabetes) (HR, 0.70; 95% CI, 0.51–0.96).[106] The rationale for the use of PHIs in DKD includes kidney hypoxia induced by DKD leading to HIF-1α activation. However, DKD may also be associated with instability of HIF-1 α with loss of downstream compensatory pathways to hypoxia and subsequent upregulation of pathogenic pathways.[107] Prolyl hydroxylase inhibitors have been demonstrated in animal models to ameliorate deleterious metabolic and transcriptional changes associated with hypoxia in DKD.[107]

Mineral Bone Disease

Imbalance in mineral metabolism increases CV risk and is associated with bone disease in DKD. Targets for parathyroid hormone (PTH), calcium and phosphate levels, along with management should be aligned to those with non-DKD (Chapter 88).

Electrolytes and Fluid Retention

Salt restriction and diuretics are the mainstay treatment of fluid retention in DKD. Metabolic acidosis can be treated with bicarbonate supplementation. In patients with hyperkalemia, diet and RASi should be reviewed, and treatment with diuretics, sodium bicarbonate, gastrointestinal potassium binders, or dose reduction or discontinuation of RASi should be considered.

END-STAGE KIDNEY DISEASE

Decisions regarding dialysis modality should be guided by patient preference. There is no evidence to suggest superiority of one dialysis modality over another in people with diabetes and kidney failure. Mortality risk in this population is high and concomitant with the presence of multiple comorbidities.

Dialysis

Hemodialysis

Considerations for vascular access placement, hemodialysis initiation, and hemodialysis prescription in DKD are similar to those in patients without diabetes.

Peritoneal Dialysis

Most peritoneal dialysis solutions utilize dextrose as an osmotic agent. The dextrose content of peritoneal dialysis solutions may worsen hyperglycemia in people with diabetes. As a result, patients may need to adapt their hypoglycemic drug regimens. Commonly used peritoneal dialysate solutions contain between 1.5 to 4.25 g/dL glucose and may provide an additional 400 to 800 kcal/day.

Non–glucose-containing solutions (e.g., icodextrin) avoid the risk for hyperglycemia and the potentially harmful effects of glucose degradation products while resulting in better ultrafiltration volume, BP control, and preservation of residual function (Chapter 102). Some metabolites of icodextrin also can act as a substrate for the glucose dehydrogenase present in blood glucose meters, resulting in potential overestimation of blood glucose levels.

Transplantation

Diabetic kidney disease remains the leading cause of ESKD among waitlisted patients. Kidney transplantation confers mortality benefit in these patients: the US Renal Data System data showed 5-year survival rates of 29% in patients with diabetes starting dialysis compared with rates of 75% and 85% in those undergoing deceased-donor

and living-donor kidney transplants, respectively.[108] When possible, preemptive kidney transplantation and living donor transplantation would be preferable to transplantation after starting dialysis and deceased donor transplantation, respectively. Considering the significant risk of remaining on dialysis and the benefit conferred by even marginal deceased donor kidney allograft, many patients with diabetes and ESKD should consider consenting for kidneys with a high kidney donor profile index (≥85%). For eligible patients with T1D, the ideal form of transplantation is simultaneous pancreas and kidney transplantation, or living-donor kidney transplant followed by deceased-donor pancreas transplantation.[35]

SELF-ASSESSMENT QUESTIONS

1. A 56-year-old man with T2D, eGFR of 38 mL/min/1.73 m^2, peripheral artery disease, and a history of myocardial infarction is referred for worsening proteinuria. His BP is 133/82 mm Hg, and his body mass index is 32 kg/m^2. His HbA1c is 9.3% using canagliflozin and metformin. Which of the following changes to his antihyperglycemic regimen should you recommend?
   - **A.** Replace canagliflozin with empagliflozin.
   - **B.** Replace metformin with extended release exenatide.
   - **C.** Add liraglutide to current regimen.
   - **D.** Add linagliptin to current regimen.
   - **E.** Add pioglitazone to current regimen.
2. Which of the following factors favors a higher (more conservative) individualized HbA1c target?
   - **A.** History of recurrent severe hypoglycemia
   - **B.** Availability of continuous glucose monitoring
   - **C.** Absence of other diabetes microvascular complications
   - **D.** Higher eGFR
   - **E.** Relatively few comorbidities
3. Which of the following statements regarding BP control in diabetes is *false?*
   - **A.** There is evidence of a reduction in the risk of stroke with an intensive systolic BP target of less than 120 mm Hg versus less than 140 mm Hg in patients with diabetes.
   - **B.** Intensive BP lowering in the SPRINT trial was associated with lower rates of eGFR decline.
   - **C.** Automated office BP measurements are preferable to those made using the auscultation technique.
   - **D.** The 2021 KDIGO clinical practice guideline for the management of BP in CKD makes a grade 2B recommendation to target a systolic BP of less than 120 mm Hg in patients with hypertension and CKD.
   - **E.** The strongest evidence for kidney protection with RAS inhibition exists in patients with DKD and severely increased albuminuria.
4. Which of the following is *true* regarding newer therapies with cardiorenal protection in DKD?
   - **A.** The DAPA-CKD trial exclusively enrolled participants with T2D, eGFR of 30 to 90 mL/min/1.73 m^2, and an albumin-to-creatinine ratio of 300 to 5000 mg/g, demonstrating the kidney benefits of dapagliflozin.
   - **B.** The CREDENCE trial demonstrated the kidney benefits of canagliflozin in participants with and without diabetes, eGFR of 25 to 75 mL/min/1.73 m^2, and albumin-to-creatinine ratio of 200 to 5000 mg/g.
   - **C.** In a subgroup analysis within DAPA-CKD, the effects of dapagliflozin with respect to kidney protection were greater in participants with diabetes compared with those without.
   - **D.** The cardiovascular benefits of SGLT2i are largely related to reductions in heart failure hospitalizations, whereas there is stronger evidence of reductions in atherosclerotic cardiovascular disease with GLP-1 receptor agonists.
   - **E.** The kidney benefits of finerenone in the FIDELIO-DKD trial were demonstrated in a population with high rates of RAS and SGLT2 inhibition.

Normal Blood Pressure Control and the Evaluation of Hypertension

William J. Elliott

NORMAL BLOOD PRESSURE CONTROL

Systemic arterial blood pressure (BP) is the pressure of the blood within the arteries exerted against the arterial wall and is produced by the contraction of the left ventricle (producing blood flow) and the resistance of the arteries and arterioles. *Systolic* blood pressure (SBP), or *maximum* BP, occurs during left ventricular systole. *Diastolic* blood pressure (DBP), or *minimum* BP, occurs during ventricular diastole. The difference between SBP and DBP is the pulse pressure.[1] The mean arterial pressure (MAP) is calculated as the DBP plus one-third of the pulse pressure.

Blood flow (Q), as defined by the hydraulic analogy of Ohm's law, varies directly with the change in pressure (P), across a blood vessel, and varies inversely with the resistance (R), defined as $Q = P/R$. Rearrangement shows that pressure varies directly with blood flow and resistance: $P = QR$. Ohm's law suffices for an overall view of the circulation. However, the flow within a vessel is governed by the Hagen-Poiseuille equation:

$$Q = \Delta P \times \left(\Pi r^4/8L\right) \times (1/\eta)$$

where r is the radius of the pipe, L is its length, and η is the coefficient of viscosity. Thus, as the lumen of a vessel decreases, the pressure increases by the fourth power of the radius to maintain the same blood flow.

Normal BP is controlled by cardiac output and the total peripheral resistance and is dependent on the heart, the blood vessels, the extracellular volume, the kidneys, the nervous system, humoral factors, and cellular events at the membrane and within the cell (Fig. 34.1). Cardiac output is determined by the stroke volume in liters per minute (L/min) and the heart rate. In turn, stroke volume is dependent on intravascular volume (regulated by the kidneys) and myocardial contractility. Myocardial contractility involves sympathetic and parasympathetic control of heart rate, intrinsic activity of the cardiac conduction system, complex membrane transport and cellular events requiring influx of calcium that lead to myocardial fiber shortening and relaxation, and effects of humoral substances (e.g., catecholamines) on increasing heart rate and myocardial fiber tension.

Total peripheral resistance is regulated by baroreflexes and sympathetic nervous system (SNS) activity, response to neurohumoral substances and endothelial factors, myogenic responses, and intercellular events mediated by receptors and mechanisms for signal transduction.[2] Baroreflexes are derived from (1) high-pressure baroreceptors in the aortic arch and carotid sinus and (2) low-pressure cardiopulmonary baroreceptors in ventricles and atria. Aortic baroreceptor nerve fibers travel via the vagus nerve (cranial nerve X); carotid sinus fibers travel via the glossopharyngeal nerve (cranial nerve IX). These receptors respond to stretch (high pressure) or filling pressures (low pressure) and send tonic inhibitory signals to the brainstem. If BP and tonic inhibition increase, inhibition of sympathetic efferent outflow occurs, decreasing vascular resistance and heart rate. However, if BP decreases, less tonic inhibition occurs, and heart rate and peripheral vascular resistance (PVR) increase, thereby increasing BP.

The brainstem cardiovascular (CV) centers are localized in the dorsomedial medulla. Neural afferents from cranial nerves IX and X are integrated in the nucleus tractus solitarius (NTS). From here, vasoconstriction and increased heart rate are mediated through the caudal and rostral ventrolateral medulla by the SNS. Efferents from the NTS communicate with the nucleus ambiguus (vagal nucleus) to decrease heart rate via the vagus nerve. Also, the central neural control of kidney function modulates renal blood flow, glomerular filtration rate (GFR), excretion of sodium and water, and renin release. These factors in turn regulate intravascular volume, vascular resistance, and BP.[3] This complex physiology has taken on greater clinical relevance recently, given the mixed results of pivotal trials of percutaneous, catheter-based renal denervation.[4,5]

Inhibitory reflexes also originate in the kidney. Increases in urine flow rate increase renal pelvic pressure, which stretches the renal pelvic wall and leads to activation of mechanosensory nerves in the pelvic wall. Activation of these sensory nerves decreases renal sympathetic nerve activity and induces diuresis and natriuresis, an inhibitory renorenal reflex response. The responsiveness of the renal sensory nerves is modulated by dietary sodium. A high sodium intake enhances the responsiveness of the afferent renal mechanosensory nerves; conversely, renal denervation may increase urinary flux and fractional excretion of sodium,[6] although not all recent studies agree.

Numerous vasoactive substances have effects on blood vessels, the heart, the kidneys, and the central nervous system (CNS) to regulate BP (Table 34.1). The renin-angiotensin-aldosterone system (RAAS) regulates volume and PVR (Fig. 34.2), particularly in the long term (hours to weeks; Fig. 34.3). Angiotensin II (Ang II) constricts vascular smooth muscle; stimulates aldosterone secretion; potentiates SNS activity; stimulates salt and water reabsorption in the proximal tubule; stimulates prostaglandin, nitric oxide (NO), and endothelin release; increases thirst; and stimulates vascular remodeling and inflammation. Aldosterone stimulates sodium channels in distal renal tubular

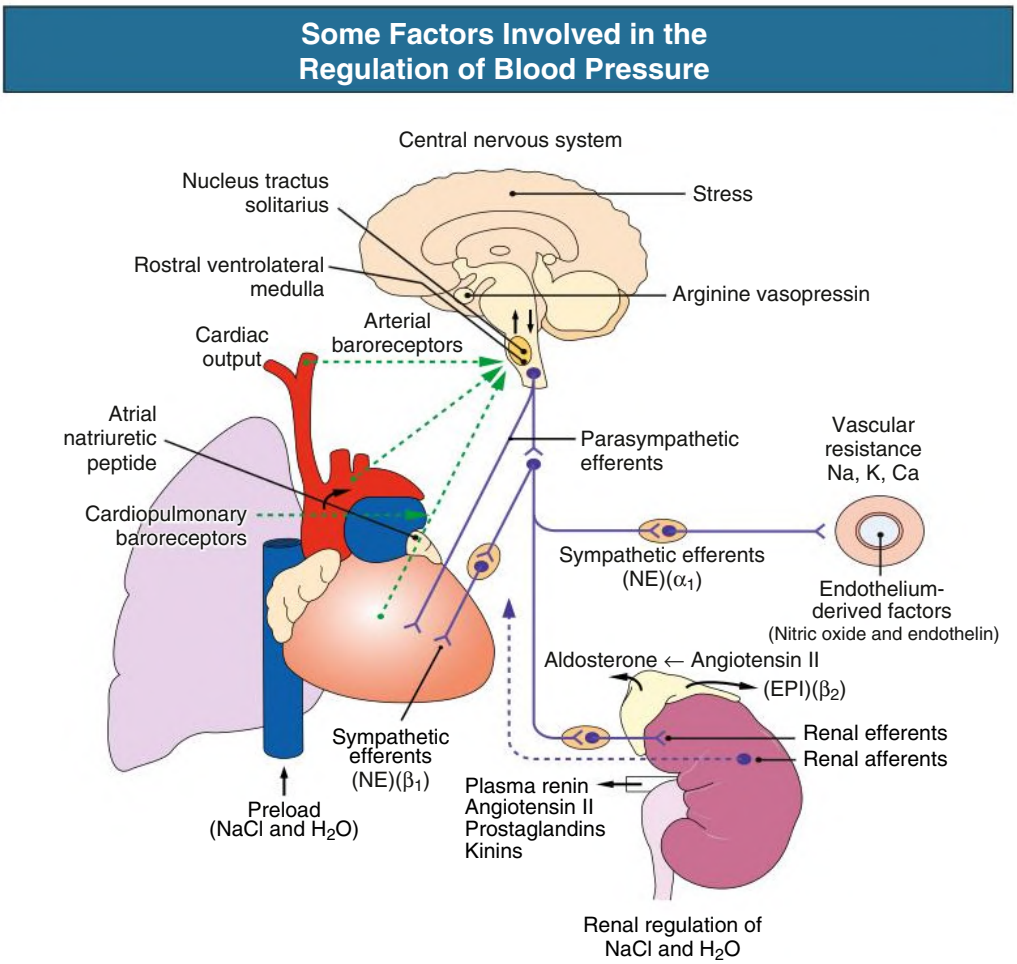

Fig. 34.1 Some Factors Involved in Regulation of Blood Pressure. *Dashed lines* refer to feedback to the central nervous system from cardiovascular *(green dash)* or renal *(purple dash)* sites. *EPI,* Epinephrine; *NE,* norepinephrine.

epithelium, leading to sodium retention and potassium excretion. Novel aldosterone antagonists have antiinflammatory and other beneficial effects in vascular cells, heart, and kidneys.[7] Plasma concentrations of renin and aldosterone are both inversely related to salt intake and are influenced by many antihypertensive medications.

The second major effector system, working primarily over seconds to minutes (see Fig. 34.3), is the SNS. Sympathetic nerve endings release the vasoconstrictor (norepinephrine) that binds the α-adrenergic receptor (adrenoceptor) on vascular cells, renal cells, and other cells (e.g., adipocytes). Epinephrine increases heart rate, stroke volume, and SBP through α- and β-adrenoceptors. The hormone is released from the adrenal medulla. Increased sympathetic tone has long-term influences on CV regulation and may cause hypertension and contribute to chronic kidney disease (CKD).[8] In the kidneys, sympathetic nerves mediate renin release. Furthermore, innervation of each individual nephron affects sodium reabsorption. In doing so, the SNS regulates both effective circulating fluid volume and PVR.

The kallikrein-kinin system counters the RAAS and produces vasodilator kinins, which stimulate prostaglandin and NO production (see Fig. 34.2). Prostaglandin E and prostacyclin block the vasoconstriction by Ang II and norepinephrine. Two endothelium-derived factors have opposite effects on the blood vessels: NO is a vasodilator, whereas the endothelins are vasoconstrictors. Natriuretic peptides, of the atrial, brain, or C-types, induce vasodilation and natriuresis and inhibit other vasoconstrictors (RAAS, SNS, endothelin). Chapter 37 discusses all the drugs that affect the previously discussed physiologic systems that regulate BP.

Other physiologic systems that control BP can be used as investigative tools but not yet therapeutically in humans. Renalase is a flavin adenine dinucleotide–dependent amine oxidase that is secreted by the kidney, circulates in the blood, and modulates cardiac function and systemic BP by metabolizing catecholamines; there is debate about whether mutations in the gene coding for renalase are associated with hypertension.[9] Heme oxygenase-1 is an intrarenal and systemic BP modulator that inhibits oxidants, resulting in decreased BP; in one study, individuals with an unfavorable gene promoter for this enzyme had a higher prevalence of hypertension and increased mortality.[10] Endogenous digitalis-like factors, which inhibit cell surface Na^+,K^+-ATPase and include an ouabain-like factor and marinobufagenin, appear to regulate BP, CV, and renal function.[11] Urotensin II is a locally expressed vasoconstrictive cyclic vasoactive peptide that stimulates proliferation of vascular smooth muscle cells and fibroblasts, inhibits insulin release, and modulates GFR. Nonetheless, high plasma urotensin II levels were associated with reduced CV complications and death in patients with CKD, stages 2 to 5.[12] In obese persons, leptin may increase BP by activating the CNS through a melanocortin pathway.[13] Although its clinical importance is still debated, higher serum uric acid levels have been associated with BP and CV outcomes in many (but not all) cohort studies, a mendelian randomization analysis, and meta-analysis of 15 clinical trials[14]; at least two hypouricemic drugs

TABLE 34.1 Some Vasoactive Substances That Modulate Blood Pressure

Group	Compound	Cellular Effects
Catecholamines	Norepinephrine, epinephrine, dopamine	Adrenergic receptors (α_1, α_2, β_1, β_2) causing protein phosphorylation and increased intracellular calcium through G proteins linked to ion channels or second messengers (cyclic nucleotides, phosphoinositide hydrolysis)
RAS	Angiotensin II	Angiotensin receptors (AT_1, AT_2, AT_4) cause increased intracellular calcium and protein phosphorylation through second messenger, phosphoinositide hydrolysis, and activated protein kinases Angiotensin II stimulates aldosterone
Mineralocorticoids	Aldosterone	*Genomic:* binds to cytoplasmic mineralocorticoid receptor, translocates to nucleus, modulates gene expression, and signal transduction and effectors (S_gK, CHIF, K_i-Ras), which increases transport proteins (increasing ENaC number and open probability)*Nongenomic:* effects through separate membrane or cytosolic proteins
Kallikrein-kinin system	Bradykinin	Bradykinin receptors (B_1, B_2), B_2-G protein coupling causes activation of phospholipase C, increased inositol phosphates, and intracellular calcium
Arachidonic acid oxidation products	Prostaglandins: PGE, prostacyclin, thromboxanes Lipoxygenase enzyme products: leukotrienes, hydroxyeicosatetraenoates	Nine prostaglandin receptors coupled to G proteins (e.g., PGI_2 [receptor IP], PGE_2 [receptors EP_1, EP_2]); $PGF_{2\alpha}$ (receptor FP)
Endothelium-derived factors	Endothelium-derived relaxing factor (nitric oxide) Endothelins (ET-1, ET-2, ET-3)	Increased levels of cyclic guanosine monophosphate cause activation of protein kinasesG proteins activate phospholipase C and L-type calcium channels. Class 2 G protein–coupled receptor
Natriuretic peptides	Atrial, brain, and C-type	Activation of three receptor types; further effects mediated by cGMP
Posterior pituitary hormones	Arginine vasopressin	Vasopressin receptors (AVPR 1A; AVPR 1B) mediated by second messenger system, phosphatidyl inositol/calcium; AVPR2 effects via adenylate cyclase (cAMP)
Cyclic vasoactive peptides	Urotensin II	Binds to G protein receptor GPR 14
Other substances	Acetylcholine, adenosine, insulin, neuropeptide Y, serotonin, sex hormones (estrogens, progesterone, androgens), glucocorticoids, other mineralocorticoids, substance P, vasopressin, renalase, heme oxygenase 1, uric acid	

Ang II, Angiotensin II; *AVPR,* arginine vasopressor receptor; *cAMP,* cyclic adenosine monophosphate; *cGMP,* cyclic guanosine monophosphate; *ENaC,* amiloride-sensitive epithelial sodium channel; *PGE,* prostaglandin E; *RAS,* renin-angiotensin system; *UT II.*

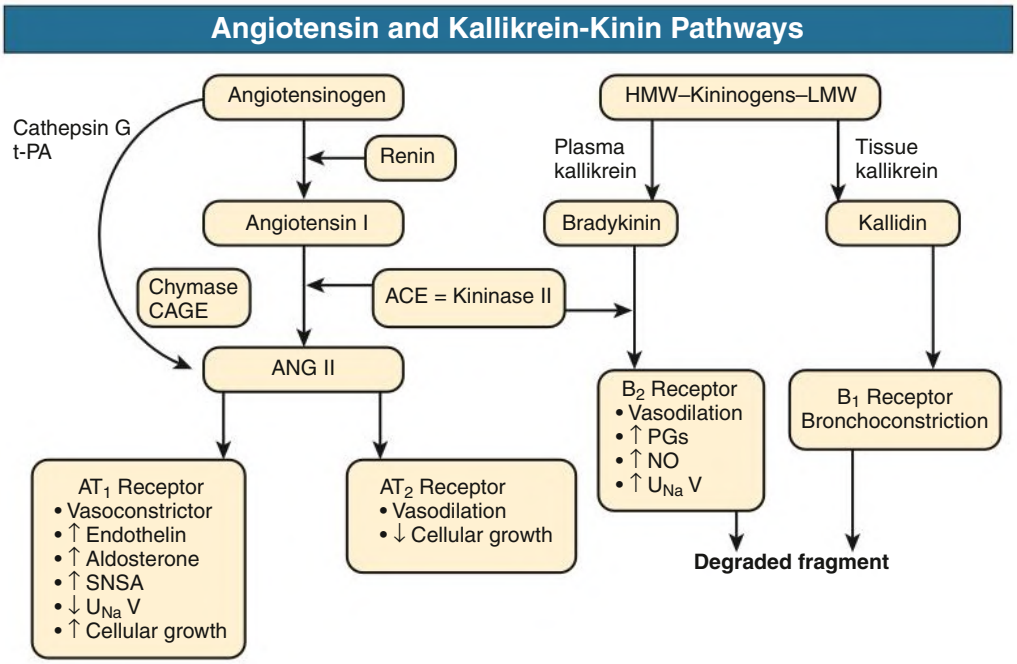

Fig. 34.2 Interactions and functions of renin-angiotensin and kallikrein-kinin systems. *ACE,* Angiotensin-converting enzyme; *ANG II,* angiotensin II; *AT_1, AT_2,* angiotensin receptors; *B_1, B_2,* bradykinin receptors; *CAGE,* chymostatin-sensitive angiotensin II–generating enzyme; *HMW,* high molecular weight; *LMW,* low molecular weight; *NO,* nitric oxide; *PGs,* prostaglandins; *SNSA,* sympathetic nervous system activity; *t-PA,* tissue plasminogen activator; *U_{Na} V,* urinary sodium excretion.

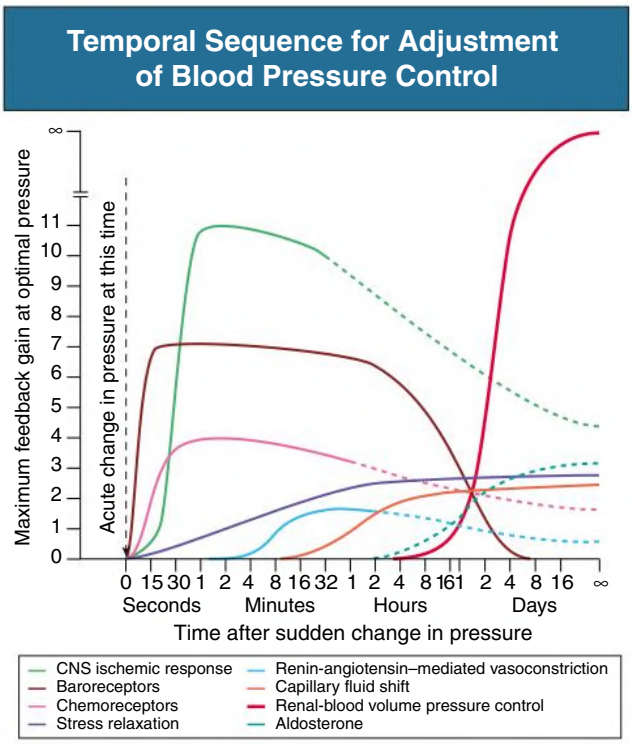

Fig. 34.3 Temporal Sequence for Adjustment of Blood Pressure Control. Degree of activity, expressed as feedback gain, of several arterial blood pressure (BP) control systems at various times after a sudden change in arterial BP. Note the infinite gain of the kidney volume mechanism for BP control. *CNS,* Central nervous system. (From Hall JE. Role of the kidneys in long-term control of arterial pressure and in hypertension: the integrated system for arterial pressure regulation. In: Hall J, Hall M. *Guyton and Hall's Textbook of Medical Physiology*. 14th ed. Philadelphia: Elsevier; 2020:229–244.)

have lowered BP in pilot studies. Intracellular urate also may activate the renin-angiotensin system (RAS), induce intrarenal oxidative stress, block endothelial NO, and directly affect the vasculature.[15] T cells also may be involved in primary hypertension, possibly via heat shock protein 70 and/or interleukin-17, and are present in kidneys and blood vessels where they release Ang II and oxidants.[16] Chemoreceptors in the brain medulla and the carotid and aortic bodies respond to changes in carbon dioxide and oxygen tension, resulting in renal vasoconstriction and dilation of the CNS and coronary vasculature; these phenomena may be reversible after device-based therapy.[17] The small guanosine triphosphatase, Rho, and its kinase stimulate vasoconstriction and may have a role in cerebral artery spasm, hypertension, heart failure, and other CV conditions; an inhibitor Rho kinase, netarsudil, was recently FDA-approved for ocular hypertension.[18]

The kidney is recognized as a source of hypertension, based on renal cross-transplantation experiments[19] and the hypotensive effects of bilateral nephrectomy in patients with end-stage kidney disease (ESKD) and severe hypertension. Activation of CNS and kidney SNS pathways are important in long-term BP control, in part by delayed effects on the kidneys.[20] Renal sympathetic denervation by radiofrequency ablation through the renal arteries has led to substantial reduction in BP in patients with resistant hypertension, but a large trial did not achieve significantly better BP control at 6 months, compared with sham-operated controls.[21,22] This negative result more likely stemmed from technical issues in the conduct of the trial rather than indicating that the SNS does not contribute to the pathophysiology of hypertension.

DEFINITION AND CLASSIFICATION OF HYPERTENSION

In the general population, casual or in-office BP follows an approximately normal distribution, with a shift to the left in the young and the opposite in older people or those with CKD. Thus, any definition of hypertension is arbitrary. Hypertension is often asymptomatic, with symptoms more commonly attributed to sequelae of hypertension or its treatment. Hypertension may be classified by its associated morbidity and mortality, as increases over arbitrary cut points, or by thresholds defining therapeutic benefit.

Blood Pressure Classification by Link to Future Morbidity and Mortality

The first approach defines hypertension by relating BP levels to the risk for morbidity and mortality. The association of SBP and DBP with CV and kidney complications is continuous over the entire BP range.[23] Death from both heart disease and stroke increases progressively and linearly from BP as low as 115/75 mm Hg upward in all age groups from 40 to 89 years (Figs. 34.4 and 34.5). In observational studies an increase in SBP of 20 mm Hg or DBP of 10 mm Hg was associated with a doubling of mortality from heart disease or stroke. Several interventional trials have observed a J-shaped curve (suggesting that mortality increases below a threshold SBP), yet this phenomenon is also seen in the bottom decile in both individual and pooled observational studies of untreated subjects (see Figs. 34.4 and 34.5), indicating that those in the lowest decile have a higher risk, irrespective of treatment. Elevated SBP has been consistently identified by the Global Burden of Disease study to be the leading contributor to disability-adjusted life years worldwide. The investigators characterized an SBP between 110 and 115 mm Hg as the "theoretical minimum risk level" for BP. Although all national and international hypertension guidelines agree about the continuous relationship between risk and BP, as well as a recommendation for lifestyle modifications in people with BP 120/80 mm Hg or greater, the thresholds and categories have continued to evolve. The Seventh Report of the Joint National Committee on Prevention, Detection, Evaluation, and Treatment of High Blood Pressure (JNC 7) introduced the term *prehypertension* for individuals with SBPs from 120 to 139 mm Hg or DBPs between 80 and 89 mm Hg (Table 34.2),[24] which was retained by the American Society of Hypertension/International Society of Hypertension 2013 guidelines and by the Expert Panel appointed to JNC 8.[25] Somewhat different terms were used by the 2018 European Society of Hypertension/European Society of Cardiology guidelines (Table 34.3)[26] and the 2020 International Society of Hypertension guidelines (Table 34.4).[27] A completely different approach (independent of specific BP thresholds) was taken by the Writing Group of the American Society of Hypertension (WG-ASH), which proposed that hypertension is a complex CV disorder that included target organ damage, early disease biomarkers (including BP), and CV risk factors[28] (Table 34.5).

Blood Pressure Classification by Population-Based Percentile

A second approach defined hypertension by the frequency distribution within a population. Until 2017, hypertension in American children was determined on a purely statistical basis: SBP or DBP at or above the 95th percentile for age, sex, and height, measured on at least three occasions.[29] In this population, age, sex, body size, and race/ethnicity are all significant and strong predictors of BP. Using a frequency distribution method is less helpful for identifying a threshold for initiation of antihypertensive treatment but is common in epidemiologic studies. The crude prevalence of hypertension in adults (older than 20 years)

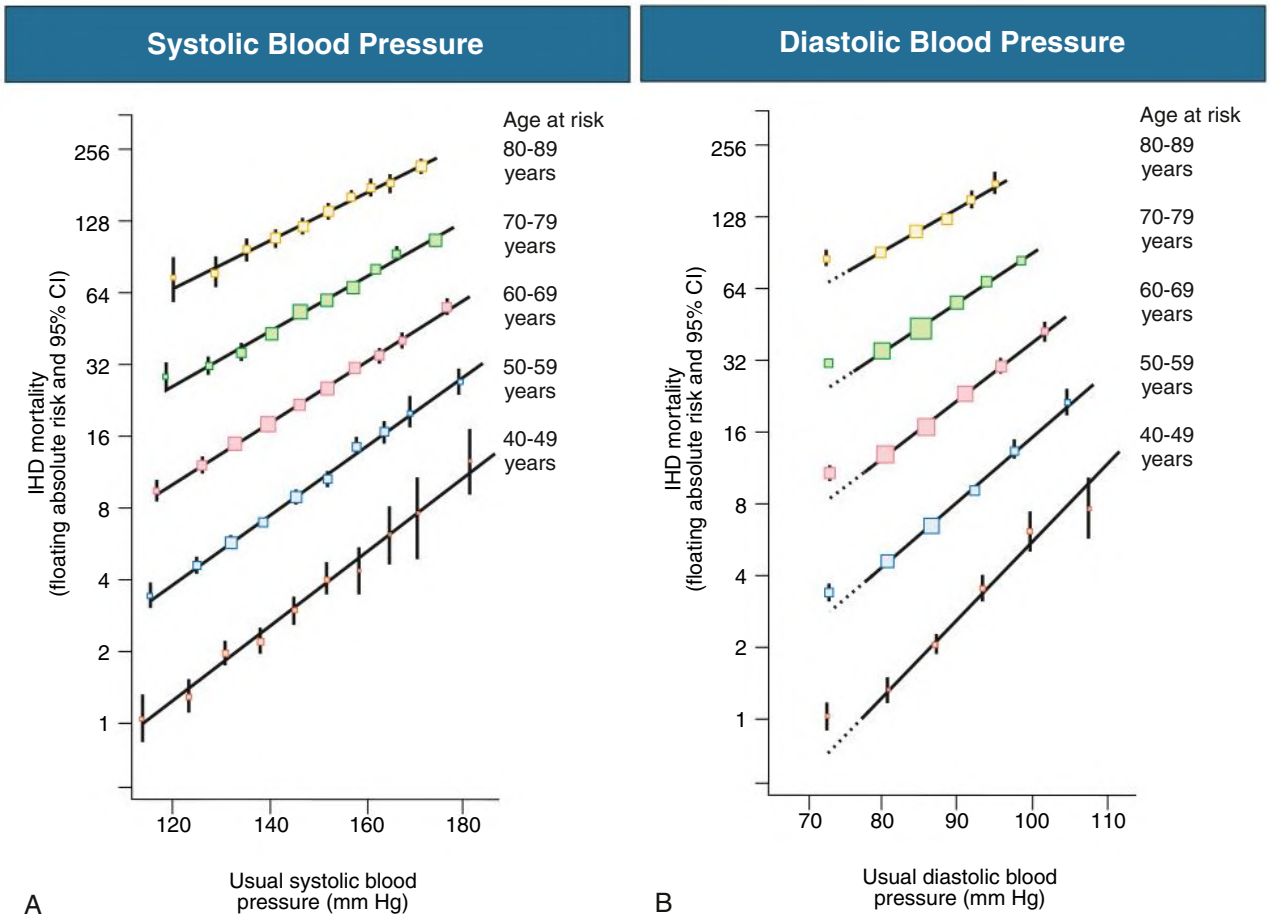

Fig. 34.4 Ischemic Heart Disease Mortality Rate in Each Decade of Age Versus Usual Blood Pressure at Start of That Decade. (A) Systolic blood pressure. (B) Diastolic blood pressure. Floating absolute risk is a relative risk score that adjusts for the absolute death rate within a particular age group. The size of the squares correlates inversely with the variance of the data collected for that data point. *CI,* Confidence interval; *IHD,* ischemic heart disease. (From Lewington S, Clarke R, Qizilbash N, et al. Prospective studies collaboration: age-specific relevance of usual blood pressure to vascular mortality—a meta-analysis of individual data for one million adults in 61 prospective studies. *Lancet.* 2002;360:1903–1913.)

in the United States, traditionally defined as BP of 140/90 mm Hg or greater or taking antihypertensive medication, has increased progressively from 11% in 1939 to 33.5% in 2013 to 2014, but has been relatively stable since the mid-1990s (31% ± 2%, after age adjustment).[30]

Blood Pressure Classification by Threshold of Therapeutic Benefit

The third concept for defining hypertension is derived from randomized controlled trials (RCTs) that compared two or more BP targets and showed significant reductions in morbidity and mortality. The Hypertension Optimal Treatment (HOT) study showed no significant outcome differences among 18,790 hypertensive subjects randomized to DBP targets of 80, 85, or 90 mm Hg or less, although a significant benefit was seen in diabetic patients with a diastolic target of less than 80 mm Hg.[31] A post hoc analysis of the in-trial BPs determined that maximal prevention of major CV events was seen at a BP of 138.5/82.6 mm Hg. Of the relatively few outcome-based RCTs comparing traditional and lower BP targets, only the Systolic Blood Pressure Intervention Trial (SPRINT) showed significant reductions in both CV events and mortality when treating to a SBP target of less than 120 compared with the traditional less than 140 mm Hg.[32] Some have argued that this benefit came at a huge (and largely unspecified) cost of more medications, more office visits, more adverse effects (including emergency department visits), and greater than 30% worsening of renal function in those without CKD at baseline. Others have cast doubt about SPRINT's generalizability, as less than 17% of adult Americans with hypertension would have been eligible to participate because of the large number of exclusion criteria (which included diabetes mellitus, prior stroke, polycystic kidney disease, or estimated GFR <20 mL/min/1.73 m^2). A network meta-analysis then combined the SPRINT results with those of 41 other randomized clinical trials, using *achieved* in-trial SBPs in 144,220 subjects as the independent variable. For both cardiovascular events and all-cause mortality, the lowest risk was seen in subjects with SBPs between 120 and 124 mm Hg, significantly lower than those with SBPs between 130 and 134 mm Hg.[33] Three other independent meta-analyses also concluded that major adverse cardiovascular events were significantly reduced in subjects treated to "lower SBPs" (typically <130 mm Hg) compared with "higher SBPs" (typically ≥140 mm Hg).

These data resulted in the 2017 ACC/AHA United States hypertension guideline.[34] This guideline "redefined" hypertension as a usual office BP at or below 130/80 mm Hg, added the new diagnostic category of "elevated blood pressure," reemphasized the value of out-of-office BP measurements, reinforced lifestyle modifications as appropriate for most people with higher than normal BPs, and revised some treatment targets for specific patient groups (see Table 34.6 for

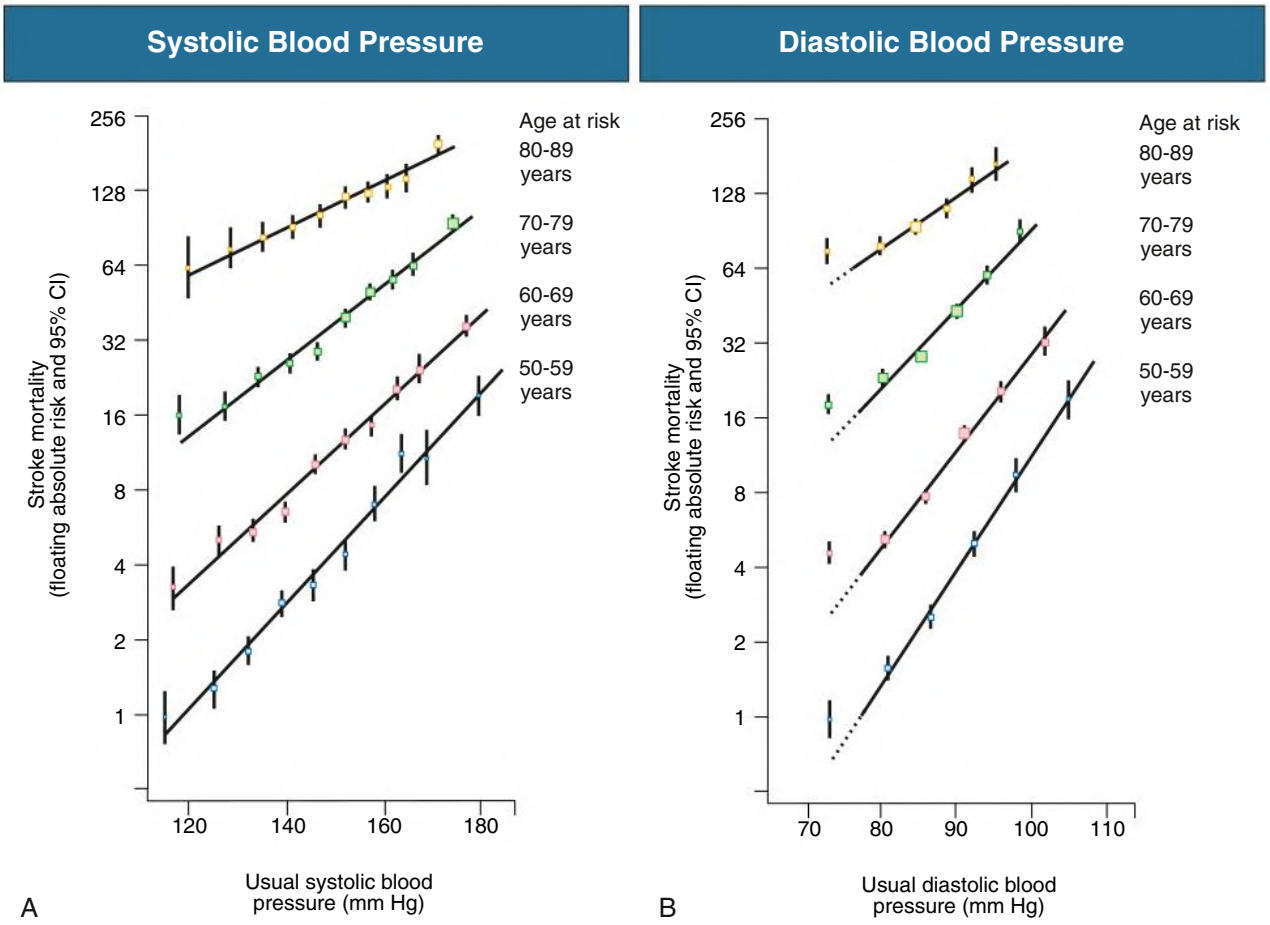

Fig. 34.5 Stroke Mortality Rate in Each Decade of Age Versus Usual Blood Pressure (BP) at Start of That Decade. (A) Systolic BP. (B) Diastolic BP. Floating absolute risk is a relative risk score that adjusts for the absolute death rate within a particular age group. The size of the squares correlates inversely with the variance of the data collected for that data point. *CI,* Confidence interval. (From Lewington S, Clarke R, Qizilbash N, et al. Prospective studies collaboration: age-specific relevance of usual blood pressure to vascular mortality—a meta-analysis of individual data for one million adults in 61 prospective studies. *Lancet.* 2002;360:1903–1913.)

more details). The 2017 US hypertension guideline of the American College of Cardiology/American Heart Association (ACC/AHA) is controversial; some societies have declined to endorse or adopt it. About 3 months earlier, the American Academy of Pediatrics released its Clinical Practice Guideline for Screening and Management of High Blood Pressure in Children and Adolescents[29]; the authors of that pediatric guideline were privy to an advance copy of the 2017 adult guideline and arranged their recommendations to be consistent with it. These new definitions have increased the overall prevalence of hypertension in US adults to 46% but decreased the prevalence in children and adolescents to 3.5%. The ACC/AHA 2017 US hypertension guideline also recommended an office BP target below 130/80 mm Hg for individuals with a 10-year cardiovascular risk greater than 10%, but retained the traditional less than 140/90 mm Hg for most lower-risk individuals.

The most recent set of hypertension guidelines from the Kidney Disease: Improving Global Outcomes (KDIGO) did not formally redefine hypertension but recommended that only "standardized office BPs," supplemented by out-of-office BP measurements, be used in clinical decision-making, and (based on "weak" evidence) that all patients with chronic kidney disease be treated to a systolic BP less than shiftenter120 mm Hg.[35] The authors concluded that this target may be harmful if "standardized" BPs are not measured.

The concept of evaluating a person's "total CV risk" had been prominent in several prior US guidelines on BP, dyslipidemia, and acute coronary syndrome. It was largely abandoned by JNC 7 but still plays a major role in other countries[26,27,36] and was incorporated in the 2017 ACC/AHA US hypertension guideline.[34] Age, sex, and ethnicity

are important nonmodifiable risk factors, whereas low-density lipoprotein (LDL) cholesterol, smoking, control of diabetes, obesity, and left ventricular hypertrophy are potentially modifiable[36] (Fig. 34.6). The cluster of risk factors that increase CV risk and are often associated with hypertension is termed the *metabolic syndrome*[37] (Table 34.7). CKD, as defined by decreased GFR or by increased urinary albumin excretion, is also recognized as an independent risk factor for ESKD, CV events, and death.[35] JNC 7 included recommendations for serial follow-up evaluation of BP and CV risk factors based on initial BP measurement (Table 34.8).

TABLE 34.6 ACC/AHA 2017 US Hypertension Guideline: Categories of Blood Pressure in Adults (mm Hg)

Category	Systolic		Diastolic
Normal	<120 mm Hg	and	<80 mm Hg
Elevated	120–129 mm Hg	and	<80 mm Hg
Hypertension			
Stage 1	130–139 mm Hg	or	80–89 mm Hg
Stage 2	≥140 mm Hg	or	≥90 mm Hg

Individuals with systolic and diastolic blood pressures in two different categories should be assigned into the higher category. Blood pressures are based on an average of ≥2 careful readings obtained on ≥2 occasions, usually separated by a week or more.

Special Definitions

Prehypertension. Although no longer a feature of the ACC/AHA 2017 US hypertension guideline,[34] prehypertension was defined in JNC 7 as SBP of 120 to 139 and DBP of 80 to 89 mm Hg.[24] Prehypertension was found in 28% of American adults in the US National Health and Nutrition Examination Survey (NHANES) 2005 to 2006.[38] Prehypertension is associated with age, obesity, dyslipidemia, impaired fasting glucose levels, a higher risk for both CV and renal events, and progression to hypertension (which was significantly delayed by drug therapy in two RCTs). Lifestyle modifications (see Chapter 36) are recommended by essentially all guidelines for affected people until the BP meets or exceeds levels corresponding to hypertension.

"White coat" hypertension. "White coat" hypertension, defined as normal BP during usual daily activities yet elevated only in a clinical setting, has a prevalence of 20% to 25% in hypertensive persons and is most accurately diagnosed by ambulatory BP monitoring (with home BP measurements a distant second choice). Unfortunately, ambulatory BP monitoring is not widely available for routine clinical use in many countries (including the United States) despite having become the gold standard for diagnosis in research settings. The white coat (or "alerting") phenomenon is less common when a nurse or technician measures the BP (compared with when taken by a physician), and is

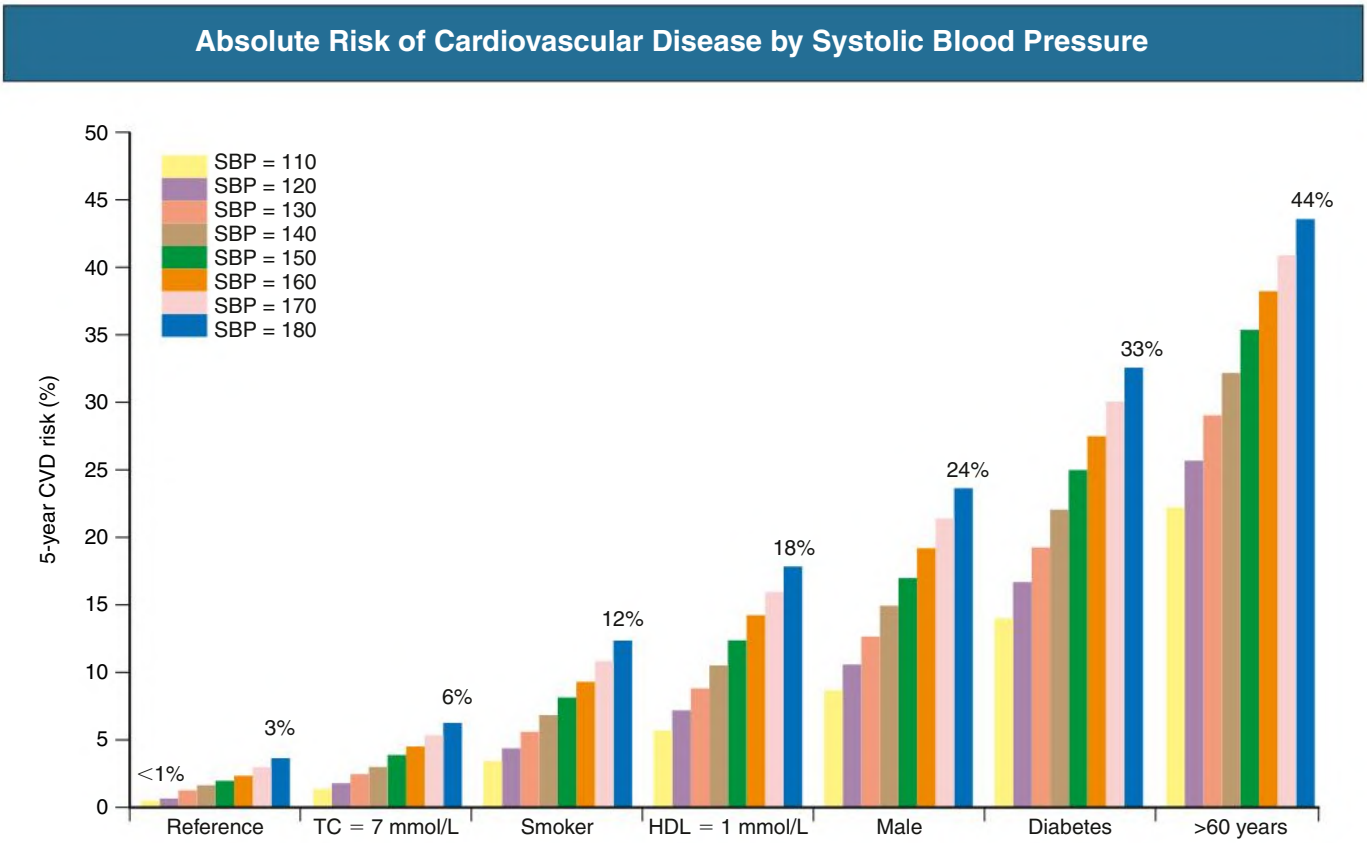

Fig. 34.6 Absolute Risk for Cardiovascular Disease During 5 Years in Patients by Systolic Blood Pressure at Specified Levels of Other Risk Factors. Reference category is a nondiabetic, nonsmoking woman age 50 years with total cholesterol (TC) level of 4 mmol/L (155 mg/dL) and high-density lipoprotein (HDL) level of 1.6 mmol/L (62 mg/dL). Risks are given for systolic blood pressure *(SBP)* levels of 110, 120, 130, 140, 150, 160, 170, and 180 mm Hg. In the other categories, additional risk factors are added consecutively; for example, the diabetes category is a diabetic 50-year-old male cigarette smoker with TC level of 7 mmol/L (270 mg/dL) and HDL level of 1 mmol/L (39 mg/dL). *CVD,* Cardiovascular disease. (Modified from Jackson R, Lawes CM, Bennett A, et al. Treatment with drugs to lower blood pressure and blood cholesterol based on an individual's absolute cardiovascular risk. *Lancet.* 2005;365:434–441.)

TABLE 34.7 Common Definitions for Metabolic Syndrome

Criterion	NCEP ATP III, 2005 Update (≥3 Criteria)	International Diabetes Federation, 2005 (Obesity + 2 Other Criteria)
Abdominal obesity	Waist circumference	Required for diagnosis
Men	>40 inches (>102 cm)	>94 cm
Women	>35 inches (>88 cm)	>80 cm
Hypertriglyceridemia	>150 mg/dL (>1.7 mmol/L)	>150 mg/dL (>1.7 mmol/L) or treatment
Low HDL		
Men	<40 mg/dL (<1.03 mmol/L)	<40 mg/dL (<1.03 mmol/L) or treatment
Women	<50 mg/dL (<1.30 mmol/L)	<50 mg/dL (<1.30 mmol/L) or treatment
Hypertension	≥130/85 mm Hg or taking antihypertensive medication	≥130/85 mm Hg or taking antihypertensive medication
Impaired fasting glucose or diabetes	Glucose ≥100 mg/dL (≥5.6 mmol/L) or taking insulin or hypoglycemic medication	Glucose ≥100 mg/dL (≥5.6 mmol/L) or taking insulin or hypoglycemic medication

TABLE 34.8 Recommendations of JNC 7 for Follow-up Based on Initial Blood Pressure Measurements for Adults

INITIAL BP (MM HG)[a]		
Systolic	Diastolic	Follow-up Recommendation
<130	<85	Recheck in 1 year
130–139	85–89	Recheck in 1 year; provide information about lifestyle modification
140–159	90–99	Confirm within 2 months
160–179	100–109	Evaluate or refer to source of care within 1 month
≥180	≥110	Evaluate or refer to source of care immediately or within 1 week, depending on clinical situation

[a]If systolic and diastolic categories are different, follow recommendations for the shorter time for follow-up. The schedule for follow-up should be modified according to reliable information about past BP measurements, other cardiovascular risk factors, or target organ disease.

Modified from Chobanian AV, Bakris GL, Black HR, et al. Joint National Committee on Prevention, Detection, Evaluation, and Treatment of High Blood Pressure; National Heart, Lung, and Blood Institute; National High Blood Pressure Education Program Coordinating Committee. Seventh report of the Joint National Committee on Prevention, Detection, Evaluation, and Treatment of High Blood Pressure. *Hypertension.* 2003;42:1206–1252.

rare when automated office BPs are taken with the patient alone in the examination room (as was recommended in the SPRINT trial[32]). Although the most recent meta-analysis of 27 observational studies suggested that people with white coat hypertension have an increased long-term risk for all-cause and CV mortality (mostly driven by data from a large Spanish registry, which have since been retracted),[39] several prior studies (using rigorous diagnostic criteria concluded that CV risk in untreated persons was not significantly elevated compared with normotensive individuals (Fig. 34.7). If CV risk is indeed elevated in white coat hypertension, it may be more appropriately attributed to subtle target organ damage and biomarkers that are intermediate between normotensive and sustained hypertensive persons. Although many people with white coat hypertension will progress to sustained hypertension, most authorities recommend initial lifestyle modifications without drug therapy, ongoing risk assessment, and close follow-up.

Masked hypertension. Masked hypertension, defined as normal BP in the medical setting but elevated during ambulatory (or, perhaps less strictly, home) BP measurements, has a prevalence of 10% to 15% in the general population. Not surprisingly, such people often have target organ damage (which is often the only clue on initial evaluation) and a CV prognosis that is not much different than individuals with sustained hypertension[40] (see Fig. 34.7).

Sustained hypertension. Sustained (sometimes persistent) hypertension is diagnosed when the BP is elevated both inside and outside the medical setting, including at home and during usual daily activities. Patients with sustained hypertension should receive antihypertensive drug therapy, which reduces their risk for CV and renal events, albeit not to the level of normotensives (see Fig. 34.7).

Pseudohypertension. Pseudohypertension is defined as a significantly higher BP measured by cuff compared with that measured by an intraarterial catheter. Typically, this condition occurs in older patients and is attributed to calcium deposition, atheromatosis, and/or medial hypertrophy of the brachial (and likely other) arteries. It is suggested by the presence of a "positive Osler maneuver," in which the nonperfused radial or brachial artery is still palpable after inflating the cuff to greater than 20 mm Hg higher than the palpated SBP. Confirmation requires arterial catheterization documenting a BP 10 to 15 mm Hg lower compared with a cuff-measured BP.

Isolated systolic hypertension. Isolated systolic hypertension (SBP ≥140 mm Hg, DBP <90 mm Hg) is recognized by current hypertension guidelines in Europe[26] but not in the United States. Its prevalence increases markedly with age, becoming by far the most common form of hypertension after the age of 60 years. It arises from vascular aging and large artery stiffening, both of which reduce their capacitance, accelerate pulse wave velocity, and widen the pulse pressure. Perhaps as a consequence of these processes, SBP continuously increases throughout life, whereas DBP usually decreases after the age of 50 years (Fig. 34.8).[41] Although there was once great concern that lowering BP in patients with isolated systolic hypertension would push the DBP below the J-curve inflection point (and increase the risk for cardiac ischemia), all three RCTs (Systolic Hypertension in the Elderly

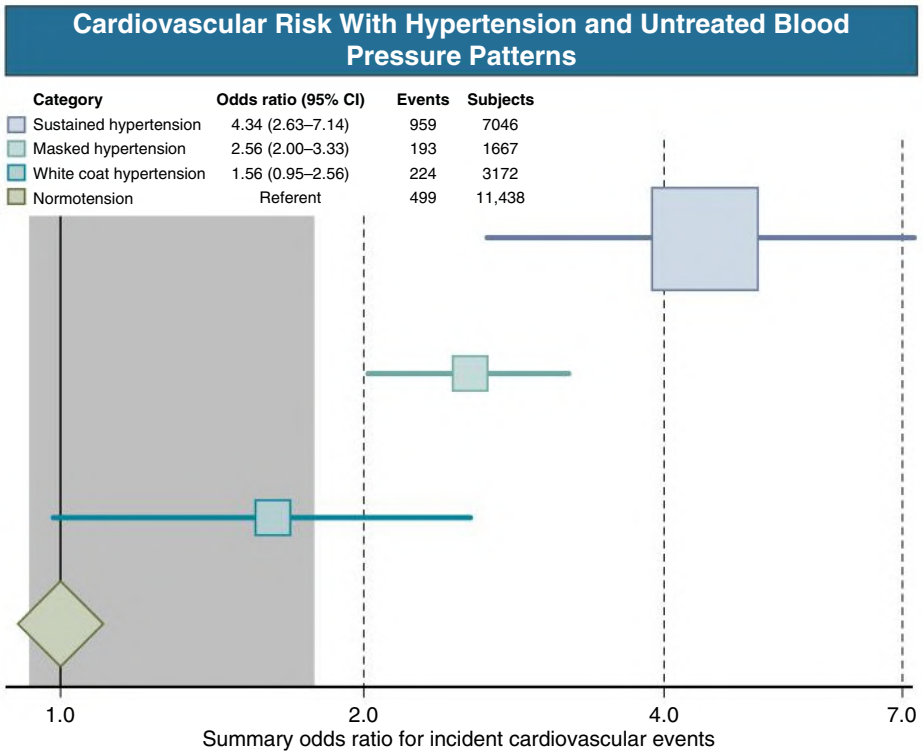

Fig. 34.7 Results of separate recent meta-analyses of various types of cardiovascular risk associated with treated and controlled hypertension and four types of untreated blood pressure patterns, as classified by ambulatory or home blood pressure monitoring: normotension, white coat hypertension, masked hypertension, and sustained hypertension. *Horizontal lines* represent the bounds of the 95% confidence intervals (CI), *squares* are drawn in proportion to the number of events. The cross-hatched area corresponds to the 95% confidence limits of the risk of treated and controlled hypertension (272 events/1829 subjects), indexed to masked hypertension (222 events/997 subjects[40]). The many sources of inhomogeneity in these data (e.g., types of cardiovascular events, treated vs. untreated subjects, baseline demographics) are ignored in these comparisons. (Modified from Cohen JB, Lotito MJ, Trivedi UK, Denker MG, Cohen DL, Townsend RR. Cardiovascular events and mortality in white coat hypertension: a systematic review and meta-analysis. *Ann Intern Med.* 2019;170:853-862; and Pierdomenico SD, Pierdomenico AM, Coccina F, et al. Prognostic value of masked uncontrolled hypertension. *Hypertension.* 2018;72:862–869.)

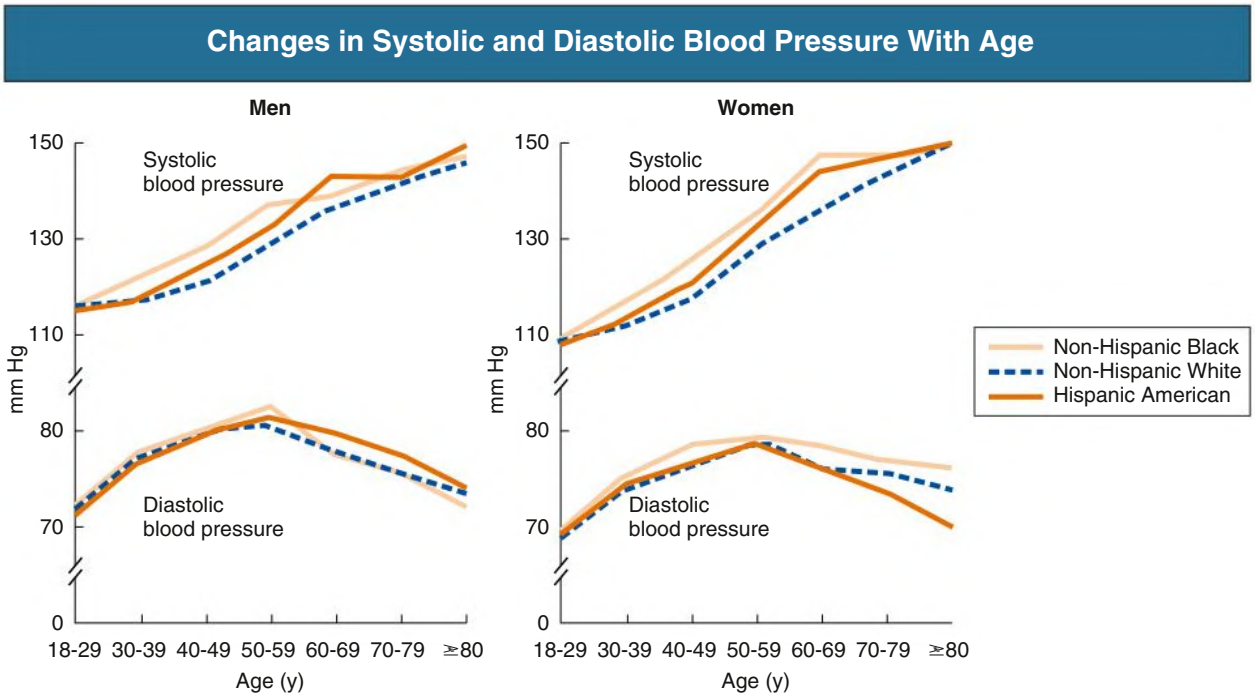

Fig. 34.8 Changes in Systolic and Diastolic Blood Pressures With Age. Systolic blood pressure and diastolic blood pressure by age and race or ethnicity for men and women older than 18 years in the US population (NHANES III, 1988–1991). (From Burt VL, Whelton P, Roccella EJ, et al. Prevalence of hypertension in the US adult population: results from the Third National Health and Nutrition Examination Survey, 1988–1991. *Hypertension.* 1995;23:305–313.)

Program in the United States, Systolic Hypertension in Europe trial, and Systolic Hypertension in China trial) showed a similar, significant decrease in stroke and no increase in cardiac events, with active drug treatment compared with placebo. The significant benefits on stroke and mortality of antihypertensive drug therapy (beginning with a thiazide-like diuretic) have now been extended to relatively healthy octogenarians (most of whom had isolated systolic hypertension) in the Hypertension in the Very Elderly Trial.[42] This RCT established a SBP target of less than 150 mm Hg for octogenarians, which was also recommended by JNC 8 for patients older than 60 years,[25] but a dissenting minority of panel members later suggested that the more traditional SBP target of less than 140 mm Hg is reasonable, even if not directly supported by RCT evidence.[43] This position was strengthened by the subgroup analysis of SPRINT subjects older than 75 years, who had a 34% reduction in the primary composite end point and a 33% reduction in mortality, if randomized to the SBP of less than 120 mm Hg.[44] The 2021 KDIGO BP guidelines did not recommend a universal diastolic BP goal, primarily because of the lack of evidence in several important renal outcomes trials (e.g., Modification of Diet in Renal Disease, African American Study of Kidney Disease and Hypertension, both of which used mean arterial pressures, not systolic/diastolic BPs).[35]

Resistant hypertension. Resistant hypertension is defined as BP above treatment goal, despite optimal doses of three antihypertensive drugs, including a diuretic.[45] Some clinical trials suggested that resistant hypertension may occur in 30% of hypertensive patients, but more population-based surveys put the US prevalence at 9% to 20%. Older age and obesity are strong risk factors; in several data sets from Southern European countries, white coat hypertension is found in up to 38% of individuals with resistant hypertension. Although nonadherence to prescribed antihypertensive drug therapy is the most common cause overall, suboptimal medication regimens and secondary hypertension (especially sleep apnea or hyperaldosteronism) are more frequently seen in referral centers.

Hypertensive emergencies and urgencies. A hypertensive emergency exists when elevated BP (usually BP >180/120 mm Hg) is associated with severe, ongoing target-organ damage (e.g., aortic dissection, hypertensive encephalopathy, cardiac ischemia, hematuria), which benefits from BP reduction within minutes to hours, typically using intravenous, short-acting antihypertensive agents in an intensive care unit (see Chapter 38). Examples include acute aortic dissection, acute decompensated heart failure, intracranial hemorrhage, eclampsia, and pheochromocytoma crisis.[46] "Hypertensive urgencies" often have similar elevations in BP but no ongoing severe target organ damage, and they can be handled in the outpatient department with oral antihypertensive agents and quick follow-up efforts. Aggressive drug therapy and intensive monitoring in this situation has little benefit.[47]

Hypertension in children and adolescents. As discussed earlier, hypertension in youth was defined in the United States (until 2017) on a purely statistical basis: SBP or DBP at or above the 95th percentile for age, sex, and height, measured on at least three occasions. Although this made quality assurance for hypertension simple in large pediatric practices, the 2017 hypertension guidelines for children and adolescents have made this rubric more complex.[29] Children have a higher risk for secondary hypertension than adults; most secondary hypertension in young children has a renal origin. Most adolescents with hypertension have primary hypertension; risk factors include a family history of hypertension and obesity, but renal causes of hypertension are more common in stage 2 hypertension (see Table 34.9).

Hypertension in pregnancy. Hypertension occurs in more than 5% of all pregnancies and in approximately 5% of women taking oral contraceptives.[48] Definitions and implications of hypertension in pregnancy are discussed in Chapters 44 and 45.

TABLE 34.9 Secondary Hypertension: Acquired Causes

Condition/ Disorder	Diseases/Comments
Kidney disorders	Kidney parenchymal disease, including acute and chronic glomerular diseases, chronic tubulointerstitial disease, PKD, diabetic nephropathy, and obstructive uropathy
	Renovascular disease: renal artery stenosis caused by atherosclerosis or fibromuscular dysplasia; arteritis; extrinsic compression of renal artery
	Other renal causes: renin-producing tumors, renal sodium retention (Liddle syndrome)
Endocrine disorders	Adrenocortical disorders: primary aldosteronism, congenital adrenal hyperplasia, Cushing syndrome
	Adrenomedullary tumors: pheochromocytoma (also extraadrenal chromaffin tumor)
	Thyroid disease: hyperthyroidism, hypothyroidism
	Hyperparathyroidism with hypercalcemia
	Acromegaly
	Carcinoid tumors
Exogenous substances and/or drugs	Oral contraceptives, sympathomimetics, glucocorticoids, mineralocorticoids, NSAIDs, calcineurin inhibitors, tyramine-containing foods and monoamine oxidase inhibitors, EPO, ergot alkaloids, amphetamines, herbal remedies, licorice (mimics primary aldosteronism), ethanol, cocaine and other illicit drugs, abrupt withdrawal of clonidine
Pregnancy	Preeclampsia and eclampsia
Coarctation of the aorta	Usually congenital, diminished pulses below the coarct, positive Hill's sign
Neurologic disorders	Sleep apnea
	Increased intracranial pressure: brain tumors
	Affective disorders
	Spinal cord injury: quadriplegia, paraplegia, Guillain-Barré syndrome
	Baroreflex dysregulation
Psychosocial factors	Hostility, time-urgency/impatience, depression, anxiety, occupational stress
Intravascular volume overload	Pedal or presacral edema, jugular venous distention, pulmonary rales
Systolic hypertension	Loss of elasticity of aorta and great vessels
	Hyperdynamic cardiac output: hyperthyroidism, aortic insufficiency, anemia, arteriovenous fistula, beriberi, Paget disease of bone
Obesity	White adipose tissue that has endocrine function: leptins, adiponectin, cytokines, chemokines, Ang II, other adipokines

Ang II, Angiotensin II; *EPO,* erythropoietin; *NSAID,* nonsteroidal antiinflammatory drug; *PKD,* polycystic kidney disease.

Classification by Cause of Hypertension

In 90% to 95% of adults with hypertension, the cause is unknown, and therefore the diagnosis is primary (or essential) hypertension (see Chapter 35). Table 34.9 lists the more common causes of secondary hypertension in descending order of prevalence in large

BOX 34.1 Guidelines for Measurement of Blood Pressure (BP): Patient Factors, Equipment, and Technique

Patient Factors

- Caffeine should not be consumed for 1 hour before the BP measurement.
- Cigarettes should not be smoked for at least 15 minutes before the BP reading.
- The standard BP measurement should be made with the patient not talking and seated comfortably, back and arm supported, and legs uncrossed. The cuff must be at the level of the heart, and the arm should be bare.
- The urinary bladder should be empty.
- Initially, BP should also be checked in both arms in the supine position after 5 minutes of rest; thereafter the arm with the higher reading is used for both supine and standing readings (after 2 minutes), especially in patients who are diabetic, older than 65 years, or receiving antihypertensive therapy. If sequential BP readings are taken in the same position, at least 30 seconds should elapse between BP readings. In patients younger than 30 years, check BP in one leg initially.
- To establish a diagnosis of hypertension, obtain BP readings on two different occasions, at least 1 week apart.

Equipment

- The bell of the stethoscope is preferred. The length of the bladder with the cuff should encircle at least 80% of the arm.
- The width of the cuff should be equal to two-thirds of the distance from the antecubital space to the axilla and should be 40% of the arm circumference. The best cuff for most adults is the 15-cm-wide cuff with a bladder of 33 to 35 cm in length. The distal edge of the cuff should be 2.5 cm (1 inch) above the antecubital fossa. For leg BP, thigh cuff length should encircle 80% of the thigh, and width should be 40% of the thigh circumference. For leg BP, the patient should be prone and popliteal artery sounds detected by auscultation.
- For infants, ultrasound equipment may need to be used.

Technique

- The initial systolic BP should be checked by palpating the disappearance of the radial or brachial pulse before auscultation and the cuff then deflated.
- The second BP check requires cuff inflation 20 mm Hg above the palpable systolic level.
- Deflate the cuff at a rate of 2 to 4 mm Hg per second for heart rates of 60 to 120, respectively.
- Record the Korotkoff sound I (appearance of sound) as the systolic BP and record the Korotkoff sound V (silence, 2 mm Hg below the last sound) as the more reproducible diastolic BP. If the sounds do not disappear, record the muffled sound (phase IV) as the diastolic BP.
- The sounds may be augmented by having the patient raise the arm and open and close the hand 10 times before inflating the BP cuff.
- Do not stop between systolic and diastolic BP readings; deflate the cuff, wait at least 30 seconds, and then reinflate. On each occasion, record at least two (and preferably three) BP readings. If the BP readings vary by more than 5 mm Hg, take additional BP readings until two are within 5 mm Hg.
- In children, the same standards apply for cuff size; Korotkoff sound V should be used. If the child is uncooperative, the systolic BP may be determined by palpation.

series. Renal parenchymal disease is most common (especially in nephrology clinics, particularly in diabetics; see Chapters 31 and 33), followed by endocrine causes (Chapters 39 and 40), renovascular hypertension (Chapter 43), sleep apnea, coarctation of the aorta, drug-induced hypertension, and rare monogenetic causes (see Chapter 49). Hypertension occurring in dialysis patients is covered in Chapter 42, while neurogenic hypertension such as can occur with stroke is discussed in Chapter 41.

TABLE 34.10 Acceptable Bladder Dimensions for Various Arm Sizes.

Usual Patient	Arm Circumference Range at Midpoint (cm)	Bladder Width (cm)	Bladder Length (cm)
Newborn	6	3	6
Infant[a]	6–15	5	15
Child[a]	16–21	8	21
Small adult	22–26	10	24
Adult	27–34	13	30
Large adult	35–44	16	38
Adult thigh	45–52	20	42

[a]To approximate a bladder width to arm circumference ratio of 0.4 more closely in children, additional cuffs are available. There is some overlap in the recommended ranges for arm circumference to limit the number of cuffs. It is suggested that the larger cuff be used if it is available.
Modified from Pickering TG, Hall JE, Appel LJ, et al. Recommendations for blood pressure measurement in humans and experimental animals, part 1: blood pressure in humans: a statement for professionals from the Subcommittee of Professional and Public Education of the American Heart Association Council on High Blood Pressure Research. Hypertension. 2005;45:142-161.

EVALUATION OF HYPERTENSION

Blood Pressure Measurement

Arterial BP is traditionally measured in the brachial artery with the cuff-based sphygmomanometer by detecting sounds that are generated (auscultatory method) or by recording vascular pulsations (oscillometric method) after decompression of a compressed artery.[49] Box 34.1 lists guidelines for traditional BP measurement. The most common error is using an inappropriately sized cuff, because cuffs that are too small routinely underestimate the BP. Table 34.10 provides acceptable bladder dimensions for varying arm sizes. Because of the low frequency of Korotkoff sounds, the bell of the stethoscope provides better detection than the diaphragm. Accurately taking BP is a teachable and testable skill, but many routine measurements are made with little effort to ensure their quality. As a result, many health care systems have transitioned to using automated oscillometric office BP measurements, which minimize the white coat effect, and after 5 minutes of quiet rest provide standardized triplicate measurements in a 5-minute period. Because elemental mercury (used in classic manometers and sphygmomanometers) has been eliminated from workplaces in most countries and aneroid ("dial") manometers are fragile, oscillometric techniques have become increasing popular. This method directly measures MAP and then uses a proprietary algorithm to estimate SBP and DBPs. Many such semiautomatic (typically for home BP readings) and fully automatic oscillometric devices have been validated against the traditional mercury column,[50] but they still require regular calibration, validation, and maintenance.

Variability of Blood Pressure

Office Versus Home Blood Pressure and Circadian Variation

BP varies considerably throughout the day and over time, even in the same individual. This intrinsic variation causes difficulty in identifying hypertensive individuals because there are many false negatives and even more false positives. Aside from measurement errors (which can be overcome by proper technique), intrinsic biologic variation can be addressed by taking at least three BP readings at a given visit. Recent US guidelines consider the lowest SBP and DBP at any given visit (even if not measured simultaneously) to be the BP for that visit.[51] Confirming elevated

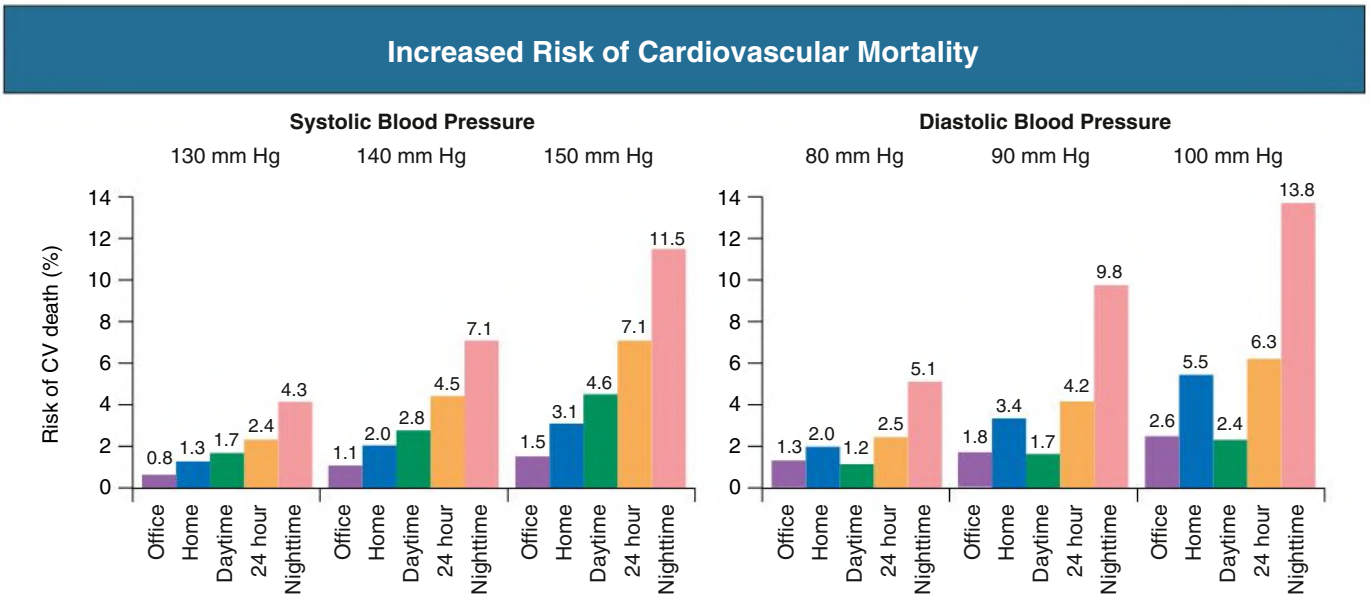

Fig. 34.9 Risk for Cardiovascular Mortality in an Early Population-Based Italian Study. Risk for cardiovascular death (%) over 11 years, for a 10 mm Hg increase in office, home, and ambulatory blood pressure (BP) readings at various initial BP values. *CV,* Cardiovascular. (From Sega R, Fachetti R, Bombelli M, et al. Prognostic value of ambulatory and home blood pressures compared with office blood pressure in the general population: follow-up results from the Pressioni Arteriose Monitorate e Loro Associazioni (PAMELA) study. *Circulation.* 2005;111:1777–1783.)

readings at a second visit takes advantage of regression to the mean to better identify the true BP for a given individual. Another widely recommended option is to measure home BPs (see later discussion).

In addition to physical/mental activity, and emotional/environmental stress, BP is affected by circadian variation. About 80% of the population display a dipping pattern, with average nocturnal BP that is 10% to 20% lower than the daytime average; this difference diminishes with increasing age. The normal morning surge in BP and heart rate that begins about 30 minutes before awakening correlates with an increased risk for death, myocardial infarction, and stroke in the early morning hours. Individuals with a nondipping nocturnal BP pattern more commonly have CKD, target-organ damage, secondary hypertension, autonomic dysfunction, and/or an increased risk for CV events.

Home and Ambulatory Blood Pressure Monitoring

Most ambulatory BP monitors use oscillometry and record BPs for 24 hours, making measurements frequently during the daytime (e.g., every 15 minutes) and less so at night (e.g., every 30 minutes). Inaccurate readings can occur with inappropriately sized cuffs, cardiac dysrhythmias, vigorous activity, inability to sleep because of pain resulting from cuff insufflation, and many other conditions. Because ambulatory BP monitoring (1) can diagnose white coat, masked, and nocturnal hypertension; (2) correlates better with both target-organ damage and future CV events than either office or home BPs; and (3) has been found to be cost-saving in many countries, it has been recommended (as at least one of several options) by many policymaking authorities, including British, European,[26] Canadian, and KDIGO Guidelines,[35] and the US Task Force on Preventive Services[52] before starting antihypertensive drug therapy. Multiple national and international expert panels have issued guidelines regarding indications, technique, reporting, and implications of the procedure.[34,49,53]

Because of the limited availability of, and scarce reimbursement for, ambulatory BP monitoring, home BP monitoring with semiautomated devices (typically duplicate measurements morning and evening for a week) has been recommended.[26,34,49,53] Home BP readings, on average, are slightly higher than ambulatory BP readings (because the latter includes nocturnal BPs) and slightly lower than office BPs. Home BP readings should be obtained with a device that has been calibrated (usually in the practitioner's office), are subject to reporting bias (which can be minimized by telemonitoring systems), and their interpretation is not often reimbursed. In general, home BP readings correlate better with target-organ damage and CV outcomes than office BP measurements but less well than ambulatory BP results (Fig. 34.9).[54] For many reasons, therefore, ambulatory BP monitoring is preferred over home BP recording in several settings[49] (Fig. 34.10 and Box 34.2).

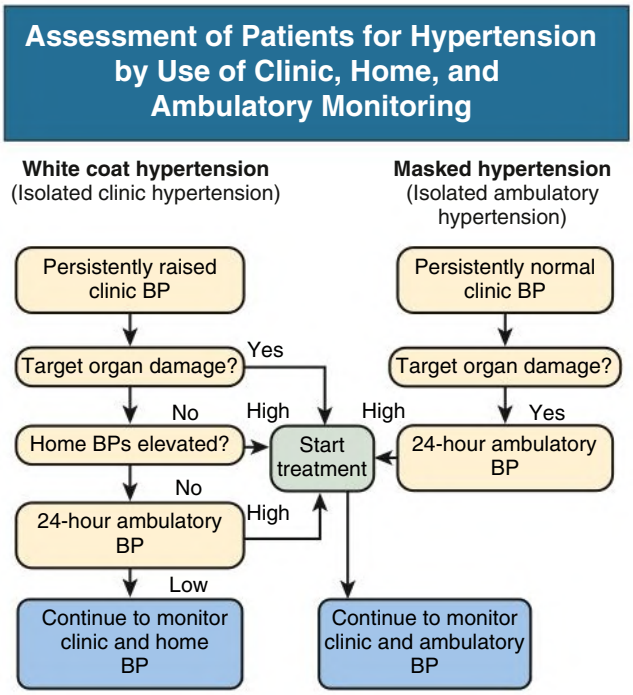

Fig. 34.10 Algorithm for diagnosis of hypertension using clinic, home, and/or ambulatory monitoring of blood pressure (BP).

BOX 34.2 Indications for Ambulatory Blood Pressure (BP) Measurement

- White coat hypertension
- Evaluation of apparent drug resistance
- Hypotensive symptoms (especially during sleep, e.g., in obstructive sleep apnea)
- Autonomic dysfunction
- Episodic hypertension
- Evaluation of nocturnal decreases in BP as a prognostic factor for target organ damage (e.g., left ventricular hypertrophy, ischemic optic neuropathy)
- Evaluation of BP changes in patients with paroxysmal nocturnal dyspnea and/or nocturnal angina
- Carotid sinus syncope
- Pacemaker syndromes
- Safety of withdrawing antihypertensive medication
- Assessment of 24-hour BP control in patient receiving once-daily medication
- Borderline hypertension with target organ damage (evaluation for masked hypertension)
- Evaluation of antihypertensive drug therapy in clinical trials

Risk Assessment in Hypertension

The medical history, physical examination, and a limited laboratory evaluation (biochemistry panel, including estimated GFR, and fasting glucose and lipid panel, urinalysis and urinary albumin-to-creatinine ratio, complete blood count, electrocardiogram) provide useful information to assess the presence and extent of target-organ damage and estimate future CV and renal risk (see Chapter 35).[24-27,34] The ACC/AHA 2017 US hypertension guideline added serum thyroid-stimulating hormone to the list of recommended initial tests.[34]

Consideration of Primary Versus Secondary Hypertension

If the history, physical examination, or screening laboratory studies suggest secondary hypertension, additional studies may be warranted (Tables 34.11 and 34.12). If renal parenchymal disease is suspected, ultrasound may be useful to evaluate renal size and echogenicity and rule out obstructive uropathy; Doppler flow studies also can help stratify risk for renovascular hypertension (see Chapter 43). Because primary aldosteronism can now be controlled either with chronic aldosterone antagonists or (occasionally) after laparoscopic surgery, a ratio of plasma aldosterone to plasma renin activity ratio may be useful (see Chapter 39). Suggested evaluations for other forms of secondary hypertension are listed in Table 34.12.

Acknowledgment

I thank the late William J. Lawton, MD, and Drs. DiBona, Kopp, and Luft for their contributions to this chapter in previous editions.

TABLE 34.11 Evaluation for Primary Versus Secondary Hypertension

Classification	Medical History	Physical Examination	Laboratory Studies
General information and evaluation of target organs	Duration and course of hypertension Prior workup and treatment Diet/lifestyle: salt intake, tobacco, caffeine	Evaluation of volume status, optic fundi, heart, lungs, peripheral vessels, and nervous system	Complete blood count, fasting glucose, lipid profile (includes HDL, LDL, cholesterol, triglyceride), uric acid Consider echocardiogram
Primary (essential or idiopathic) or secondary (?)	Family history: Hypertension, cardiovascular and renal diseases Symptoms of target organ disease (related to eyes, central nervous system, cardiorespiratory, and peripheral vasculature)	See Table 34.12 for signs suggestive of secondary hypertension	See Table 34.12 for additional laboratory studies to rule out secondary hypertension

HDL, High-density lipoprotein; *LDL,* low-density lipoprotein.

TABLE 34.12 History, Physical Examination, and Initial Laboratory Evaluation for Secondary Hypertension

Target Organ/System	Medical History	Physical Examination	Laboratory Studies
Kidney			
Kidney parenchymal	History of kidney disease (including glomerulonephritis, nephrotic syndrome, calculi, urinary tract infection) Symptoms include nocturia, frequency, dysuria, hesitancy, urgency, incomplete emptying, dribbling, hematuria, pyuria, flank pain	Tenderness in costovertebral angles; palpable kidneys, edema	BUN, serum creatinine; urinalysis, urine culture if indicated; first morning UACR
Renovascular hypertension		Epigastric bruit; other vascular bruits	Kidney ultrasound with duplex Doppler flow study; consider angiography or magnetic resonance angiography

TABLE 34.12 History, Physical Examination, and Initial Laboratory Evaluation for Secondary Hypertension—cont'd

Target Organ/System	Medical History	Physical Examination	Laboratory Studies
Endocrine			
Primary aldosteronism	Muscle weakness, cramps		Serum aldosterone/plasma renin activity ratio
Cushing syndrome	Weight gain, muscle weakness, changes in body habitus	Body habitus: Central obesity, dorsocervical fat pad, abdominal striae	Midnight salivary cortisol; consider morning serum cortisol after dexamethasone suppression
Pheochromocytoma	Headaches, vasomotor symptoms, (inappropriate sweating, pallor), cardiac symptoms (awareness, tachycardia, palpitations)	Paroxysmal or intermittent hypertension (50% of patients)	24-hr urine for VMA, metanephrines, and catecholamines or plasma fractionated metanephrines
Carcinoid	Flushing		24-hour urine for 5-hydroxyindoleacetic acid
Hyperthyroidism	Weight loss, tachycardia, palpitations, sweating, heat intolerance	Palpable thyroid	Ultrasensitive serum thyroid-stimulating hormone level
Hypothyroidism	Weight gain, dry skin, cold intolerance, hair loss	Palpable thyroid	Serum ultrasensitive thyroid-stimulating hormone level
Hyperparathyroidism	Nausea, vomiting, bone pain, nephrolithiasis		Serum calcium, intact parathyroid hormone levels
Acromegaly	Change in size of head, hands, or feet (adult)	Appearance	Serum insulin-like growth factor-1 level (see Box 40.1)
Medication			
	Review of prescribed and over-the-counter medications (especially oral contraceptives, NSAIDs, sympathomimetic agents [cold and allergy remedies], illicit or recreational drugs, including alcohol, herbal remedies)		
Coarctation of the Aorta			
	Onset or detection of hypertension in childhood or adolescence	Simultaneous palpation of radial and femoral arteries to detect pulse lag in femoral arteries; leg blood pressure	Chest radiograph for heart size, configuration of aorta, rib notching; consider echocardiogram
Neurologic Disorders			
Sleep apnea	Obesity; weight gain; daytime somnolence; snoring, poor sleep habits (frequent awakening, not rested on arising); early-morning headache	Obesity, narrowed airway in hypopharynx, redundant pharyngeal tissue	Berlin questionnaire; consider formal sleep study (polysomnography)
Increased intracranial pressure	Headache, neurologic symptoms	Papilledema	Increased cerebrospinal fluid pressure
Affective disorders[a]			
Spinal cord injury[a]			
Psychosocial Factors			
	Family and support structure, occupation, education, stressors		
Volume Overload			
	Excess salt and water intake (may be iatrogenic with excess parenteral fluid)	Increased jugular venous distention, pulmonary crackles, presacral and peripheral edema, hepatomegaly	Chest radiograph
Isolated Systolic Hypertension			
		Pseudohypertension (positive Osler maneuver), cardiac and vascular examination (aortic insufficiency, arteriovenous fistula)	

[a]Medical history, physical examination, and laboratory tests are beyond the scope of this discussion.
A more detailed discussion is provided in other relevant chapters. Pregnancy-associated hypertension is discussed in Chapters 44 and 45.
BUN, Blood urea nitrogen; *NSAID,* nonsteroidal antiinflammatory drug; *UCAR,* urine albumin-to-creatinine ratio; *VMA,* vanillylmandelic acid.

SELF-ASSESSMENT QUESTIONS

1. Short-term (within seconds to minutes) regulation of blood pressure in normal humans is most often attributed to which of the following physiologic systems?
   A. Atrial natriuretic peptides
   B. Endothelin
   C. Kallikrein-kinin system
   D. Renin-angiotensin-aldosterone system
   E. Sympathetic nervous system
2. An asymptomatic, presumably healthy 67-year-old man visits the physician's office and has seated blood pressures of 140/96, 138/94, and 142/88 mm Hg, as measured personally and appropriately by the physician. According to guidelines promulgated by the Healthcare Effectiveness Data and Information Set (HEDIS) 2021 and the ACC/AHA 2017 US hypertension guideline, his blood pressure at this visit is most appropriately classified using which of the following terms?
   A. Normal
   B. Elevated
   C. Stage 1 hypertension
   D. Stage 2 hypertension
   E. Isolated systolic hypertension
3. A 62-year-old White man visits the nephrologist because his routine tests last week showed that his estimated glomerular filtration rate was 59 mL/min/1.73 m^2 and his first morning voided urine contained 28 mg (normal <30) of albumin/gram of creatinine. Past medical history includes "prehypertension" since 2015, but he takes no medications. Blood pressures are 136/84, 134/86, and 132/82 mm Hg when measured personally and appropriately by the nephrologist. His 10-year risk of a cardiovascular event is estimated at 9.2%. According to the ACC/AHA 2017 US hypertension guideline, the most appropriate recommendation for this patient is which of the following?
   A. Recheck blood pressure in this office in 1 year.
   B. Recheck blood pressure in this office in 1 year, and provide guidance about lifestyle modifications.
   C. Repeat blood and urine tests in 3 months, and recheck blood pressure in this office soon thereafter.
   D. Recheck blood pressure within 2 months.
   E. Institute antihypertensive drug therapy today with an angiotensin converting-enzyme inhibitor or angiotensin II receptor blocker.
4. A 32-year-old woman is referred to the nephrologist because her ophthalmologist noted grade II hypertensive retinopathy last month, and her obstetrician/gynecologist noted 2+ proteinuria on dipstick (without blood or nitrite), despite normal office blood pressures last week. Past medical history is remarkable for preeclampsia 4 and 6 years ago, but both of her children were delivered without complications, and her blood pressure has since been normal. Office blood pressures are 128/84, 126/82, and 124/80, measured by a calibrated automated oscillometric device. In addition to the retinopathy, electrocardiogram shows voltage criteria for left ventricular hypertrophy, and a random urinalysis shows 3+ protein. According to recent surveys, her condition is most commonly seen in what proportion of which population?
   A. Less than 1% of people older than 65 years
   B. 5% to 10% of the hypertensive population
   C. 10% to 15% of the general population
   D. 20% to 25% of the hypertensive population
   E. 29% to 32% of the general population
5. A 56-year-old non-Black man is referred to the nephrologist because his blood pressures in his primary care medical home have never been below 190/120 mm Hg, yet the rest of his evaluation is normal. A request for prior authorization for ambulatory blood pressure monitoring was denied by his insurance plan. His home blood pressures, measured with a validated semiautomatic oscillometric device, have a mean and standard deviation of 128 ± 4/78 ± 3 (122 measurements over 3 months). He has no family history of hypertension. Office blood pressures, taken with the same machine, were 194/122, 196/120, and 192/118 mm Hg. Physical examination and laboratory studies were unremarkable. The most appropriate recommendation for him is which of the following?
   A. A renal biopsy is indicated to identify the cause of his hypertension.
   B. He should have an iothalamate clearance measured to assure that the estimated glomerular filtration rate is accurate.
   C. He should undergo renal ultrasound with Doppler flow studies, a 24-hour urine collection for vanillylmandelic acid and metanephrines, and a plasma aldosterone/renin activity ratio to rule out common causes of secondary hypertension.
   D. He should start an angiotensin converting-enzyme inhibitor or an angiotensin II receptor blocker today and return to this office in 1 month for repeat blood pressure measurement by his home device.
   E. He should continue to monitor his home blood pressures and call for another appointment when/if they meet or exceed 125/75 mm Hg.

Primary Hypertension

Bernardo Rodríguez-Iturbe, George L. Bakris, Richard J. Johnson

DEFINITION

Primary (essential) hypertension is defined by most international societies as an office-based blood pressure (BP) with systolic pressure of 140 mm Hg or higher or diastolic pressure of 90 mm Hg or higher,[1] but in 2017 it was defined by the American College of Cardiology/American Heart Association (ACC/AHA) as BP of 130/80 mm Hg or higher without an identifiable cause[2] (Table 35.1). The ACC/AHA guidelines have a more stringent definition because of the recognition of a graded increase of cardiovascular (CV) events that exist even in those with systolic BP of 120 to 129 mm Hg and less than 80 mm Hg (which is now termed *elevated BP*). An argument against the ACC/AHA guidelines is that they will lead to a majority of adults being given the diagnosis of hypertension requiring therapy.

Blood pressure is normally variable and related to a natural circadian rhythm, with the most significant increase in BP in the morning (6–10 AM). Blood pressure falls during sleep secondary to a decrease in sympathetic nervous system (SNS) tone and reduced activity of other neuroendocrine systems. There are also minute-to-minute variations in BP (Fig. 35.1). Transient elevations in BP, reaching 150 mm Hg systolic, occur in most normotensive individuals in any given day, especially during exercise.[3] Thus, diagnosis of elevated BP and/or hypertension should involve multiple measurements (see Chapter 34).

When only the systolic BP (SBP) is elevated (SBP >140 and diastolic BP [DBP] <90 mm Hg), the term used is *isolated systolic hypertension.* "*White coat*" *hypertension* is an increase of more than 20 mm Hg in SBP noted only in the physician's office and above that seen at home or in another setting. In contrast, *masked hypertension* is BP that is normal in the office but elevated by more than 20 mm Hg when measured by ambulatory BP measurement.

Other terms used to describe specific clinical presentations include *hypertensive emergency,* associated with acute end organ damage requiring immediate treatment, usually in a critical care setting, and *hypertensive urgency,* in which there is no acute organ damage and BP needs correction in hours or a few days (see Chapter 38). In hypertensive emergencies in which an acute decrease of kidney function occurs, the reduction of BP will halt, prevent, or reverse decreasing glomerular filtration rate (GFR). These terms have replaced "malignant hypertension" and "accelerated hypertension." *Resistant hypertension* is defined as hypertension that remains greater than 140/90 mm Hg (or 130/80 by US guidelines) despite use of three maximally dosed antihypertensive medications of different classes, including a diuretic. Patients that require four or more medications are also considered to have resistant hypertension. The definition of resistant hypertension is arbitrary and aims to identify patients that may benefit from special diagnostic or therapeutic considerations. *Pseudoresistant* hypertension defines uncontrolled hypertension that appears resistant but is due to other causes, usually poor adherence to therapy or inappropriate measurement (e.g., using an inappropriately small blood pressure cuff).

EPIDEMIOLOGY

Hypertension affects nearly one-third of adults worldwide, with a higher prevalence in low- and medium-income countries (31.5%, 1.04 billion people) than in high-income countries (28.5%, 349 million people).[4] The prevalence of hypertension rose significantly in the twentieth century from approximately 5% in the United States in the early 1900s (based on studies using 140/90 mm Hg as the cutoff), possibly because of the increasing longevity of the population and the rising prevalence of obesity (Fig. 35.2).

There are multiple risk factors for primary hypertension (Table 35.2). Older age is a strong risk factor, especially after the age of 65 years, such that by 80 years of age, 90% of individuals are hypertensive.[5] Interestingly, the age-related increase in prevalence of hypertension has not been uniformly observed in all populations (e.g., the Yanomamo Indians on their native hunter-gatherer diet). Hypertension is more common in men, although the prevalence in women is similar to and slightly exceeds that of men after age 55 years. Certain ethnic groups are at increased risk of hypertension, especially African Americans, Filipino Americans, Australian Tiwi, and the Maori of New Zealand. Other risk factors for hypertension include family history, obesity, insulin resistance, hyperuricemia and/or gout, sleep disorders including sleep apnea, and persistent high-stress environments either at work or home. Certain physical features, such as elevated heart rate or an increased BP response to exercise, are also predictive, as is elevated hematocrit.

Genetic factors play a role in 20% to 30% of patients with primary hypertension, likely from the cumulative effect of multiple susceptibility genes. To date over 90 genetic polymorphisms have been identified that are associated with primary hypertension,[6] including polymorphisms linked with natriuretic peptide, vasoactive mediators (angiotensinogen, endothelial nitric oxide synthetase, prostacyclin synthase, β_2-adrenoceptor, 20-HETE synthase [*CYP4F2* gene], G protein β3), mediators of vascular smooth muscle tone (calcium-dependent potassium channel, *KCNMA*), immune signaling (e.g., heat shock proteins), and mediators controlling kidney sodium transport (α-adducin and 11β-hydroxysteroid dehydrogenase type 2, aldosterone synthase, "with no lysine" kinase [WNK] kinases). Although genetic polymorphisms involving sodium excretion are common in persons with primary hypertension,[7] more than 80% also have effects on the immune system.[6]

Hypertension is also more likely to occur if the mother has a history of hypertension, obesity, preeclampsia, or malnutrition. A history of intrauterine growth restriction or low birthweight also are risk factors for hypertension.

TABLE 35.1 Categories of Blood Pressure in Adults

Category	SBP (mm Hg)		DBP (mm Hg)
ACC/AHA Hypertension Guidelines (2017)			
Normal	<120	and	<80
Elevated	120–129	and	<80
Hypertension			
Stage 1	130–139	and	80–89
Stage 2	≥140	and	≥90
European Society of Hypertension Guidelines (2018)			
Optimal	<120	and/or	<80
Normal	120–129	and/or	80–84
High-normal	130–139	and/or	85–89
Grade 1 hypertension	140–159	and/or	90–99
Grade 2 hypertension	160–179	and/or	100–109
Grade 3 hypertension	≥180	and/or	≥110
Isolated systolic hypertension	≥140	and	<90

ACC/AHA, American College of Cardiology/American Heart Association; *DBP,* diastolic blood pressure; *SBP,* systolic blood pressure.

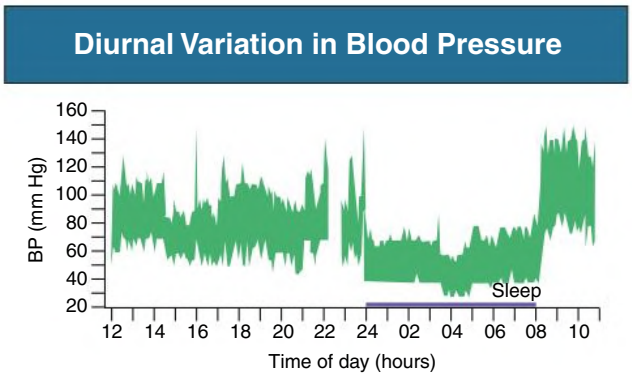

Fig. 35.1 Blood Pressure (BP) Variability in a Normotensive Individual. In most individuals, systolic blood pressure reaches 150 mm Hg at least once daily. (From Bevan AT, Honour AJ, Stott FH. Direct arterial pressure recording in unrestricted man. *Br Heart J.* 1969;31[3]:387–388.)

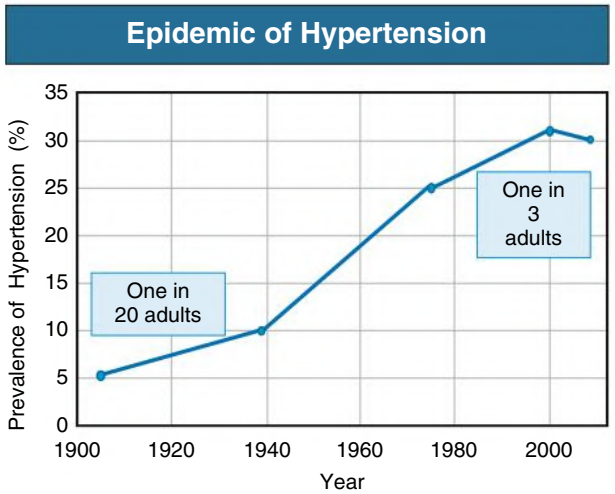

Fig. 35.2 Epidemic of Hypertension. The prevalence of primary hypertension (defined as blood pressure >140/90 mm Hg) in the United States increased from 11% in 1939 to 31% in 2008, leveling to 29% of the population in 2012.

TABLE 35.2 Major Risk Factors for Primary Hypertension

Genetic	Family history Polymorphisms (adducin, endothelial nitric oxide synthase, angiotensinogen, β_2-adrenoceptor, human G protein β3 subunit)
Congenital	Low birthweight, low nephron number, maternal hypertension, maternal preeclampsia, maternal malnutrition
Physical	Obesity, older age, African American, African Caribbean, some Bantu-speaking peoples in Africa, increased heart rate (>83 beats/min), increased emotional stress
Diet/toxin	Increased sodium intake, low potassium intake, low dairy products intake, heavy alcohol intake, high intake of added sugars, low level lead or cadmium intoxication
Metabolic[a]	Elevated serum uric acid, insulin resistance, elevated hematocrit
Other	Low socioeconomic status, urban versus rural residence

[a]Laboratory-based parameters.

Dietary and environmental factors also contribute to the risk for hypertension. Obesity, with or without features of insulin resistance and metabolic syndrome, is a major risk factor for hypertension, and the increased incidence of obesity parallels the rise in hypertension in most countries. Epidemiologic and interventional studies have linked high salt and low potassium intake with persistent BP elevation (especially in African Americans), whereas increasing potassium intake lowers BP in both experimental and human studies. Intake of added sugars (e.g., sucrose, high-fructose corn syrup) predicts higher BP, and excessive alcohol consumption, physical inactivity, and chronic low-level exposure to lead and cadmium have all been associated with the development of hypertension.

ETIOLOGY AND PATHOGENESIS

Primary hypertension is thought to be due to a defect in kidney sodium handling. Whereas increasing salt intake will only increase BP slightly (several mm Hg) in normal individuals, in subjects with *salt-sensitive hypertension*, the BP response is shifted rightward with a change in slope, leading to a greater relative increase in BP for the same load of salt (Fig. 35.3).[8] In contrast, some hypertensive patients, especially those younger than 40 years, are considered to have *salt-resistant hypertension*, as the response to a salt load is similar to that in normal individuals but simply shifted rightward. There is some evidence that individuals can begin with salt-resistant hypertension and evolve to being salt-sensitive.

The importance of salt in primary hypertension is supported by a direct association between dietary sodium content and the prevalence of hypertension in diverse populations, and intervention studies in which salt restriction has led to improvement in hypertension.[9] Several hypotheses have been proposed to explain the kidney defect in sodium excretion in primary hypertension.

Genetic (Polygene) Hypothesis

Lifton and colleagues determined that many monogenic forms of both hypertension and hypotension involve genes regulating kidney sodium transport (Chapter 49).[7] Lifton has suggested that polymorphisms in genes that favor sodium reabsorption in the kidney, coupled with excessive salt intake (>10 g/day) that is pervasive in Western diets, may underlie the pathogenesis of primary hypertension.[7] Likewise,

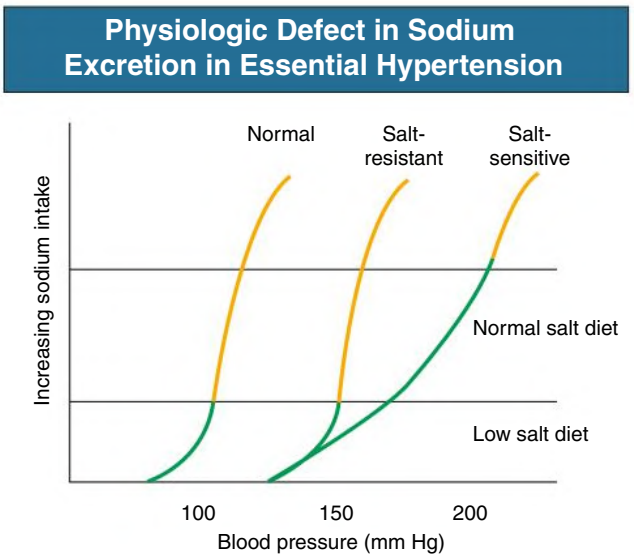

Fig. 35.3 Physiologic Defect in Sodium Handling in Primary Hypertension. Evidence suggests that increasing salt in the diet will only slightly increase blood pressure (BP) in subjects with normal BP or subjects with salt-resistant hypertension, whereas subjects with salt-sensitive hypertension will show an exaggerated BP response. (Modified from Guyton AC, Coleman TG, Cowley AV Jr, Scheel KW, Manning RD Jr, Norman RA Jr. Arterial pressure regulation. Overriding dominance of the kidneys in long-term regulation and in hypertension. *Am J Med.* 1972;52[5]:584–594.)

mutations that favor sodium excretion might provide protection from hypertension, such as polymorphisms involving the Na-K-2Cl cotransporter SLC12A1, the inward rectifier K^+ channel KCNJ1 (carrier state for Bartter syndrome), and the Na-Cl cotransporter SLC12A3 (carrier state for Gitelman syndrome).

Nevertheless, the single-nucleotide polymorphism (SNP) variants identified by genome-wide association studies account for only 4% to 13% of the BP variability in studies of quantitative changes in BP,[2,10] and studies that analyzed hypertension as a dichotomous trait found only two SNPs corresponding to hypertension: one associated with the uromodulin gene and the other located near the endothelial nitric oxide synthase gene.[11]

Congenital (Low Nephron Number) Hypothesis

Environmental stress during pregnancy may cause epigenetic changes that affect the fetus and translate into hypertension later in life (fetal programming). Infants with low birthweight (LBW) are at increased risk for hypertension in addition to diabetes and obesity.[12] Mothers of LBW infants frequently have hypertension, obesity, preeclampsia, or malnutrition, and these maternal factors also carry an increased risk for hypertension in the infant. Brenner and colleagues[13] proposed that this excess risk among LBW infants is driven by lower nephron number, which may predispose to the development of hypertension and the progressive loss of nephrons with aging. Indeed, maternal malnutrition in laboratory rats predisposes to small pups, low nephron number, and the future predisposition for hypertension. A study of nine white subjects with primary hypertension who died of accidental causes also found almost 50% fewer nephrons than in age- and sex-matched controls.[14]

Other studies, however, did not confirm a relationship between birthweight or low nephron number and hypertension. One study reported that LBW infants have a 25% risk for developing hypertension as an adult, but infants with high birthweight also carried a 20% risk.[15] Thus, LBW and low nephron number likely reflect risk factors for development of hypertension rather than the underlying mechanism.

Role of the Immune System and Subtle Kidney Injury

Recently, a role of the immune system has been identified in primary hypertension.[16] The initiating mechanism is not fully understood but may be initiated by renal vasoconstriction that results from a borderline hyperactive SNS, endothelial dysfunction, or oxidative stress and that is precipitated by diet (high salt or high sugar), metabolic mechanisms (hyperuricemia), emotional stress, a borderline hyperactive SNS, or other mechanisms.[17]

The renal vasoconstriction causes ischemia that stimulates low grade T-cell and macrophage infiltration (Fig. 35.4). Low-grade T-cell and macrophage infiltration in the interstitium occurs in 90% or more of kidney biopsy samples from patients with primary hypertension.[18] Historically, the inflammatory and microvascular changes were considered the consequence of hypertensive kidney damage, but newer studies suggest that persistent kidney inflammation may have a role in causing the hypertensive response, possibly by causing renal vasoconstriction and impairing the ability to excrete sodium.

The mechanism is thought to be mediated by activation of the innate immune system followed by stimulation of adaptive immunity in which the T cells become sensitized to neoantigens, leading to an autoimmune mediated hypertension (Fig. 35.4). To date, two autoantigens have been identified, including heat shock protein 70 (HSP70) and oxidized isoketal-containing proteins (i.e., proteins oxidatively modified by highly reactive γ-ketoaldehydes).[19,20] A role for HSP70 as a neoantigen is supported by experimental studies in which blocking T-cell sensitization to HSP70 can block hypertension, whereas sensitization of T cells to HSP70 in the kidney can induce a rise in BP. Clinical studies also have found evidence for both autoantibodies and T-cell sensitization to HSP70 in humans with primary hypertension.[19] Isoketal accumulation in dendritic cells may also act as an autoantigen as it can induce costimulatory CD80 and CD86 proteins. Isoketal-modified proteins have been demonstrated in circulating dendritic cells and monocytes of hypertensive patients, and scavengers of isoketals prevent or ameliorate hypertension in several models of hypertension.[20]

It is thought that the immune response to the autoantigens is orchestrated by T cells, B cells, and macrophages, with the CD8 T cells primarily driving the hypertensive response, whereas the regulatory T-cell populations counterregulate the response.[16,21,22] Blocking the inflammation with immunosuppressive therapy can both prevent or correct the development of hypertension in experimental models.[16] Pilot studies also suggest that blocking the immune system, such as by mycophenolate mofetil (MMF), can lower BP in subjects with primary hypertension.[16]

How Does Sodium Retention Lead to Hypertension?

Although the classical view has been that salt loading causes acute volume expansion followed by vasoconstriction and pressure-induced sodium excretion (pressure-natriuresis), in recent years the role of transient hypertonicity as driving the hypertensive response has become dominant (Fig. 35.5).

For example, an acute salt load increases blood pressure immediately through its effects to raise sodium concentration and vasopressin levels.[23] Hypertonicity also stimulates SNS activity in the brain that has systemic and kidney hemodynamic effects that increase BP and sodium retention. Hypertonicity also activates the immune response, stimulating dendritic cell activation, the production of interleukin-17 (IL-17) from T helper cells, cytokine release from T and B cells, and inducing immune cell infiltration in the kidney.[24,25] Overproduction of IL-17, in addition to its effects on autoimmunity, also stimulates the

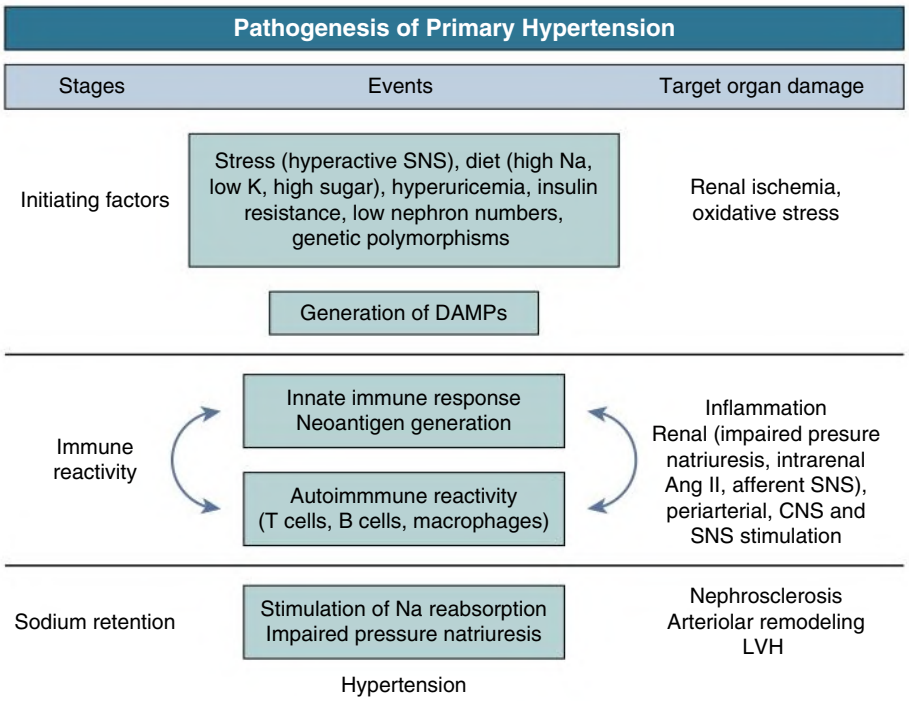

Fig. 35.4 Pathogenesis of Primary Hypertension. Initiating factors induce renal ischemia and oxidative stress with the stimulation of innate immune reactivity, neoantigen formation, and autoimmune reactivity that drives inflammation in the kidney, in the adventitia in the arteries, and in the central nervous system that stimulates the sympathetic nervous system. Sodium retention results from increased reabsorption and impaired pressure natriuresis as a consequence of renal inflammation. Established hypertension drives target organ damage. *Ang II,* angiotensin II; *CNS,* central nervous system; *DAMP,* damage-associated molecular patterns; *LVH,* left ventricular hypertrophy; *SNS,* sympathetic nervous system.

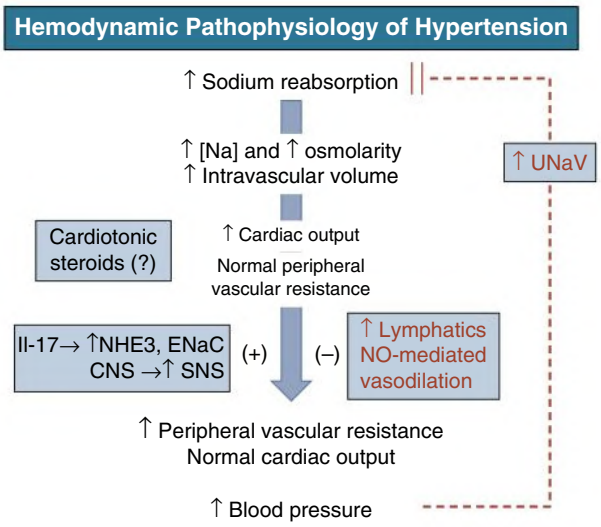

Fig. 35.5 Hemodynamic Pathophysiology of Hypertension. Sodium retention induces increase in sodium concentration, hyperosmolarity, and rise in intravascular volume with an increase in cardiac output, possibly driven in part by the generation of cardiotonic steroids. This transient state is followed by sustained increment in peripheral vascular resistance and normalization of the cardiac output. These events result from the combined effects of immune (IL-17) stimulated increase in sodium reabsorption and stimulation of the sympathetic nervous system (SNS). These effects are counterbalanced by vascular endothelial growth factor type C–mediated increase in the lymphatic network and endothelial nitric oxide (NO) generation induced by intravascular dilation (see text). The increase in blood pressure tends to correct sodium retention by stimulating pressure natriuresis. *CNS,* Central nervous system; *ENaC,* endothelial sodium channel; *NHE3,* sodium-hydrogen exchanger 3; *UNaV,* urinary sodium excretion.

sodium-hydrogen exchanger 3 (NHE3) in the proximal tubule and in the sodium chloride cotransporter (NCC) and epithelial sodium channel (ENaC) in the distal and collecting ducts, respectively, favoring sodium retention.[26]

The hypertonicity and sodium retention also stimulates the release of cardiotonic steroids from the adrenal glands, such as ouabain and marinobufagenin, that partially block Na^+,K^+-ATPases, thereby stimulating natriuresis by downregulating kidney sodium transporters. However, they do this at the expense of raising blood pressure by increasing vasoconstriction and myocardial contractility by increasing cytosolic Ca^{2+} in vascular smooth muscle cells and cardiomyocytes.[27]

There are also countering mechanisms that block the hypertensive response. Sodium retention activates the tonicity enhancer binding protein (TONEBP) in macrophages that produce vascular endothelial growth factor type C that stimulates the development of a lymphatic network that attenuates the hemodynamic effects of sodium retention.[28] Sodium retention may not be sequestered in an osmotically independent compartment[29] as originally considered[28]; nevertheless, the role of macrophages is well demonstrated because macrophage depletion accentuates hypertension. Another mechanism that counters the salt-induced increase in blood pressure is the endothelial production of nitric oxide stimulated by intravascular volume expansion.[30]

Pathogenic Mechanisms Driving the Current Epidemic of Hypertension

The rise of hypertension in the last century is largely thought to be the consequence of the rise in obesity, and also the increase in life span that occurred during that time. Although obesity-associated hypertension likely involves all three mechanisms previously discussed, it may also result from other related mechanisms, including diet (salt and sugar), subtle kidney injury, coexistence of endothelial

Fig. 35.6 Grades of Hypertensive Retinopathy. (A) Mild hypertensive retinopathy with arteriolar narrowing and arteriovenous nicking. Kinyoun, University of Washington.)

dysfunction and oxidative stress, activation of the SNS and intrarenal renin-angiotensin-aldosterone system (RAAS), and effects of hyperleptinemia and hyperinsulinemia.[31,32] Chronically elevated leptin levels, which are common in obese persons, can activate the SNS in the central nervous system (CNS) through proopiomelanocortin neurons that activate melanocortin-4 receptors.[32]

Other proposed mechanisms include hyperuricemia, possibly driven by intake of fructose-containing sugars and purine-rich foods.[17] Studies also have implicated a hyperactive SNS in early hypertension, particularly in young or borderline hypertensive patients.[33] Postulated mechanisms include a defect in baroreceptor sensitivity and an increase in SNS response to emotional or work-related stress. Activation of either the systemic or the local renin-angiotensin system (RAS) is also common in hypertension. Whereas plasma renin activity is elevated in 20% of patients, renin activity is either normal (50%) or low (30%) in the majority. However, normal renin activity may be inappropriately high in relation to the total body sodium.[34] Some hypertensive patients also have elevated plasma aldosterone, especially if the RAS is inhibited with angiotensin-converting enzyme (ACE) inhibitors or angiotensin receptor blockers (ARBs).[35] This condition is known as *aldosterone breakthrough* and is often observed in persons who are obese or have hyperinsulinemia.

CLINICAL MANIFESTATIONS

Evaluation of a patient with hypertension requires careful history and physical examination, an evaluation of risk factors for hypertension, a search for potential secondary causes, and evaluation for end organ damage.

Blood pressure should be measured on at least three occasions to confirm persistent hypertension using the techniques described in Chapter 34. Home BP monitoring or 24-hour ambulatory BP monitoring is recommended to determine whether the hypertension is white coat hypertension or masked hypertension. White coat and masked hypertension can be associated with end organ disease, including left ventricular hypertrophy (LVH) and mildly increased albuminuria; diagnosis should be followed by assessment of CV risk factors and frequent reevaluation of BP.

The history should investigate the onset and duration of hypertension and the presence of a family history of hypertension or cardiokidney disease. The history should identify risk factors for hypertension (obesity, diabetes, physical activity, gout, alcohol, smoking, diet, emotional or work-related stress) and any hypertension-related morbidity as well as consumption of over-the-counter and prescribed medications that may increase BP.

Hypertension is often asymptomatic, but even childhood-associated hypertension can be associated with impaired memory and mental performance, and hypertension remains a major risk factor for vascular dementia. Hypertension, especially when severe (BP >160/100 mm Hg), also may be associated with headache, classically occipital and pulsatile. In hypertensive emergency, encephalopathy rarely occurs, sometimes with altered mental status and seizures. Rarely, patients may lose vision from papilledema. Hypertension, especially over 160/100 mm Hg, also places individuals at acute risk for myocardial infarction (MI), congestive heart failure (CHF) with pulmonary edema, aortic dissection, cerebrovascular accident (stroke), and kidney failure.

Physical examination includes BP measurement in both arms and cardiac examination. Attention should be focused on both the large vessels (by both palpation and listening for bruits) and the retina to evaluate the microvasculature (Fig. 35.6). Lab tests should include hematocrit, electrolytes, creatinine (and estimated GFR), calcium and phosphate (to look for primary hyperparathyroidism), fasting lipid profile (cholesterol and triglycerides), uric acid, and urinalysis. A chest radiograph and electrocardiogram should be performed to assess cardiac size and look for aortic dilation.

Additional tests include 24-hour urine sodium and potassium excretion. Urinary Na^+ and K^+ excretion correlates with intake if the patient is in steady state (desirable values are <100 mmol/L Na^+ and >100 mmol/L K^+ in 24 hours). A spot urine albumin-creatinine and an echocardiogram may uncover additional evidence of end organ damage, especially in diabetic patients and those with cardiac problems, respectively (Fig. 35.7).

PATHOLOGY

Primary hypertension is characterized by arteriolosclerosis of the preglomerular afferent arteriole and interlobular artery. Arteriolosclerosis, seen in 90% of patients, involves the replacement of smooth muscle cells of the media in the afferent arteriole with connective tissue, often with hyaline material (plasma proteins) in the subintima (hyalinosis)[18] (Fig. 35.8). Glomerular and tubular ischemia are common, with shrinkage of the glomerular tuft, tubular atrophy, and interstitial fibrosis. Occasionally, glomerulosclerosis and severe tubulointerstitial injury are seen. With hypertensive emergency, a proliferative arteriolopathy occurs, occasionally with fibrinoid necrosis. Concentric layers of connective tissue and cells may give an onion-skin appearance to

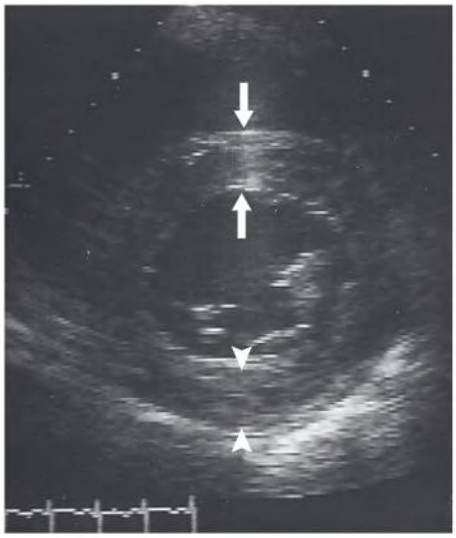

Fig. 35.7 Echocardiogram Showing Concentric Left Ventricular Hypertrophy. Septal thickness *(between arrows)* and posterior wall thickness *(between arrowheads)* are increased (to 16 mm) in a patient with primary hypertension (normal is ≤11 mm). (Courtesy A. Pearlman, University of Washington.)

the intima, which may progress to a total obliteration of the lumen. In addition to vascular changes, immune cell infiltration in tubulointerstitial regions is present even at stages when the vascular changes are minimal or nonexistent.[18,36]

DIAGNOSIS

Diagnosis of primary hypertension requires the elimination of secondary causes. Suspicion of secondary causes of hypertension should be raised by finding new onset hypertension in very young or elderly patients (renovascular hypertension), drug-resistant hypertension, hypokalemia in the absence of being on diuretic therapy (primary aldosteronism from hyperplasia or tumors), or with impaired kidney function (kidney parenchymal disease). Medications that increase BP include nonsteroidal antiinflammatory drugs, corticosteroids, sympathomimetics, and oral contraceptives, as well as excessive alcohol intake and cocaine use. Table 34.9 in Chapter 34 provides a list of secondary causes along with recommended evaluations.

NATURAL HISTORY

Although hypertension is often asymptomatic (referred to as the "silent killer"), it represents a major risk factor for CV mortality, especially related to pressure-related morbidities such as heart failure (HF), stroke, aortic aneurysms and dissection, chronic kidney disease (CKD), and vascular dementia. Hypertension is also a risk factor for coronary artery disease, although the association is less strong.

Increased Risk for Cardiovascular Disease

Hypertension is the most common cause of both stroke and HF associated with preserved ejection fraction (Fig. 35.9).[37] In essence, hypertension causes concentric LVH with supernormal systolic function. However, subendocardial inflammation and fibrosis also occur, resulting in a stiffer myocardium and impairing diastolic filling and eventually causing heart failure. Almost 80% to 90% of patients with heart failure have a history of hypertension.[38]

Hypertension can also cause vascular changes that can lead to aortic dissection, cerebral and aortic aneurysms, and stiffening of blood vessels from changes in collagen content that can result in higher pulse pressures.[39,40] Both elevated systolic BP and elevated pulse pressure confer increased risks for stroke, but high pulse pressure is additionally complicated as it may limit the magnitude with which systolic BP can be lowered.[41] Studies in people with diabetes suggested that diastolic BP should not be lowered below 60 mm Hg as CV risk will start to increase.[42] A post hoc analysis of the ONTARGET and TRANSCEND trials support the notion that DBP less than 70 mm Hg or greater than 80 mm Hg is associated with a higher risk in patients with an SBP of 120 to 140 mm Hg. These findings support European guidelines, which take DBP at optimal SBP control into consideration.[1]

Hypertension also increases the risk of coronary heart disease (Fig. 35.9), peripheral vascular disease, and carotid atherosclerosis with or without cerebral emboli. Hypertension is also associated with increased risk for vascular dementia.

Increased Risk for Chronic Kidney Disease

Most patients with newly diagnosed primary hypertension have normal kidney function, stage 1 CKD (GFR ≥ 90 mL/min/1.73 m^2), or stage 2 CKD (GFR 60–90 mL/min/1.73 m^2) with or without mildly increased albuminuria (formerly termed microalbuminuria). Despite relatively preserved kidney function, kidney biopsy, if done, usually shows early arteriolosclerosis, hyalinosis, and interstitial inflammation (see Fig. 35.8).

Mildly increased albuminuria, which is a marker of vascular disease and CV risk, occurs in 15% to 30% of patients, whereas more severe albuminuria is uncommon and nephrotic-range proteinuria rare.[43] Elevations in serum creatinine over time develop in 10% to 20% of patients with poorly controlled BP, and the risk is greater in diabetic patients, African Americans, the elderly, patients with gout or hyperuricemia, and those with higher SBP (>160 mm Hg).[44] In 2% to 5% of those with poorly controlled SBP (>160 mm Hg), progression to kidney failure will occur over 10 to 15 years (Figs. 35.10 and 35.11).[45,46] Despite the relative infrequency for primary hypertension to progress to kidney failure, hypertension is recorded as the second most common cause of treated kidney failure after diabetes in the United States and Europe.[47] Furthermore, almost all patients with diabetes have hypertension when they start dialysis.

The incidence of kidney failure in African Americans with hypertension is twofold to sixfold greater than in Whites (Fig. 35.11).[46,47] Kidney biopsies of African Americans with hypertension show more severe hypertensive injury, with more prominent vascular changes and increased frequency of segmental and global glomerulosclerosis. The increased frequency of glomerulosclerosis may be caused in part by a polymorphism in apolipoprotein L1 (APOL1), the product of which is expressed in the podocyte.[48] The mechanism by which *APOL1* polymorphisms increase the risk for progression of kidney disease is unclear but may relate to effects on the podocyte that include lysosomal swelling, mitochondrial dysfunction, and blockade of autophagy.[49,49a]

Although hypertension is a risk factor for CKD, as CKD progresses the prevalence and severity of hypertension also increases and requires more medications to achieve control.[50] Multiple mechanisms likely account for this, including sodium retention, increased afferent sympathetic tone induced by kidney inflammation,[51] activation of the intrarenal RAS,[52] endothelial dysfunction,[53] and the frequent occurrence of sleep apnea. These effects are associated with loss of nocturnal BP dipping, and BP may even increase at night, which is associated with an increase in CV complications and progression of CKD.[54]

Effects of Antihypertensive Therapy on Cardiovascular Disease and Kidney Outcomes

Effect of BP Control on Cardiovascular Mortality

Blood pressure control has been consistently shown to reduce CV outcomes (especially stroke and heart failure) and vascular dementia (Table 35.3).[55,56] The Systolic Blood Pressure Intervention Trial (SPRINT) found that lowering SBP to 120 to 130 mm Hg provided greater CV protection in nondiabetic subjects than a target BP of 140 mm Hg.[57] However, intensive BP lowering treatment carried a higher risk of hypotension, syncope, and acute hemodynamically associated kidney injury, which resolved within a month in almost 90% of the cases without change in BP goal.[58] However, the SPRINT study showed that the benefits of lowering BP outweigh the associated risks. In contrast, a similar study, known as the Action to Control Cardiovascular Risk in Diabetes Blood Pressure (ACCORD), did not demonstrate overall CV protection in diabetics in which SBP was targeted to 120 mm Hg compared with 140 mm Hg.[14] Nevertheless, recent analyses suggest a CV risk reduction, with more intensive BP treatment with achieved BP closer to 125 mm Hg.[59,60]

Although lowering BP protects against progression of CKD, the target BP has been controversial. Intensive BP control in the SPRINT trial did not provide any additional protection for CKD progression, but the SPRINT trial did not enroll patients with more than 1 g proteinuria per day. However, the Modification of Diet in Renal Disease (MDRD) and the African American Study of Kidney Disease (AASKD) studies did enroll patients with significant albuminuria and found less kidney disease progression in this subgroup with intensive BP lowering.[61,62] Despite the lack of benefit on kidney disease in patients without severe albuminuria (<300 mg/day), the benefit on CV protection suggests that lower BP targets should be sought in these patients. These findings have led to the general recommendation of a target BP of 130/80 mm Hg for all patients, including the elderly, those with diabetes, and those with CKD by the American College of Cardiology, the European Guidelines,[1] and by the American Diabetes Association.[63]

A discussion of pharmacologic management of hypertension is provided in Chapter 37. Blood pressure control in patients with high CV risk and/or CKD usually requires at least two medications, of which one should be a RAAS blocker at maximally tolerated doses. In the AASKD study, use of an ACE inhibitor (ramipril) was more effective at slowing CKD progression than either amlodipine (Fig. 35.12) or metoprolol.[64] Similar results were seen in the Irbesartan Diabetic Nephropathy Trial (IDNT) trial, where irbesartan was superior to amlodipine in slowing diabetic nephropathy progression.[65] Furthermore, in the high-risk hypertensive population, there is also evidence from the ACCOMPLISH trial that better CV protection can be provided if the ACE inhibitor is combined with a calcium channel blocker rather than a thiazide diuretic.[66]

In people with CKD and hypertension, a diuretic is often required. Nevertheless, diuretics should be used only as needed. Some studies

Ramipril Is Superior to Amlodipine in Reducing Renal Events in Hypertensive African Americans with Renal Impairment

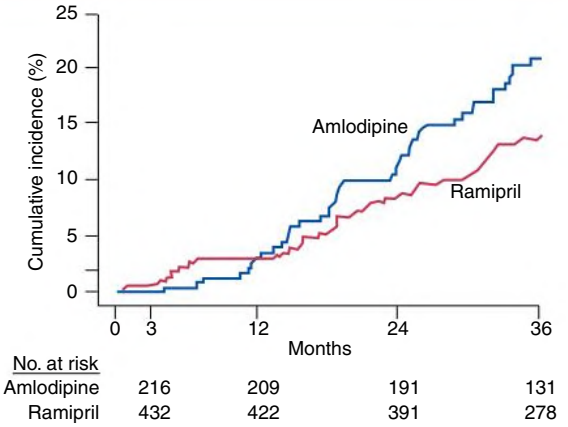

Fig. 35.12 Ramipril is Superior to Amlodipine in Reducing Kidney Events in Hypertensive African Americans With Mild to Moderate Kidney Impairment. The angiotensin-converting enzyme inhibitor ramipril resulted in fewer kidney end points (proteinuria, decline in kidney function, treated kidney failure, death) compared with the dihydropyridine calcium channel blocker amlodipine, in the African American Study of Kidney Disease. (From Agodoa LY, Appel L, Bakris GL, et al. Effect of ramipril vs amlodipine on renal outcomes in hypertensive nephrosclerosis: a randomized controlled trial. *JAMA.* 2001;285[21]:2719–2728.)

suggest that thiazide and thiazide-like diuretics are associated with worsening of kidney function in patients with hypertension. In the European Working Party on High Blood Pressure in the Elderly trial[67] and in the Systolic Hypertension in the Elderly trial,[68] serum creatinine increased significantly in patients treated with thiazide diuretics compared with placebo. Similarly, in the Antihypertensive and Lipid-Lowering Treatment to Prevent Heart Attack Trial (ALLHAT), the chlorthalidone-treated group showed statistically worse kidney function than either the amlodipine or the lisinopril group at both 2- and 4-year end points despite its better reduction of strokes and heart failure.[69] This could likely be accounted for by volume depletion in many cases, but diuretics have been shown to induce mild kidney injury in various animal models, possibly because of hypokalemia, hyperuricemia, and stimulation of the RAAS.[70]

Acute BP lowering with any medication may cause a rise in serum creatinine of up to 30% in the first month of therapy, and treatment should be continued if there are no electrolyte abnormalities or hypotension.[71,72] In numerous trials including SPRINT and ACCORD, kidney disease progression is slowed and CV risk (especially from heart failure) markedly reduced. Furthermore, RAAS blockade should not be stopped due to small, limited increases in creatinine, as a retrospective analysis found that the discontinuation of ACE inhibitor or ARB therapy for acute decreases in eGFR (<30 mL/min/1.73 m^2) was not associated with increased risk of kidney failure but carried a 39% higher risk of mortality and 37% increase in major adverse CV events (MACE).[73]

SELF-ASSESSMENT QUESTIONS

1. Primary hypertension is characterized by all of the following *except:*
   - **A.** Primary hypertension is more common in older patients.
   - **B.** Salt sensitivity is less common in older patients.
   - **C.** Primary hypertension is associated with a reduction in kidney blood flow and usually mild reduction in GFR.
   - **D.** Primary hypertension is more common in individuals with low birthweight and low nephron number.
   - **E.** The presence of the *APOL1* polymorphism is associated with more rapid progression of kidney disease in African Americans with hypertension.
2. The kidney pathology in patients with primary hypertension may consist of all of the following *except:*
   - **A.** arteriolosclerosis with arteriolar fibrosis or hyalinosis.
   - **B.** evidence of tubular ischemia change is commonly present.
   - **C.** glomerulosclerosis may be present, especially in African Americans.
   - **D.** kidney histologic studies can rarely appear normal.
   - **E.** transmural necrosis of medium-sized vessels can occasionally be observed.
3. Which of the following is *not* a dietary risk factor for primary hypertension?
   - **A.** Sodium
   - **B.** Potassium
   - **C.** Sugar
   - **D.** Alcohol
   - **E.** Coffee

Nonpharmacologic Prevention and Treatment of Hypertension

Brian Rayner, Karen E. Charlton, Wayne Derman, Erika Jones

Diets that include increased fat and refined carbohydrate intake combined with reduced physical activity have resulted in a pandemic of obesity, type 2 diabetes mellitus, and hypertension that is most pronounced in underserved and indigenous populations. Adoption of healthy lifestyles is critical in preventing and managing high blood pressure (BP). According to the American College of Cardiology/American Heart Association (ACC/AHA)[1] and International Society of Hypertension (ISH) Global Practice Guidelines, lifestyle interventions lower BP,[2] enhance efficacy of antihypertensive medication, and reduce overall cardiovascular (CV) risk.[3] The lifestyle changes that are widely agreed to lower BP and CV risk are smoking cessation, weight reduction, moderation of alcohol intake, increased physical exercise, reduced salt intake, increased fruit and vegetable intake, and decreased total fat, trans fat, and sugar intake (Table 36.1). These interventions may lower BP to a similar extent compared with single-drug therapy. However, lifestyle changes should not delay the initiation of drug therapy in patients at higher CV risk.

PREVENTION

The importance of primary prevention has been underscored by the recognition that hypertension is common, treatment is lifelong, the control of BP in hypertensive individuals does not restore CV risk to normal, and the majority of hypertensive individuals do not reach goal BP readings. The most important individuals to target are those with elevated BP (120–129/80–89 mm Hg)[4] or high BP (>130/90 mm Hg) as defined by the ACC/AHA guidelines.[1] Those with elevated BP have increased prevalence of early vascular damage, increased risk for incident hypertension, and increased risk for CV events compared with those who have optimal BP levels (<120/80 mm Hg).[5] The World Health Organization (WHO) Global Non-Communicable Disease (NCD) Alliance Action Plan advocates the following voluntary global targets for country member states: 10% reduction in harmful use of alcohol, 10% reduction in sedentary lifestyle, 30% reduction in mean population intake of salt, and 30% reduction in current tobacco use. Up to 80% of cardiovascular disease (CVD) can be prevented through lifestyle measures that include maintenance of healthy weight, adequate physical activity, a healthy diet, and avoidance of tobacco.[6] These targets align with the *Lancet*'s Commission on Hypertension (2016) that identifies key actions to prevent elevated BP at both the population and individual level.[7] A life-course approach is recommended, which focuses on early lifetime programming. Exposure to CV risk factors in early childhood has been shown to promote adverse vascular damage in early adulthood and increase the trajectory of vascular aging.[8]

WEIGHT LOSS

Obesity is epidemic throughout the world; for example, 65% of the adult population in the United States is either overweight, with a body mass index (BMI) of 25.0 to 29.9 kg/m^2, or obese, with a BMI at or above 30 kg/m^2. Obese individuals have a threefold increase in the prevalence of hypertension. Possible mechanisms for obesity-induced hypertension include overactivity of the sympathetic nervous system (SNS), hyperinsulinemia (which may increase renal sodium reabsorption), increased leptin, hyperuricemia, activation of the renin-angiotensin system, and sleep apnea. Visceral obesity is a greater predictor of both hypertension and CV risk than other types of body fat distribution. *Visceral obesity* is defined by waist circumference greater than 88 cm (>35 in) in women and greater than 102 cm (>40 in) in men. These reference values were developed in White populations and may need to be modified for other ethnic groups.

In obese hypertensive patients or those with elevated BP, weight loss of as little as 4 to 5 kg (9–11 lb) is often associated with a significant reduction in BP. A meta-analysis has demonstrated that a weight reduction of 5.1 kg reduced systolic BP (SBP) by 4.4 mm Hg and diastolic BP (DBP) by 3.6 mm Hg.[9] A rule of thumb is that for every kilogram lost, there is a reduction of 1 mm Hg in SBP and DBP. To minimize the risk for relapse and maintain sustainability of the weight loss program, the initial target should be 5% to 10% of current weight, or 1 to 2 BMI units. Marked oscillations in weight (weight cycling or yo-yo dieting) should be avoided because this increases the risk for development of hypertension in obese, normotensive persons.[10] A randomized trial of the effectiveness of four popular diets on sustained weight loss and CV disease risk reduction concluded that a variety of diets can similarly reduce weight and BP, but only a minority of individuals can maintain high dietary adherence for prolonged periods.[11]

Very-low-carbohydrate diets, such as the Atkins diet and others with a carbohydrate content below 20% of energy, are not recommended because they result in a greater increase in low-density lipoprotein cholesterol, despite resulting in a greater weight loss over the short term, compared with a traditional low-fat diet.[12] The pan-European Diet, Obesity and Genes (DiOGenes) study found that BP reduction after weight loss is better maintained when the intake of protein is increased at the expense of carbohydrates, to around 23% to 28% energy from protein, compared with usual lower protein intakes of between 10% and 15% energy.[13]

Weight reduction should be accompanied by recommendations to increase physical activity unless it is contraindicated. Bariatric surgery and pharmacologic interventions for weight loss may be useful to achieve weight loss in some patients, but always as an adjunct rather than a substitute for lifestyle modification.

TABLE 36.1 Lifestyle Modifications for Prevention and Management of Hypertension

COR	LOE	Recommendations for Nonpharmacologic Intervention
1	A	Weight loss is recommended to reduce BP in adults with elevated BP or hypertension who are overweight or obese
1	A	A heart-healthy diet, such as the DASH diet, that facilitates achieving a desirable weight is recommended for adults with elevated BP or hypertension
1	A	Sodium reduction is recommended for adults with elevated BP or hypertension
1	A	Potassium supplementation, preferably in dietary modification, is recommended for adults with elevated BP or hypertension unless contraindicated by the presence of CKD or use of drugs that reduce potassium excretion
1	A	Increased physical activity with a structured exercise program is recommended for adults with elevated BP or hypertension
1	A	Adult men and women with elevated BP or hypertension who currently consume alcohol should be advised to drink no more than two and one standard drinks[a] per day, respectively
1	A	Complete cessation of smoking

[a]In the United States, one standard drink contains roughly 14 g of pure alcohol, which is typically found in 360 mL (12 fl oz) of regular beer (usually about 5% alcohol), 150 mL (5 fl oz) of wine (usually about 12% alcohol), and 45 mL (1.5 fl oz) of distilled spirits (usually about 40% alcohol).

PHYSICAL ACTIVITY AND EXERCISE TRAINING

Physical and Sedentary Activity and Risk Mitigation for Hypertension

Physical inactivity may account for 5% to 13% of the risk for developing hypertension.[14] In addition, physical inactivity accounts for 5.5% to 25.1% of the population attributable risk for coronary heart disease. Regular physical activity and reduced sedentary activity lowers all-cause morbidity and mortality and provides the basis for public health recommendations. The 2020 WHO guidelines suggest that all adults should undertake, per week, 150 to 300 minutes of moderate-intensity, or 75 to 150 minutes of vigorous-intensity physical activity, or some equivalent combination of moderate-intensity and vigorous-intensity aerobic physical activity. The guidelines recommend regular muscle-strengthening activity for all age groups. Additionally, reducing sedentary behaviors is recommended across all age groups and has an important preventive effect with respect to hypertension and gestational hypertension.[15]

A recent review reported that patients with high BP who participated in any level of physical activity had a lower risk (by 16%–67%) of CV mortality, whereas a greater than twofold increase in CV mortality risk was observed in sedentary individuals.[16]

Effects of Exercise Training in Reduction of Blood Pressure in Normotensive and Hypertensive Individuals

In a meta-analysis of studies involving more than 1500 patients, exercise training in normotensive individuals has been shown to reduce SBP and DBP by 3.0 ± 1 and 1.7 ± 1 mm Hg, respectively.[17] However, in hypertensive patients, the effect of exercise training is even more marked. In a meta-analysis involving 27 randomized controlled trials (RCTs) and 1480 patients, aerobic activity was shown to reduce BP on average by 10.8 ± 4.7 mm Hg in hypertensive patients.[18]

Historically, it was accepted that only aerobic (dynamic) exercise was effective in lowering BP in hypertensive individuals. Other forms of exercise training, including resistance exercise, isometric resistance training, and high-intensity interval training (HIIT), are also considered safe, and they are recommended as effective exercise modalities.[1,19] However, there is no consensus whether HIIT exercise is superior to low-intensity continuous aerobic training for lowering BP.[20,21] There also appears to be benefit from a wide range of different exercise modalities, including tai chi[22] (which lowered BP by 6.58/0.57 mm Hg in a meta-analysis), qigong,[23] strength training,[24] and yoga.[25] Regular exercise also prevents the development of left ventricular hypertrophy that is independent of BP in young patients with stage 1 hypertension.[26]

Some studies indicate that mild to moderate exercise intensity (40%–70% of maximal age-predicted heart rate) is effective for lowering BP with little additional benefit associated with further increases in intensity.[17] However, exercise of higher intensity (75% maximum) is associated with a more marked and prolonged reduction in postexercise BP compared with lower-intensity exercise (50% maximum).[27] Other studies have indicated that HIIT also effectively reduces BP in hypertensive individuals. Thus, limitations in the literature remain regarding the effects of different intensity and duration of exercise on BP. Available studies are hampered by varying methodological quality, selective reporting of BP outcomes, and few participants with diagnosed hypertension.[28]

Monitoring of Blood Pressure During Exercise

A standardized approach to monitoring BP before and during exercise should be considered for hypertensive patients. If resting BP is poorly controlled, exercise training should be postponed (SBP >180 mm Hg or DBP> 110 mm Hg) until control is improved. Furthermore, if SBP rises to more than 250 mm Hg and/or DBP to more than 115 mm Hg during exercise, the training session should be terminated.[29]

Mechanisms of Blood Pressure–Lowering Effects of Exercise

The mechanism(s) involved with reducing BP in hypertensive individuals are multiple and complex. The reduction in BP immediately after exercise has been linked to a sympathetic inhibition and increased release of vasodilator substances. The mechanisms by which exercise lowers BP over the longer term are less well understood, but possibilities include reductions in systemic vascular resistance secondary to neurohumoral and structural adaptations. It has further been suggested that physical inactivity negatively affects brain areas associated with sympathetic outflow. SNS overdrive is thought to account for more than 50% of all cases of hypertension, and a lack of balance between parasympathetic and sympathetic modulation has been observed in hypertensive subjects.[30] In a recent meta-analysis of 14 trials, exercise improved the arterial stiffness that is associated with hypertension, particularly aerobic exercise, isometric exercise (static muscle contraction), and a

BOX 36.1 Practical Guidelines for Exercise in Patients With Hypertension

All apparently healthy individuals should undergo preexercise screening to determine health risk status. The American College of Sports Medicine (ACSM) recognizes that two or more of the following risk factors increase the risk associated with exercise, and individuals should undergo preexercise graded exercise testing. Risk factors include male sex (>45 years) or female sex (>55 years), serum cholesterol concentrations greater than 5.2 mmol/L, impaired glucose tolerance or diabetes mellitus, smoking, obesity (BMI ≥30), inactivity, and family history of cardiovascular disease.

Patients with uncontrolled hypertension should embark on exercise training only after evaluation and initiation of therapy. Furthermore, patients should not participate in an exercise training session if resting systolic blood pressure is above 200 mm Hg or diastolic blood pressure is above 115 mm Hg.

Many patients with hypertension are overweight and should therefore be encouraged to follow a program that combines both exercise training and restricted calorie intake.

- *Type* of exercise: this should be predominantly endurance physical activity, including walking, jogging, cycling, swimming, or dancing. This should be supplemented by resistance exercise that can be prescribed according to the ACSM or American Heart Association guidelines.
- *Frequency* of exercise: most or preferably every day, but at least 5 days a week.
- *Intensity* of exercise: moderate intensity at 40% to 60% of maximal oxygen consumption ($\dot{V}O_2$ peak).
- *Duration* of exercise: more than 30 minutes of continuous or accumulated moderate physical activity daily.

Modified from Pescatello LS, MacDonald HV, Ash GI, et al., eds. Assessing the existing professional exercise recommendations for hypertension: a review and recommendations for future research priorities. Mayo Clinic Proceedings. Elsevier; 2015; and Leosco D, Parisi V, Femminella GD, et al. Effects of exercise training on cardiovascular adrenergic system. *Front Physiol.* 2013;4:348.

combination of the two.[31] Long-term exercise training is also associated with weight loss and a reduction of serum uric acid levels, both of which could reduce BP.

Antihypertensive Medication and Guidelines for Exercise

Box 36.1 provides exercise guidelines for patients with hypertension.[32] β-Blockers decrease exercise tolerance. β-Blockers and diuretics also may alter thermoregulation in hot environments and provoke hypoglycemia. Patients using these medications should be educated about exercising in the heat, proper clothing, adequate hydration, and methods to prevent hypoglycemia.[33] However, β-blockers are not the first-line treatment for physically active hypertensive patients. Angiotensin-converting enzyme (ACE) inhibitors, angiotensin receptor blockers, and calcium channel blockers may be better suited for patients who exercise frequently or athletes with hypertension.

For patients undergoing supervised exercise training, the monitoring of postexercise BP may be helpful, so medications may be adjusted to avoid postexercise hypotension, especially with calcium channel blockers or in patients exercising in a hot environment.

DIET

Salt Intake

The prevalence of hypertension is directly related to dietary salt intake in all societies in which Na intake exceeds 50 to 100 mmol/day (3–6 g salt or NaCl) (Fig. 36.1).[34] In societies in which daily intake is below that range, hypertension is rare. Salt intake also plays an important role in age-related increase in BP (Fig. 36.2).[35] However, not all individuals respond similarly to a high salt intake. "Salt sensitivity" describes a group of individuals who significantly decrease or increase their BP during periods of salt restriction or salt loading, respectively. Those at greatest risk of salt sensitivity include Black ethnicity, older age, obese, type 1 or 2 diabetes, treatment with calcineurin inhibitors, and chronic kidney disease (CKD).

Putative mechanisms for salt sensitivity are alterations in circulating levels of (or renal responses to) atrial natriuretic factor,

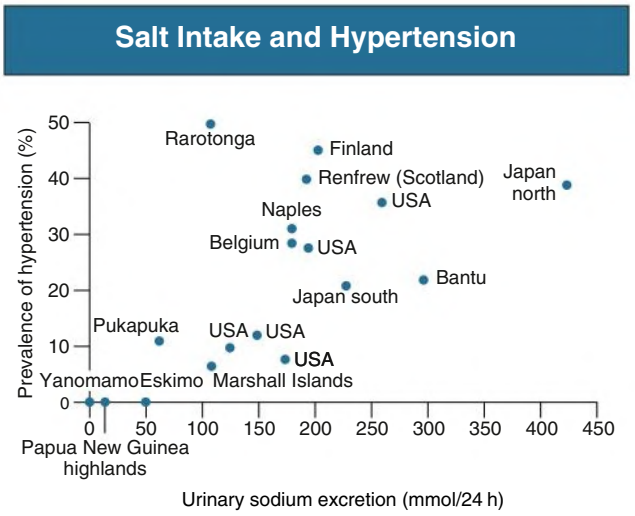

Fig. 36.1 Relationship of Salt Intake to Prevalence of Hypertension in Different Populations. (Modified from MacGregor GA. Sodium is more important than calcium in essential hypertension. *Hypertension.* 1985;7[4]:628–640.)

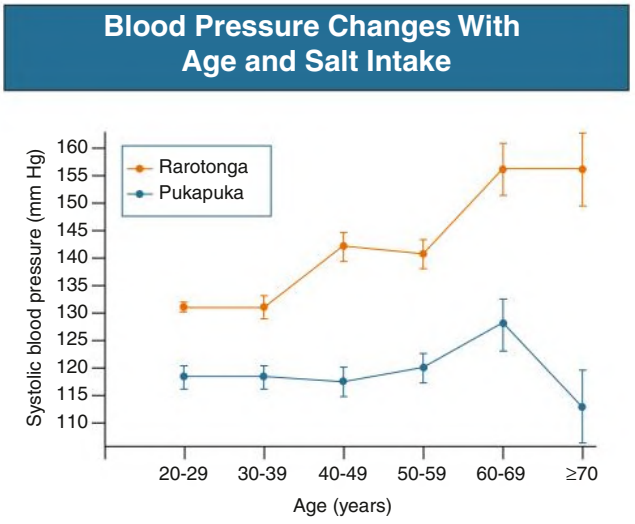

Fig. 36.2 Blood Pressure Changes With Age and Salt Intake. The increase in systolic blood pressure (SBP) with age correlates with a higher salt intake in two Polynesian populations. In men of Rarotonga Island, where the sodium intake averages 130 mmol/day, SBP increases with age. In contrast, it remains constant in men of Pukapuka Island, where the sodium intake averages 50 to 70 mmol/day. (Modified from Prior I, Evans JG, Harvey H, Davidson F, Lindsey M. Sodium intake and blood pressure in two Polynesian populations. *N Engl J Med.* 1968;279[10]:515–520.)

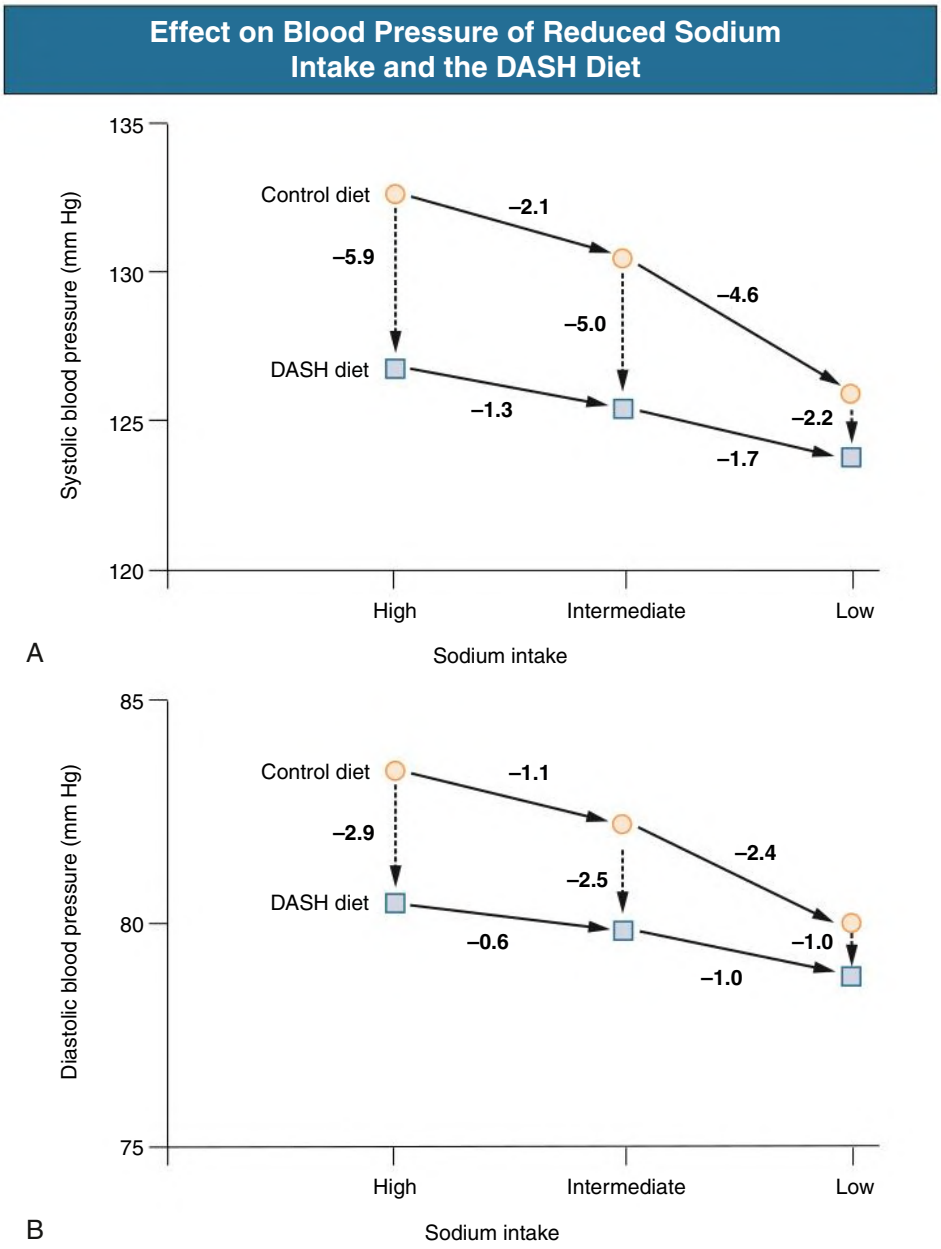

Fig. 36.3 Reduced Sodium Intake and Dietary Approaches to Stop Hypertension (DASH) Diet. Effect on systolic blood pressure (A) and diastolic blood pressure (B). (B, Modified from Sacks FM, Svetkey LP, Vollmer WM, et al. Effects on blood pressure of reduced dietary sodium and the Dietary Approaches to Stop Hypertension (DASH) diet. *N Engl J Med.* 2001;344[1]:3–10.)

kallikrein, prostaglandins, and nitric oxide (NO); increased levels of norepinephrine; abnormal suppression of both renin and aldosterone; genetic mechanisms; congenital reduction in nephron number; and acquired renal microvascular and tubular injury. More recent studies show that sodium-dependent serum osmolarity may have a higher correlation with BP[36] and the progression to hypertension.[37]

In a Cochrane systematic review of 34 trials, the effect of modest salt reduction on BP was studied. The pooled mean change in urinary sodium (Na) was −75 mmol/24 h (equivalent to reduction of 4.4 g of salt) resulting in a mean reduction in SBP of −4.18 mm Hg and DBP of −2.06 mm Hg, respectively. Meta-regression analysis showed that older age, Black ethnicity, hypertensive status, and overall change in 24-hour urinary Na were associated with a greater fall in BP.[38]

In the Dietary Approaches to Stop Hypertension (DASH) sodium trial, the additional benefits of salt restriction over and above the DASH diet were investigated (Fig. 36.3).[39] Reduction of sodium intake from high intake (150 mmol/day, or 9 g salt) to either intermediate (100 mmol/day, or 6 g salt) or low (65 mmol/day, or 4 g salt) intake resulted in a stepwise reduction in BP, which was approximately twice as great in the control group than those following the DASH diet (see Fig. 36.3). In those following the DASH diet, the addition of salt restriction resulted in a relatively small additional decrease in BP (3.0 and 1.6 mm Hg for SBP and DBP, respectively). Thus, the greatest benefits of salt restriction are seen in those with the typical Westernized high-fat, low-nutrient diet.

Most hypertension guidelines and the WHO now recommend a reduction of salt intake to less than 5 g salt (90 mmol Na) per day.

The US Department of Agriculture and US Department of Health and Human Services Joint Dietary Guidelines for Americans call for stricter reduction in salt intake to no more than 65 mmol/day, or 4 g salt in African Americans, those older than 51 years, and patients with hypertension, diabetes mellitus, or CKD.[40]

In countries where population-based reduction in salt intake has occurred (Finland, United Kingdom, and Japan), there has been an accompanying fall in BP and CV mortality. A recent AHA Presidential Advisory review concluded that the evidence supporting the effectiveness of population-level salt reduction to prevent hypertension and reduce the incidence of CV disease and stroke remains robust and persuasive for policy development.[40]

In the United States, as in most high-income countries, a major challenge to salt reduction efforts is the widespread use of sodium in the food supply, with more than 75% of total sodium intake from packaged and restaurant foods.[41] One of the most cost-effective ways to lower salt intake in the general population is to reduce salt in processed foods, as shown in an experimental study in South Africa.[42] In Belgium, reduction in the salt content of bread between the mid-1960s and the early 1980s was accompanied by marked reductions in 24-hour urinary sodium excretion. However, a multipronged approach is recommended to achieve overall salt reduction, as outlined by the WHO SHAKE Technical Package for Salt Reduction,[43] that addresses five key areas for action:

- Surveillance: measure and monitor salt use in populations.
- Harness industry: promote the reformulation of foods and meals to contain less salt.
- Adopt standards for labeling and marketing: implement standards for effective and accurate labeling and marketing of food.
- Knowledge: educate and communicate to empower individuals to eat less salt.
- Environment: support settings to promote healthy eating.

The United Kingdom was the first country to set voluntary sodium reduction targets for categories of foods through its Food Standards Agency (2009), closely followed by Australia, the United States, and Canada. South Africa was the first country to adopt mandatory regulation for maximum sodium levels across a wide range of processed food categories that are major contributors to salt intake in that population; namely, bread, margarine and spreads, savory snacks, processed meats, soup powders, and stock cubes.

Potassium Intake

One of the confounding factors of the relationship of salt and BP has been the inverse relationship between the intake of salt and that of potassium. Typically, diets with a high salt content are relatively deficient in potassium (and calcium); but in persons who consume little salt, the potassium (and calcium) intake is high.

In normotensive individuals with an average potassium intake above 1.95 g/day (50 mmol/day), potassium supplementation has no significant effect on BP. However, among hypertensive patients who are potassium deficient because of diuretic treatment or low potassium intake, potassium supplementation lowers BP (Fig. 36.4).[44] The DASH diet lowers BP and is high in potassium because of the high fruit and vegetable content and inclusion of low-fat dairy products (Table 36.2). However, the synergistic effect of the various food groups in the DASH diet makes it difficult to ascertain the contribution of the individual nutritional components. The mechanisms by which a low-potassium diet may contribute to hypertension are poorly understood but may relate to stimulation of intrarenal angiotensin II (Ang II), oxidants, and endothelin; inhibition of intrarenal NO and prostaglandins; and induction of renal ischemia.

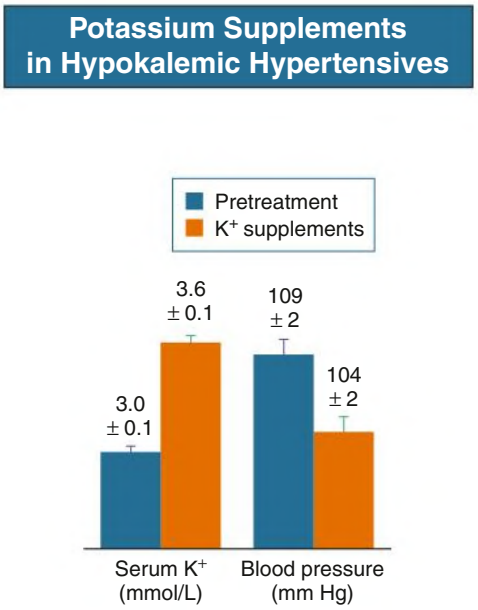

Fig. 36.4 Potassium Supplementation Lowers Blood Pressure in Hypokalemic Hypertensive Patients. Treatment with potassium chloride (60 mmol/day potassium for 6 weeks) resulted in an increase in serum potassium concentration and a decrease in mean arterial pressure in hypertensive patients taking thiazide diuretics. (Modified from Kaplan NM, Carnegie A, Raskin P, Heller JA, Simmons M. Potassium supplementation in hypertensive patients with diuretic-induced hypokalemia. *N Engl J Med.* 1985;312[12]:746–749.)

A systematic review of clinical trials identified that a lower 24h urine Na/K ratio was associated with a significantly greater reduction in both systolic and diastolic BP. Dietary strategies to achieve an increase in potassium while at the same time lowering sodium would be beneficial in lowering BP.[45] Overall, it appears to be beneficial to optimize potassium intake in hypertensive patients to minimize hypokalemia, being careful to avoid the risk for hyperkalemia, especially in those with reduced glomerular filtration rate. If kidney function is normal, optimal potassium intake is 80 to 120 mmol/day. For CVD prevention, the WHO recommends a potassium intake that will keep the urine Na/K ratio close to 1 (i.e., 70–80 mmol/day if Na guidelines are met).

Calcium, Vitamin D, and Dairy Food Intake

Cross-sectional population surveys of self-reported nutrient intake suggest an inverse relationship between calcium intake and BP. The relationship is more convincing at low levels of calcium consumption (<300–600 mg/day). There may be a threshold of 700 to 800 mg/day, above which any further reduction in BP is attenuated. A meta-analysis of randomized calcium supplementation trials (mostly with 1 or 1.5 g calcium daily) demonstrated reductions in SBP (−0.9 to −1.7 mm Hg) that are of little clinical importance.[46] Although calcium in milk may contribute to BP lowering, dairy products may lower BP by other mechanisms. Biologically active peptides formed during the milk fermentation process, such as the casein-derived tripeptides isoleucine-proline-proline and valine-proline-proline, have ACE-inhibiting properties. Vitamin D, which is often added to milk, also may help reduce BP by reducing renin expression, but in a randomized controlled clinical trial, vitamin D had no effect on BP compared with placebo.[47] At present, the AHA does not recognize dairy consumption as a dietary approach to the prevention and management of hypertension. Nevertheless, low-fat dairy products are recommended as an integral part of the DASH diet.

TABLE 36.2 Dietary Approaches to Stop Hypertension (DASH) Diet[a]

Food Group	Daily Servings	Serving Sizes	Examples and Notes	Contribution to the DASH Diet Pattern
Grains and grain products	7–8	1 slice bread ½ cup dry cereal ½ cup cooked rice, pasta, or cereal	Whole-wheat bread, muffin, pita bread, bagel, cereals, oatmeal	Major sources of calories and fiber
Vegetables	4–5	1 cup raw, leafy vegetables ½ cup cooked vegetables 6 oz vegetable juice	Tomatoes, potatoes, carrots, peas, squash, broccoli, turnip greens, kale, spinach, artichokes, green beans, sweet potatoes	Rich sources of potassium, magnesium, and fiber
Fruits	4–5	1 medium fruit ½ cup dried fruit 6 oz fruit juice ½ cup fresh, frozen, or canned fruit	Apricots, bananas, dates, oranges, orange juice, grapefruit, grapefruit juice, mangoes, melons, peaches, pineapples, prunes, raisins, strawberries, tangerines	Important sources of potassium, magnesium, and fiber
Low-fat or nonfat dairy foods	2–3	8 oz milk 1 cup yogurt 1.5 oz cheese	Skim or low-fat (2%) milk, skim or low-fat buttermilk, nonfat or low-fat yogurt, nonfat or low-fat cheeses	Major sources of calcium and protein
Meats, poultry, and fish	≤2	3 oz cooked meats, poultry, or fish	Select only lean meats; trim away visible fats; broil, roast, or boil instead of frying; remove skin from poultry	Rich sources of protein and magnesium
Nuts, seeds, and legumes	4–5/wk	1.5 oz or ½ cup nuts ½ oz or 2 tbsp seeds ½ cup cooked legumes	Almonds, mixed nuts, peanuts, walnuts, sunflower seeds, kidney beans, lentils, split peas	Rich sources of calories, magnesium, potassium, protein, and fiber

[a]The DASH eating plan shown is based on 2000 kcal/day. Depending on energy needs, the number of daily servings in a food group may vary from those listed.

Magnesium Intake, Other Micronutrients, and Bioactive Food Components

A weak inverse relationship has been reported between dietary intake of magnesium and BP, and in a meta-analysis of 34 RCTs, magnesium supplementation with a median dose of 368 mg/day was associated with a 2 mm Hg and 1.78 mm Hg reduction in SBP and DBP, respectively.[48]

In contrast, the inverse association between fruit and vegetable intake and BP and other CV risk factors is well established. Epidemiologic evidence suggests that polyphenol compounds found in fruit may partially explain the cardioprotective properties of fruits. Intervention trials have shown that fruits containing relatively high concentrations of flavonols, anthocyanins, and procyanidins, such as pomegranate, purple grapes, and berries, were effective at reducing CVD risk factors. Regular consumption of flavonol-rich foods, cocoa products, tea, and red wine may reduce BP. Folate, B vitamins, and L-arginine supplementation[49,50] may also lower BP and decrease overall CV risk. Foods that have a high content of inorganic nitrate (NO_3), such as beetroot, are considered to be a potential complementary treatment for hypertension.[51-53] Inorganic NO_3 supplementation may compensate NO-disrupted pathways in hypertension and increase NO bioavailability, an important physiologic mediator in regulating BP.[54] The latest ISH guidelines for lifestyle modification include advice for moderate intake of beetroot juice, pomegranate juice, and cocoa.[2]

Dietary Sugars and Fats

Added sweeteners, such as table sugar and high-fructose corn syrup, have been linked with the epidemics of obesity, hypertension, metabolic syndrome, diabetes, and CV disease.[55] Experimental studies suggest that fructose may increase the risk for obesity and diabetes because of its unique ability to reduce intracellular adenosine triphosphate levels and generate uric acid.[56] One study has reported that reducing soft drink intake by one drink per day is associated with a decrease of 1.8 mm Hg SBP.[57]

Interestingly, whole fruits appear to be beneficial despite containing fructose, possibly as a result of the high content of protective nutrients such as vitamin C, antioxidants, flavanols, potassium, and fiber. Possibly because of this, a systematic review and meta-analysis of three prospective cohort studies in 37,375 men and 185,855 women reported no association of fructose consumption with the incidence of hypertension.[58] However, although there was no excess risk associated with average levels of fructose consumption, a positive association was identified between the incidence of hypertension and high intake of fructose.

Supplementation with omega-3 fatty acids reduces the risk for myocardial infarction (MI) and sudden cardiac death, but their effect on BP is small. In a meta-analysis, omega-3 supplementation significantly reduced DBP by a mean of 1.8 mm Hg but had no effect on SBP, fibrinogen level, or heart rate.[59] About 10 portions of oily fish per week or 9 or 10 fish oil capsules per day are required (equivalent to ~3 g/day long-chain n-3 fatty acids), but this is not tolerated by most because of belching and fishy taste. Concerns about the cholesterol content, as well as dioxin and polychlorinated biphenyl content (environmental pollutants that have carcinogenic potential and, being fat soluble, can accumulate in the body) of some fish oil supplements also raise questions about the safety of very large doses. As a guideline for overall health, individuals with hypertension should aim to consume about 2 to 3 portions (200–400 g) of oily fish (e.g., herring, kippers, mackerel, pilchards, sardines, salmon, trout, fresh tuna, swordfish) per week.

Dietary Approaches to Lower Blood Pressure

Although individual nutrients and components of foods can have an effect on BP, it is necessary to consider these within the context

of a total dietary approach because of potential synergistic effects.[60] A meta-analysis of 41 studies of plant-based diets showed that these diets lowered the SBP and DBP, irrespective of sex and BMI, by 4.29 mm Hg and 2.79 mm Hg, respectively.[61] These dietary patterns included the DASH diet, the Mediterranean diet, and the Nordic diet, and the key factor is that they all emphasize plant-based foods, rich in fruits, vegetables, whole grains, legumes, nuts, seeds, dairy, and fish and low in processed foods and red meat. Both the DASH diet and the Mediterranean diet have been shown to decrease the decline in renal function, progression to dialysis, and mortality.[62]

SMOKING

Cigarette smoking is a major risk factor for CV disease, but its specific role in the development of hypertension is not well elucidated and not routinely included in recommendations for prevention and treatment of hypertension. The relationship with hypertension may be confounded by changes in weight during and after the cessation of smoking. In a large epidemiologic study of middle-aged and older men from the United States, smoking was associated with a modest but important risk for development of hypertension.[63] Furthermore, BP is elevated immediately after using nicotine-containing products.[64] In addition, smoking increases the risk for CKD progression, as well as morbidity and mortality from multiple causes, so all smokers should be advised to stop.

ALCOHOL

There is a linear relationship between alcohol consumption, BP levels, and prevalence of hypertension. In Japan, alcohol intake above 300 g/wk (about three drinks daily) was associated with significantly greater increases of BP during a 7-year period, and baseline BP was higher in drinkers consuming 200 g/wk.[65] Heavy drinking is associated with increased risk for stroke, increase in BP after alcohol withdrawal, and attenuation of antihypertensive efficacy. Paradoxically, alcohol has a J-shaped relationship with coronary heart disease, with moderate consumption (one to two drinks daily) having the lowest risk. In a large epidemiologic study, modest alcohol consumption was protective against first MI.[66] Alcohol may increase BP through activation of the SNS, whereas its protective effects include increasing high-density lipoprotein cholesterol, lowering fibrinogen, and inhibiting platelet activation. The ACC/AHA guidelines recommend that in adult men and women with elevated BP or hypertension who currently consume alcohol should be advised to drink no more than two and one standard drinks per day, respectively (Table 36.1).[1] One standard drink is equivalent to 360 mL (12 fl oz) beer, 150 mL (5 fl oz) wine, or 45 mL (1.5 fl oz) 80-proof spirit.

CAFFEINE

Caffeine is the most widely used psychoactive substance worldwide. Caffeine stimulates the CV system through the blockade of vascular adenosine receptors. In a meta-analysis of RCTs of coffee ingestion, there was no effect on BP or risk for hypertension, although the quality of the evidence was low.[67] The ISH global guidelines recommend moderate consumption of tea or coffee, but pharmacologic ingestion of caffeine and the use of "smart drinks" supplemented with caffeine should be avoided.[2]

PSYCHOLOGICAL STRESS

Chronic psychological stress is a contributor to the development and maintenance of hypertension. Men exposed to job strain had a 10.7 mm Hg and 15.4 mm Hg higher work and home ambulatory SBP than did controls, respectively.[68] The INTERHEART study showed that psychosocial stress was associated with a two-fold increase in the risk for the first MI.[66] Although stress reduction techniques may be beneficial for other reasons, there are few long-term data on efficacy in reducing BP. However, there is rising evidence that stress reduction may assist in blood BP control,[25] and it is recommended in the most recent ISH global hypertension guidelines.[2]

ADOPTING LIFESTYLE MODIFICATIONS

Maintaining adherence to lifestyle changes has always been challenging. The Prevention of Myocardial Infarction Early Remodeling (PREMIER) trial evaluated the effects of implementing JNC 7 lifestyle recommendations and the DASH diet in adults with prehypertension or untreated stage 1 hypertension.[69] At 6 months, there was little additional benefit in adding the DASH diet to JNC recommendations, but both these intervention groups had greater BP reductions compared with a general advice-only group. Importantly, participants purchased their own foods instead of being provided with foods as in the DASH and DASH low-salt diet studies. In the DASH low-salt diet study in which all foods were provided, salt reduction alone resulted in a BP-lowering effect of −6.7/−3.5 mm Hg.[39] A meta-analysis of 34 salt restriction trials in which participants mostly prepared their own low-salt meals reported an effect size of only −4.18/−2.06 mm Hg.[38] Thus, even highly motivated individuals usually cannot meet DASH dietary goals unless their meals are provided.

The TOHP II study demonstrated the problems of sustainability of dietary intervention and the need for regular counseling.[70] The effect of adding salt restriction to weight loss appeared to offer no further decrease in BP, but this was explained by poor compliance to salt reduction. Higher attendance at counseling sessions was associated with a greater reduction in urinary sodium, and the targets were met only in those participants who attended more than 80% of counseling sessions. In summary, the sustainability of long-term lifestyle interventions remains problematic, but it appears that regular and long-term counseling can improve adherence to both medication and lifestyle changes.[71]

SELF-ASSESSMENT QUESTIONS

1. In regard to exercise and hypertension, select the *incorrect* answer:
   - **A.** Physical inactivity may account for 5% to 13% of the risk for developing hypertension.
   - **B.** Regular physical activity and reduced sedentary activity lowers all-cause morbidity and mortality.
   - **C.** The 2020 World Health Organization guidelines suggest that all adults should undertake 150 to 300 minutes of moderate-intensity physical activity or 75 to 150 minutes of vigorous-intensity physical activity.
   - **D.** The guidelines do not recommend regular muscle-strengthening activity for all age groups.

2. For every kilogram reduction in weight, it is estimated that the systolic blood pressure will be reduced by:
   A. 0.5 mm Hg.
   B. 1 mm Hg.
   C. 2 mm Hg.
   D. 3 mm Hg.
3. Which of the following patients should not be targeted for stricter sodium reduction, according to the US Department of Agriculture and the US Department of Health and Human Services?
   A. African Americans
   B. Patients with chronic kidney disease
   C. Hypertensive individuals
   D. People younger than 40 years
4. In regard to alcohol consumption, which of the following statements is *incorrect?*
   A. There is a linear relationship between alcohol consumption, blood pressure levels, and prevalence of hypertension.
   B. Abstinence from alcohol may reduce the risk of myocardial infarction.
   C. Reduction of alcohol consumption to 1 to 2 standard drinks is recommended.
   D. Heavy drinking is associated with increased risk for stroke.

Pharmacologic Treatment of Hypertension

Bryan Williams

High blood pressure (BP) is a major preventable cause of premature death globally.[1-3] Accordingly, the treatment of hypertension is one of the most cost-effective interventions in modern medicine.[4,5] This chapter relies heavily on the 2017 US American Heart Association/American College of Cardiology (AHA/ACC)[6] and the 2018 European Society of Cardiology/European Society of Hypertension (ESC/ESH) hypertension guidelines,[7] referred here as the US and European guidelines, respectively. Both guidelines record the importance of lifestyle interventions prior to and in conjunction with pharmacologic treatment of hypertension, noting that they can delay the development of hypertension and can potentiate the efficacy of BP-lowering therapies (see Chapter 36). Nevertheless, most patients with confirmed hypertension will require lifelong drug treatment, invariably with more than one drug (Table 37.1). International hypertension guidelines have recently converged to prioritize simplicity and pragmatism, although some nuances and differences remain.[8] This chapter summarizes these recommendations for treatment of hypertension.

DEFINING WHO SHOULD RECEIVE PHARMACOLOGIC TREATMENT FOR HYPERTENSION

BP follows a normal distribution within populations; thus *hypertension* is arbitrarily defined by diagnostic thresholds that are subject to change as new evidence from clinical trials emerges. Hypertension is best defined as *that level of blood pressure at which treatment to lower blood pressure results in significant clinical benefit.* The BP at which treatment results in "significant clinical benefit" for any individual will depend on their absolute cardiovascular (CV) risk.[1-5] This varies because some people are more vulnerable than others to end organ damage at a given BP. Moreover, some patients (e.g., the frail elderly) will be less tolerant of more aggressive BP lowering than others. Consequently, complex differential BP thresholds and targets emerged in previous guidelines, grouping patients into categories defining their threshold BP for therapeutic intervention and optimal BP goals. In some cases, specific drug classes were also given "compelling indications" and "compelling contraindications" for specific groups of patients. Although useful in tailoring therapy, these recommendations were often misinterpreted as indicating that the specific drug was more important than the achieved BP, which is not the case. As guidelines have evolved, the BP threshold for intervention with drug therapy and the recommended treatment targets have been simplified, and the drug treatment algorithms are more pragmatic and focused on logical combinations of therapy. Key principles underpinning current guidance are that (1) most people need more than one drug to achieve currently recommended BP targets, and (2) the magnitude of BP reduction and the achievement of BP control are the most important drivers of benefit.[4,5]

Blood Pressure Thresholds for Intervention (Office Blood Pressure)

There is unequivocal evidence that drug treatment of a seated "office" BP of 160/100 mm Hg or higher (grade 2 hypertension) reduces the risk for stroke, myocardial infarction (MI), heart failure, and mortality.[4-7] Treating pressures of 140/90 mm Hg or higher, especially in higher-risk patients, is similarly beneficial.[4-7] Consequently, most international guidelines define hypertension as an office BP of 140/90 mm Hg or higher.[9] The exception is the 2017 US hypertension guideline,[6] which defined stage 1 hypertension as a BP of 130/80 mm Hg or higher. Note that the US hypertension guidelines refers to "stages" of hypertension, whereas other guidelines refer to "grades" of hypertension. The US guideline recommends lifestyle advice for such patients and drug treatment to lower BP to less than 130/80 mm Hg if there is coexisting cardiovascular disease (CVD) or an estimated 10-year risk for CVD greater than 10%.[6] This was a major change, especially setting the diagnostic threshold for "hypertension" at 130/80 mm Hg or higher, resulting in as many as 50% more people being diagnosed as "hypertensive," with the majority, especially older patients, recommended for drug treatment. Other international guidelines have retained a diagnostic threshold for hypertension of 140/90 mm Hg for adults.[9] The European guidance in 2018 remained more cautious about the initiation of drug therapy in patients aged 80 years or older, recommending a treatment threshold of 160/100 mm Hg for previously untreated patients.[7] However, a 140/90 mm Hg threshold is now more widely adopted, especially for the fit and active elderly in this age group.

Table 37.2 contrasts the US guidance and the 2018 European (ESC/ESH) guidelines, which are representative of most other international guidelines. All guidelines identify a category of patients with "high normal BP" (often referred to as borderline hypertension or prehypertension), which highlights people at high risk for progression to hypertension and in whom lifestyle changes can be beneficial.

Blood Pressure Thresholds for Intervention (Ambulatory and Home Blood Pressure Monitoring)

International guidelines favor the use of out-of-office BP measurement to confirm the diagnosis of hypertension, better identify masked hypertension or "white coat" hypertension, and monitor BP control. When the office BP is elevated, the elevation in BP should ideally be confirmed by ambulatory blood pressure monitoring (ABPM) or home BP monitoring.[6,7,10,11] This is not necessary when BP is markedly elevated in patients requiring urgent treatment (i.e., in the presence of hypertension-mediated clinical complications or organ damage). ABPM or home BP is also recommended to confirm the quality of BP control, especially in higher-risk patients. Moreover, the US guidelines cite evidence suggesting that home BP monitoring may better engage patients in their treatment and lead to better BP control. The shift

toward increased awareness and use of home BP has accelerated during the COVID-19 pandemic as patients became more isolated from their routine clinic visits, and this is likely to be a continuing trend.

Diagnostic thresholds for hypertension vary according to the method of measurement. When ABPM and home BP monitoring are used to classify hypertension, the diagnostic thresholds are lower than office BP because they represent the average of a greater number of measurements under different conditions. Table 37.3 summarizes the diagnostic thresholds for hypertension according to different methods of measurement (see Chapter 34).

TABLE 37.1 Development of Therapeutic Strategies for Hypertension

Year	Therapy
Nondrug	
1920s	Strict low-sodium diet
1929	Lumbar sympathectomy
1944	Kempner rice diet
Drug	
1930s	Veratrum alkaloids
1940s	Thiocyanates
1948	Reserpine, phenoxybenzamine
1950	Ganglion blockers
1951	Monoamine oxidase inhibitors
1958	Thiazide diuretics (chlorothiazide)
1960s	Central α_2-receptor agonists, non-DHP CCBs, β-blockers
1970s	ACE inhibitors, α_1-receptor blockers
1980s	DHP CCBs
1990s	ARBs
2000s	Renin inhibitors, ARNIs

ACE, Angiotensin-converting enzyme; *ARB,* angiotensin receptor blocker; *ARNI,* angiotensin receptor neprilysin inhibitor; *DHP CCB,* dihydropyridine calcium channel blocker.

BLOOD PRESSURE TREATMENT GOALS

There is no single BP treatment goal that will be optimal, achievable, and well tolerated by all. The ideal BP treatment goal is likely to be patient specific. Guidelines should therefore be conservative and pragmatic, curbing the zeal of specialists to advocate ever-lower BP goals, and should only make recommendations supported by solid evidence. Until recently, there was international consensus that two BP goals were appropriate: less than 140/90 mm Hg for those with "uncomplicated hypertension" and a lower goal of less than 130/80 mm Hg for those at higher risk (i.e., patients with diabetes, established CVD or cerebrovascular disease, or chronic kidney disease [CKD]). The SPRINT trial challenged this consensus when it showed that more intensive BP lowering (targeting an office systolic BP <120 mm Hg) was more effective at reducing major CV events and mortality than the current, less intensive systolic BP goal of less than 140 mm Hg.[12] The SPRINT results are supported by a more recent and similar study in older patients from China.[13] Importantly, BP was measured in SPRINT using a very specific methodology: an automated device after 5 minutes of seated rest in a quiet room (either attended or unattended) followed by three oscillometric measurements. This approach to BP measurement undoubtedly results in lower BP readings compared with usual office BP measurements in clinical practice. Indeed, a recent study comparing routine BP measurement using routine electronic health record data from patients also participating in the SPRINT study showed that routine clinic readings were significantly higher than the SPRINT BP recordings, such that the lower attained systolic BP in the SPRINT cohort (121 mm Hg) was equivalent to 128 mm Hg in contemporaneously routinely measured clinic BP. Furthermore, a mean systolic BP of 135 mm Hg in the less intensively SPRINT cohort group was equivalent to 139 mm Hg using routine clinic BP.[14] These findings concur with the view that the office

TABLE 37.2 Blood Pressure Classification and Definition of Hypertension According to International Guidelines

BP Category	Systolic (mm Hg)		Diastolic (mm Hg)	BP Threshold (mm Hg)
ESC/ESH Classification of Hypertension (2018)				
Optimal	<120	and	<80	Age <80 yr: 140/90
Normal	120–129	and/or	80–84	Age ≥80 yr: 160/90
High-normal	130–139	and/or	85–89	
Grade 1 hypertension	140–159	and/or	90–99	
Grade 2 hypertension	160–179	and/or	100–109	
Grade 3 hypertension	≥180	and/or	≥110	
Isolated systolic hypertension	≥140	and	<90	
US Classification of Hypertension (2017)				
Normal	<120	and	<80	130/80 if existing CV disease or 10-yr CVD risk >10%
Elevated	120–129	and	<80	140/90 in all others
Hypertension				
Stage 1	130–139	or	80–89	
Stage 2	≥140	or	≥90

Erratum *J Am Coll Cardiol.* 2018;71(19):2275–2279.

SBP should be treated to less than 140 mm Hg and ideally less than 130 mm Hg, if tolerated. This is consistent with the US guidance, which recommends a BP target of less than 130/80 mm Hg in all treated patients, irrespective of age or comorbidities.[6]

The ESC-ESH 2018 guidance recommended a target range, noting that the first objective should be to treat all patients to an office BP of less than 140/90 mm Hg and that the optimal systolic BP goal would for most treated patients be from less than 140 mm Hg down to 120 mm Hg, also noting that attempting to lower systolic BP below 120 mm Hg in all patients might be beneficial in some but may be hazardous to others.[7] The guidance stated that the aim should be to reduce systolic BP to 130 mm Hg if possible, and lower if tolerated (which the guidance noted was likely to be more likely in patients <65 years). Thus, in reality, there is little difference between the US and European guidance for most patients with respect to BP treatment targets, except that the European guidance is more nuanced with respect to the likelihood of achieving the lower end of the BP target range in older and especially frailer patients. The diastolic target in all guidelines is less than 80 mm Hg, although in most patients, this will be less difficult to achieve than the systolic targets. The simple takeaway from all of this is to aim to reduce systolic BP to less than 140/90 mm Hg in all patients, aiming for less than 130/80 mm Hg, and ideally lower if tolerated. Tables 37.4 and 37.5 summarize the treatment targets from the US and European guidelines, respectively.

GUIDE TO SELECTION OF ANTIHYPERTENSIVE AGENTS

Key Principles from Clinical Trials

Some important guiding principles with regard to treatment strategies for hypertension are as follows:

1. Effective BP lowering is overwhelmingly important to reduce risk of major CV events and death in people with hypertension. Thus, the first priority in treatment is to control BP.
2. Early studies focused on diastolic BP as the treatment target, but systolic BP is invariably more difficult to control and more closely linked to CV outcomes; thus it should now be the primary but not the sole focus of treatment.
3. Most patients will require more than one drug (i.e., combination therapy) as part of their treatment strategy, especially with the lower BP targets advocated in the most recent guidance.
4. The response to any class of BP-lowering medication is heterogeneous, with important effects of age and ethnicity, but this heterogeneity is diminished by combination therapy.
5. Some trials have suggested that certain comorbidities (e.g., diabetes) or target organ damage (e.g., left ventricular hypertrophy [LVH], CKD) provide compelling indications for inclusion of specific classes of drug therapy in the treatment regimen, usually renin-angiotensin system (RAS) blockade, but this consideration has become less relevant now that recommended combinations typically include RAS blockade.
6. On average, lowering of BP by 20/10 mm Hg in hypertensive patients will reduce the risk for major CV events by half.
7. The reduction in stroke risk and heart failure appears to follow the predicted reduction in risk based on the epidemiologic association between these morbidities and BP.
8. The observed benefits of BP lowering on coronary events are lower than expected based on epidemiologic predictions, which is best addressed by attention to concomitant risk factors, especially statin therapy.
9. The risk reduction associated with BP lowering is continuous across a wide range of BP, with the benefit from treatment greatest in those with the highest absolute CVD risk. This provides the rationale for advocating the use of complementary strategies to reduce CVD risk (e.g., statins for those with established vascular disease, with target organ damage, or at high calculated CVD risk [i.e., ≥10% during 10 years], and antiplatelet therapy for secondary prevention).

TABLE 37.4 Summary of BP Thresholds and Treatment Goals (Office BP) Recommended by the US 2017 Hypertension in Adults Treatment Guidelines

Clinical Condition(s)	Threshold (mm Hg)	Goal (mm Hg)
General		
Clinical CVD or 10-year ASCVD risk ≥10%	≥130/80	<130/80
No clinical CVD and 10-year ASCVD risk <10%	≥140/90	<130/80
Older persons (≥65 years; noninstitutionalized, ambulatory, community-living adults)	≥130 systolic	<130 systolic
Specific Comorbidities		
Diabetes mellitus	≥130/80	<130/80
CKD	≥130/80	<130/80
CKD after kidney transplantation	≥130/80	<130/80
Heart failure	≥130/80	<130/80
Stable ischemic heart disease	≥130/80	<130/80
Secondary stroke prevention	≥140/80	<130/80
Secondary stroke prevention (lacunar)	≥130/80	<130/80
Peripheral arterial disease	≥130/80	<130/80

Selection of Drug Therapy

Modern guidelines recommend that routine drug treatment of hypertension should be based on 5 major classes of drugs; angiotensin-converting enzyme (ACE) inhibitors, angiotensin receptor blockers (ARBs), calcium channel blockers (CCBs), diuretics, and β-blockers, with the latter predominantly reserved for specific indications.[6,7,9] Recent guidelines also advocate wider use of combinations of BP-lowering drugs, even as initial therapy, to achieve optimal BP control. Thus, the previous lists of compelling indications for individual drug classes for patients with specific comorbidities are less relevant than they were previously. The focus now is on which combinations of drugs are appropriate for each clinical scenario. Nevertheless, it is important to understand the properties and mechanisms of action of individual drug classes that form the basis of treatment for hypertension, as well as their relative risks and benefits (Table 37.6 and Fig. 37.1) and contraindications for the use of specific classes of BP-lowering therapy in specific clinical situations (Table 37.7) and common adverse effects (Table 37.8). These lists are not comprehensive and are subject to change as new evidence emerges, and up-to-date prescribing information should always be consulted. Fig. 37.2 shows the major sites of action of major antihypertensive drug therapies.

TABLE 37.6 Relative Risk and Benefit of Antihypertensive Drug Classes

Outcome	Thiazide Diuretics	Calcium Channel Blockers	β-Blockers	ACEis/ARBs[a]
Unstable angina	0.89	0.88	0.98	0.97
Myocardial infarction	0.78	0.79	0.85	0.81
Diabetes	0.98	0.80	1.13	0.72
Stroke	0.69	0.65	0.85	0.73
Heart failure	0.53	0.73	0.76	0.64
Death	0.91	0.88	0.93	0.90

[a]ACE inhibitors and ARBs were grouped as a single class for the purposes of this analysis.
Effectiveness of drugs: 1.0 = no benefit/harm, <1.0 = benefit, and >1.0 = potential harmful effect (from a meta-analysis of major blood pressure–lowering trials conducted for the United Kingdom).
ACEis, Angiotensin-converting enzyme inhibitors; *ARBs,* angiotensin receptor blockers.
Modified from National Institute for Health and Clinical Excellence [NICE] Hypertension Guideline Development Group, 2006. https://www.nice.org.uk/guidance/cg127.

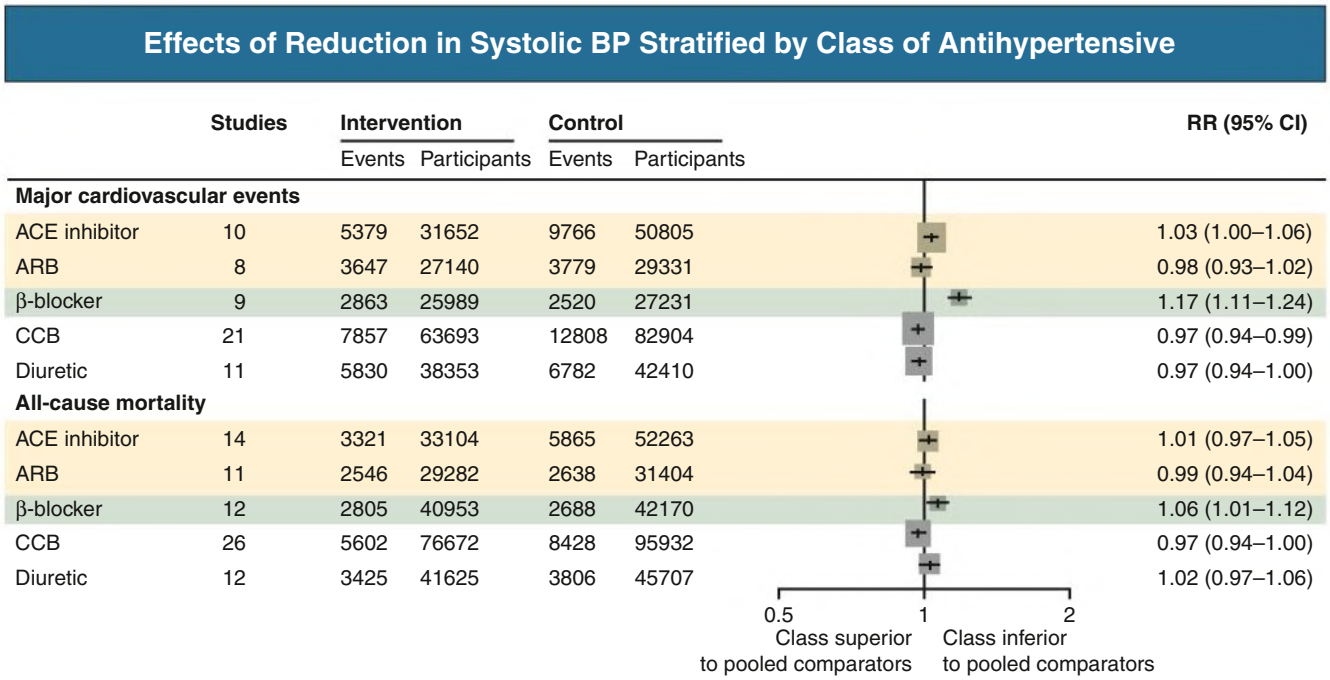

Fig. 37.1 Effects of Reductions in Systolic Blood Pressure (BP) Stratified by Class of BP-Lowering Drug. *ACE,* Angiotensin-converting enzyme; *ARB,* angiotensin receptor blocker; *CCB,* calcium channel blocker; *CI,* confidence interval; *RR,* relative risk. (From Ettehad D, Emdin CA, Kiran A, et al. Blood pressure lowering for prevention of cardiovascular disease and death: a systematic review and meta-analysis. *Lancet.* 2016;387[10022]:957–967.)

Thiazide and Thiazide-like Diuretics

The class of diuretics includes the traditional thiazide diuretics such as hydrochlorothiazide and bendroflumethiazide, as well as thiazide-like diuretics such as chlorthalidone and indapamide. The latter are termed *thiazide-like* because, like the thiazides, they act primarily by inhibiting the Na^+-Cl^- cotransporter in the distal tubule, promoting sodium excretion, which is integral to their antihypertensive effect. However, the thiazide-like diuretics have different structure than the thiazides and differing actions on other aspects of kidney tubular function, such as carbonic anhydrase inhibition in the proximal tubule. Thiazide and thiazide-like diuretics remain an important therapeutic option for the treatment of hypertension. The early changes in salt and water balance they induce are usually accompanied by counteractivation of several vasoconstrictor mechanisms, including the RAS, which may transiently raise peripheral vascular resistance (PVR) and attenuate BP lowering. Subsequently, a gradual reduction in PVR and a new steady state of reduced total body sodium and BP are established, usually after about 2 months of treatment.

The sustained actions of these diuretics on the kidney make them preferable to loop diuretics for the control of BP. Although loop diuretics are more potent promoters of acute sodium and water loss, their shorter duration of action can result in compensatory sodium retention during the latter part of the dosing interval, thereby reducing their BP-lowering efficacy. Loop diuretics have no place in the routine management of primary hypertension in patients with well-preserved glomerular filtration rate (GFR). However, thiazide and thiazide-like diuretics lose efficacy in patients with GFR less than 30 mL/min/1.73 m^2. In such patients, loop diuretics are often required for effective BP lowering, especially when there is clinical evidence of sodium and water retention.

The main adverse effects of thiazide and thiazide-like diuretics are metabolic: hypokalemia, hyponatremia (less frequently),

TABLE 37.7 Contraindications to Specific BP-Lowering Therapies

Pharmacologic Therapy	CONTRAINDICATIONS	
	Compelling	Possible
Thiazide diuretics	Gout	Metabolic syndrome Glucose intolerance Pregnancy
β-Blockers	AV block (grade 2 or 3)	Peripheral artery disease Metabolic syndrome Glucose intolerance Athletes, physically active patients COPD Asthma (use cardioselective β-blocker)
Calcium antagonists (dihydropyridines)		Tachyarrhythmias Heart failure
Calcium antagonists (verapamil, diltiazem)	AV block (grade 2 or 3) Heart failure β-Blocker therapy	
ACE inhibitors	Pregnancy Angioneurotic edema Hyperkalemia Bilateral renal artery stenosis	
ARBs	Pregnancy Hyperkalemia Bilateral renal artery stenosis	
Diuretics (antialdosterone)	Hyperkalemia	CKD stages 4 and 5[a]
Direct renin inhibitors	Pregnancy Hyperkalemia Bilateral renal artery stenosis	

[a]Use only low doses and with extreme caution with respect to potassium levels in patients with advanced CKD.
ACE, Angiotensin-converting enzyme; *ARB,* angiotensin receptor blocker; *AV,* atrioventricular; *BP,* blood pressure; *CKD,* chronic kidney disease; *COPD,* chronic obstructive pulmonary disease.

TABLE 37.8 Common Side Effects Associated With Various Classes of Antihypertensive Drugs

Class	Side Effects
ACE inhibitors	Cough, hyperkalemia
ARBs	Much less frequent hyperkalemia compared with ACE inhibitors
CCBs	
DHP CCBs	Pedal edema, headache
Non-DHP CCBs	Constipation (verapamil), headache (diltiazem)
Diuretics	Frequent urination, hyperglycemia, hyperlipidemia, hyperuricemia, sexual dysfunction
Central α-agonists	Sedation, dry mouth, rebound hypertension, sexual dysfunction
α-Blockers	Pedal edema, orthostatic hypotension, dizziness
β-Blockers	Fatigue, bronchospasm, hyperglycemia, sexual dysfunction
Potassium channel openers	Hypertrichosis (minoxidil); lupus-like reactions, pedal edema (hydralazine)

ACE, Angiotensin-converting enzyme; *ARBs,* angiotensin receptor blockers; *CCBs,* calcium channel blockers; *DHP,* dihydropyridine.

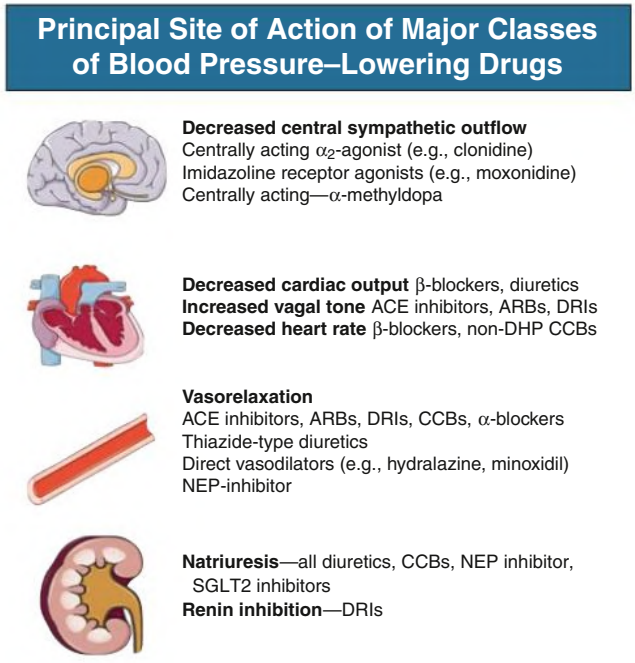

Fig. 37.2 Principal Site of Action of Major Classes of Blood Pressure–Lowering Drugs. *ACE,* Angiotensin-converting enzyme; *ARB,* angiotensin receptor blocker; *CCB,* calcium channel blocker; *DRI,* direct renin inhibitor; *NEP,* neprilysin; *non-DHP CCB,* nondihydropyridine calcium channel blocker; *SGLT2,* sodium-glucose cotransporter-2.

impaired glucose tolerance, and small increments in blood levels of low-density lipoprotein (LDL) cholesterol and triglycerides. These diuretics also elevate serum uric acid levels and should be avoided in patients predisposed to gout, as well as in those receiving lithium because of a high risk for lithium toxicity. Lithium reabsorption is similar to sodium in the proximal tubule, and thus distal sodium loss caused by thiazide and thiazide-like diuretics can promote proximal reabsorption of sodium and lithium, potentially leading to lithium toxicity. An incidental advantage of thiazide and thiazide-like diuretics may be reduced risk of osteoporosis, especially in women, as a result of calcium retention.

There has been a recent trend to reduce the recommended dose of these diuretics to minimize these metabolic effects. The dose response for BP to thiazide and thiazide-like diuretics is flat (unlike the adverse effect profile); however, some patients respond well to higher doses, which they tolerate. Moreover, when thiazide or thiazide-like diuretics are combined with drugs that block the RAS, such as ACE inhibitors or ARBs, the dose response is steeper and higher doses (e.g., hydrochlorothiazide 25–50 mg or chlorthalidone 25 mg) may be especially effective in patients with more resistant hypertension. Guidelines favor the use of thiazide-like diuretics, such as chlorthalidone and indapamide, because they are longer acting than traditional thiazides, such as hydrochlorothiazide, and because there are limited outcome data with the latter when used at low doses.

Potassium-Retaining Diuretics

This class of agents includes spironolactone, eplerenone, and amiloride. Finerenone is a recently approved nonsteroidal mineralocorticoid receptor antagonist that has shown benefits in reducing the progression of diabetic kidney disease[15] and CV morbidity and mortality in patients with diabetes.[16] However, there is less data available on the use of finerenone for the treatment of hypertension.

Spironolactone is an aldosterone receptor antagonist that acts in the distal tubule and collecting ducts, decreasing the reabsorption of sodium and water and decreasing the excretion of potassium. The main action of spironolactone is to decrease tubular expression of epithelial sodium channels (ENaC) and kidney outer medullary potassium channels, and thus it has a relatively slow onset and offset of action. Because its main site of action is on sodium and water handling in distal tubule and collecting ducts, spironolactone as monotherapy is a relatively weak diuretic. Nevertheless, it is effective as a BP-lowering agent although rarely used as initial therapy for hypertension. Spironolactone has the advantage over thiazide-like diuretics in that it does not cause hypokalemia or hyperuricemia and it does not impair glucose tolerance. However, spironolactone has antiandrogen activity by binding to the androgen receptor and preventing it from interacting with dihydrotestosterone. Consequently, it can cause nipple tenderness and gynecomastia in some male patients (~6%) that is dose dependent and can limit its use. Another concern with potassium-sparing diuretics is the risk for hyperkalemia in people with substantially reduced GFR (see later discussion).

Eplerenone is more selective for the aldosterone receptor than spironolactone and consequently avoids its antiandrogen effects. There is very limited experience with the use of eplerenone for the routine management of hypertension. Empirically, milligram per milligram, eplerenone is less potent than spironolactone and less effective at lowering BP.

Amiloride is an antagonist of ENaC in the distal convoluted tubules and collecting ducts, decreasing sodium and water reabsorption and impairing potassium excretion. Previously, amiloride was a popular treatment of primary hypertension, when, like spironolactone, it was often used in combination with thiazide-like diuretics. Amiloride is now less frequently used even though it shares the advantage of spironolactone over thiazide-like diuretics of not causing hypokalemia, hyperuricemia, or impaired glucose tolerance. Amiloride is the treatment of choice in patients with Liddle syndrome.

The decline in popularity of potassium-sparing diuretics for the initial treatment of primary hypertension may reflect the increasing use of ACE inhibitors and ARBs for the management of hypertension and the increased risk for hyperkalemia when these are combined with spironolactone or amiloride, especially in patients with kidney impairment. Spironolactone and amiloride are increasingly used as additional diuretic therapy in multidrug strategies for the treatment of resistant hypertension, when these drugs can be very effective (see "Resistant Hypertension" section).[17-19]

β-Adrenoceptor Blockers

β-Blockers reduce BP and CV events in patients with hypertension. Most β-blockers, with the exception of those with strong intrinsic sympathomimetic activity, reduce cardiac output by their negative chronotropic and inotropic effects. As with diuretics, short-term hemodynamic responses can be offset by counteractivation of vasoconstrictor mechanisms, which may limit initial BP lowering. Longer-term reduction in arterial pressure occurs because PVR is restored to pretreatment levels. Partial blockade of renin release from the kidney may contribute to the later hemodynamic response.

β-Blockers differ in their duration of action, selectivity for β_1 receptors, lipophilicity, and partial agonist activity. Side effects include lethargy, muscle aches with exercise, impaired concentration and memory, aggravation of depression and psoriasis, erectile dysfunction, vivid dreams, and exacerbation of symptoms of peripheral vascular disease and Raynaud syndrome. Nonselective β-blockers are contraindicated in asthma patients and can cause impaired glucose tolerance and worsening of dyslipidemia, notably reduced high-density lipoprotein (HDL) cholesterol and raised triglyceride levels. β-Blockers increase the likelihood of new-onset diabetes, particularly in combination with thiazide-type diuretics.[20,21] Moreover, meta-analyses have consistently suggested that β-blocker–based treatment of hypertension reduces the risk of CV events (especially the risk of stroke) to a lesser extent than treatment with other major drug classes[4,22,23] (Fig. 37.1). As a consequence, US and European guidelines both state that β-blockers are not preferred as initial therapy for routine treatment of hypertension and should be used only when there is a compelling indication other than BP control (e.g., in patients with angina, chronic heart failure, or for heart rate control, as well as hypertension).[6,7]

Another exception is in younger women in whom β-blockers are often effective at lowering BP and are safer than ACE inhibitors or ARBs in women anticipating pregnancy. The good BP-lowering efficacy in younger people most likely reflects higher renin levels, and the BP-lowering action of β-blockers, at least in part, relates to suppression of renin release.

Newer Generation of β-Blockers: β_1 Adrenoceptor Blockade Plus Vasodilation

Concerns regarding β-blockers predominantly reflect studies conducted with unselective or, more commonly, β_1-cardioselective adrenoceptor blockers, especially atenolol. The newer generation of β-blockers retains β_1-cardioselective adrenoceptor blockade but also has a vasodilator action, either through (1) associated α-adrenoceptor blocking activity (e.g., carvedilol or labetalol) or (2) nebivolol, via associated β_3-adrenoceptor agonist activity, which dilates via nitric oxide–mediated mechanisms and also mediates favorable effects on glucose and lipid metabolism, offsetting the unfavorable metabolic effects of nonselective or selective β_1-adrenoceptor blockade. Labetalol has a rapid onset of action, making it a useful intravenous medication for the treatment of hypertensive emergencies. Labetalol is also safe in pregnancy and in patients with coronary disease because it does not increase heart rate. Labetalol should not be used without prior adequate α-blockade in patients with hyperadrenergic states, such as pheochromocytoma, because unopposed, inadequately blocked α-adrenergic activity can increase BP if β-blockade is not complete.

Carvedilol and nebivolol have been shown to improve outcomes in randomized controlled trials (RCTs) in heart failure.[24] Despite this, these agents have not been emphasized in most guidelines because of the lack of clinical outcome data from RCTs demonstrating that they improve outcomes when used to treat hypertension.

Calcium Channel Blockers

CCBs reduce BP,[4,5] are effective antianginal agents, and have no adverse effects on glucose tolerance or lipid parameters. CCBs are especially effective at smoothing BP variability, which is an independent risk factor for stroke. Systematic reviews have shown CCBs (particularly amlodipine) to be the most cost-effective treatment option for hypertension, mainly because they are the most effective agent at preventing stroke.[4,5,23] BP response to CCBs is largely determined by the magnitude of BP elevation, more so than with other drugs. Thus, patients with higher baseline BP experience greater BP lowering with CCBs than those with only modest elevations of BP. This property also may explain the smoothing effect of CCBs on BP variability.

There are two main groups of CCBs: the dihydropyridines (e.g., amlodipine, nifedipine) and the nondihydropyridines (e.g., diltiazem, verapamil). The dihydropyridine (DHP) CCBs act mainly by inducing relaxation of arterial smooth muscle by blocking L-type calcium channels, thereby inducing a fall in PVR and arterial pressure. Nondihydropyridine (non-DHP) CCBs block calcium channels in cardiac muscle and reduce cardiac output. Verapamil has an additional antiarrhythmic action through its effects on the atrioventricular node. DHP and non-DHP CCBs have occasionally been combined, but no robust data are available on the BP-lowering efficacy or clinical outcomes of this approach, and it is not a recommended combination therapy in international guidelines.

Earlier formulations of some DHP CCBs, such as capsular nifedipine, had a rapid onset and a short duration of action, with unpredictable effects on BP. These responses were often accompanied by reflex sympathetic stimulation and tachycardia. These shorter-acting oral preparations of CCBs have no place in the routine management of hypertension. Longer-acting formulations of DHP CCBs produce more sustained and predictable responses.

Side effects of DHP CCBs include dose-dependent peripheral edema, which is caused by transudation of fluid from the vascular compartments into the dependent tissues as a result of precapillary arteriolar dilation. This edema does not respond to diuretic therapy but is alleviated by limb elevation or coadministration of an ACE inhibitor or ARB (because of their effects on venous capacitance). Gum hypertrophy can occur with DHP CCBs but is rarely seen with non-DHP CCBs. Non-DHP CCBs cause less peripheral edema but are negatively inotropic and negatively chronotropic and should therefore be avoided in patients with compromised left ventricular function and in combination with β-blockers. Verapamil use is commonly accompanied by constipation.

Renin-Angiotensin System Blockers

Inhibition of RAS is predictably effective at lowering BP by inhibiting the various central and peripheral pressor effects of angiotensin II (Ang II). Blockade of RAS also may lower BP by other mechanisms involving improvements in endothelial function, vagal tone, and baroreceptor function and through inhibition of the kidney tubular reabsorption of sodium. In addition, RAS inhibition has been popularized by clinical trial evidence showing reduced morbidity and mortality in patients with heart failure, delayed progression of kidney disease, and reduced CV events in those at high CV risk.[6,7,9] Two major classes of drugs directly target the RAS, ACE inhibitors, and ARBs. Direct renin inhibitors were also developed for this purpose but have declined in use and are not recommended for routine treatment of hypertension in international guidelines because of a lack of evidence that they improve CV outcomes.

Angiotensin-converting enzyme inhibitors. ACE inhibitors block the conversion of Ang I to Ang II by inhibiting ACE. The resulting reduction in levels of Ang II leads to vasodilation and a fall in BP. Ang II has many additional actions that are potentially harmful to the CV system and has been implicated in the pathogenesis of structural changes in the heart, blood vessels, and kidneys in hypertension. Sharp falls in BP after the introduction of ACE inhibitors may occur when the RAS is activated (e.g., in patients who are dehydrated, in heart failure, or have accelerated hypertension). This is rarely a problem when therapy is initiated in uncomplicated hypertensive patients.

Side effects of ACE inhibitors include the development of a persistent dry cough in about 20% of users. This is more common in women and in people from East Asia and the Pacific Rim. The cough disappears only after discontinuation of the drug. Another rare but important complication is angioedema, which occurs in about 1% and is much more common in the Black population (~4%). ACE inhibitors should be avoided in women of childbearing potential because of the danger of fetal malformation, especially from exposure in the first trimester, when women may be unaware they are pregnant. ACE inhibitors should not be used in patients with significant bilateral renal artery disease because they may precipitate deterioration in kidney function and kidney failure. Careful monitoring of kidney function and serum potassium concentration is also required in patients with more advanced kidney impairment of any cause, because of the risk for hyperkalemia.

Angiotensin receptor blockers. ARBs are highly selective inhibitors of the Ang II type 1 receptor (AT_1). As with ACE inhibitors, ARBs inhibit the actions of Ang II on the CV system and kidney. ARBs reduce BP as effectively as ACE inhibitors and generally have a longer duration of action. ACE inhibitors and ARBs appear to be equally effective in reducing albuminuria and preserving GFR[24] and have similar efficacy for preventing major CV events in patients with established CVD.[4,25] Because of their selectivity and specificity for the AT_1 receptor, the ARBs are well tolerated, with a placebo-like adverse effect profile. Cough and angioedema are much less likely to occur with ARBs than with ACE inhibitors, and most guidelines recommend switching patients to an ARB when an ACE-induced cough occurs. Cautions and contraindications are similar to those outlined for ACE inhibitors.

α-Adrenergic Blockers

The original members of the α-adrenergic blocking class (e.g., prazosin) were short-acting drugs that blocked the activation of α_1-adrenoceptors in the vasculature, leading to vasodilation. Initially, the recommended dosage was too high, and postural hypotension and syncope were frequent. The use of lower doses and the development of longer-acting agents (e.g., doxazosin) have largely overcome this problem. Blockade of sphincteric receptors improves symptoms in men with benign prostatic hypertrophy but can worsen stress incontinence in women. Uniquely among antihypertensive drugs, the α_1-antagonists produce modest favorable changes in plasma lipids, with a reduction in total and LDL cholesterol and triglyceride levels and an increase in HDL cholesterol. α_1-Antagonists are not recommended for routine treatment of hypertension and are largely reserved for their specific indications (e.g., prostatic outflow obstruction) or as "add-on" treatment for resistant hypertension when alternative treatments are not tolerated.

Centrally Acting Sympatholytic Drugs

Some of the earliest drugs developed to treat hypertension targeted the activation of the sympathetic nervous system (SNS) at various levels, including the CV regulatory nuclei in the brainstem, the peripheral autonomic ganglia, and the postganglionic sympathetic neuron. Few of these agents are used today because side effects are common.

Methyldopa reduces sympathetic outflow from the brainstem and frequently causes sedation, impaired psychomotor performance, dry mouth, and erectile dysfunction. Its unfavorable effect on quality of life resulted in methyldopa being gradually replaced by more effective drugs, although it is still extensively used in the management of hypertension of pregnancy, which is now its main indication.

Clonidine is now rarely used because of its short duration of action and risk for withdrawal syndrome, which occurs when sudden discontinuation results in a rebound rise in catecholamines with features that may resemble those of pheochromocytoma, such as severe hypertension, tachycardia, and sweating. This is exacerbated when patients are also receiving nonselective β-blockers such as propranolol. The syndrome is treated by readministration of the drug and then gradual

discontinuation or the intravenous infusion of labetalol in an emergency. Clonidine is still used occasionally and can be effective in some patients with resistant hypertension. Extended-release formulations of clonidine are now available.

A newer centrally acting agent, *moxonidine,* is an imidazoline receptor agonist that reduces sympathetic outflow and BP. It has a lower incidence of side effects and is better tolerated than other centrally acting agents. Moxonidine has no clinical trial evidence to support its use as a preferred first-line agent but is used empirically in some patients intolerant of other agents or in resistant hypertension.

Direct Vasodilators

Hydralazine is no longer recommended as a first-line agent for hypertension management. The main disadvantages of hydralazine are sympathetic activation and the development of a lupus-like syndrome, particularly in patients with the slow acetylator genotype. Also, multiple daily dosing is required. It is still very occasionally used in severe hypertension and hypertension associated with pregnancy.

Minoxidil is a potent vasodilator, and its use is largely confined to occasional use in specialist centers for the treatment of severe and resistant hypertension. Its side effect profile includes stimulation of body hair growth; tachycardia and severe fluid retention reflect its potent vasodilator action and concomitant reflex SNS activation. For this reason, minoxidil is usually combined with a potent loop diuretic and a β-blocker as part of a triple-therapy approach to severe hypertension. Long-term use can be associated with insidious development of peritoneal and pericardial effusions (especially in patients with impaired kidney function), which usually respond to treatment withdrawal.

Emerging Drug Therapies for Hypertension

ARB/Neprilysin Inhibition

Treatment with an angiotensin receptor neprilysin inhibitor (ARNI; e.g., sacubitril) has become well established in heart failure and improves patient outcomes compared with prior standard of care.[26] The ARNI effectively lowers BP over 24 hours, especially nocturnal BP, and is more effective than ARB alone.[27,28] The BP lowering effect relates to the mechanism of action whereby neprilysin (NEP) inhibition blocks the breakdown and potentiates the actions of natriuretic peptides, producing a diuretic and vasodilator action that is augmented by concomitant RAS blockade with the ARB component. Although the ARNI has not been widely promoted to treat hypertension, there is ample data showing its efficacy at BP lowering, and it has the potential to be a highly effective and well-tolerated treatment, either alone or in combination with either a CCB and/or thiazide diuretic.

Sodium-Glucose Cotransporter-2 Inhibitors

These drugs (e.g., empagliflozin and dapagliflozin) were developed as treatments to lower blood glucose in patients with diabetes by inhibiting the active proximal convoluted tubular reabsorption of glucose via inhibition of sodium-glucose cotransporter-2 (SGLT2). Thus, SGLT2-inhibition also inhibits the proximal tubular reabsorption of sodium, promoting natriuresis, particularly if additional diuretics are present. This inevitably results in significant reductions in BP that are rarely commented upon but have been clearly documented.[29,30] It is likely that the natriuresis and BP-lowering effects of SGLT2 inhibition have contributed to improved CV outcomes and kidney outcomes in patients with diabetes, and heart failure outcomes in patients with and without diabetes.[30-32] In the context of difficult-to-control hypertension, especially in patients with diabetes, SGLT2 inhibition may complement and enhance the BP-lowering effect of other agents, even though not formally recommended for this purpose.

An intriguing aspect of treatment with drugs with diuretic actions that promote natriuresis is that they seem to be particularly effective at reducing nocturnal BP.[28] This is often not appreciated as nocturnal BP is rarely recorded unless ABPM is performed. However, this may be important because nocturnal BP is the most powerful predictor of adverse outcomes and death in patients with hypertension and is more likely to be elevated in high-risk patients with diabetes and/or CKD, perhaps because of their predisposition to sodium retention.

Hypertension Treatment Strategies

Despite decades of guidelines for the treatment of hypertension, the control of BP has remained lamentably poor, with typically fewer than 50% of treated patients achieving optimal BP control.[33] This relates to a number of factors that have been inadequately appreciated: (1) the complexity of guidance and overemphasis on specific indications for individual drug therapies versus the overriding importance of getting BP controlled; (2) treatment inertia (i.e., the slow uptitration of therapy and/or failure to escalate treatment by combining drugs to achieve BP control); and (3) poor recognition of the fact that poor adherence to therapy, especially multipill therapy, was a major factor in poor BP control; that is, the BP was not so much resistant to treatment as the patient was resistant to taking multiple drugs.

Recent iterations of the US and European guidance have aligned and dramatically shifted their approach by advocating the following:

1. Similar preferred drug classes for the routine treatment of hypertension, ACE inhibition or ARBs, CCBs, thiazide/thiazide-like diuretics (the US guidance specifically prefers chlorthalidone).
2. Simple and pragmatic treatment algorithms based on treatment with RAS blockade (ACE inhibition or ARB) as the foundation of therapy for most patients, in combination with a CCB and/or a thiazide/thiazide-like diuretic, or all three when required.
3. Initial therapy with two drugs, that is, RAS blockade plus a CCB or thiazide/thiazide-like diuretic for most patients when BP is 140/90 mm Hg or higher and certainly when 20/10 mm Hg or higher above the intended target—the exceptions being the frail elderly where monotherapy may be preferred, or patients with BP just above 140/90 mm Hg, when monotherapy may be sufficient. This recommendation effectively normalizes initiating therapy with two drugs for most people with hypertension.
4. Single-pill combination therapy for dual- and triple-drug therapy, when available at reasonable cost, to reduce the pill burden and improve patient adherence. The European guideline specifically advocates a "single-pill strategy" to treat hypertension.[7]
5. A three-drug combination (i.e., RAS blockade plus CCB plus thiazide/thiazide-like diuretic when the two-drug combination is insufficient).
6. Further diuretic therapy (usually spironolactone unless contraindicated) if further treatment is required (i.e., in resistant hypertension; see "Resistant Hypertension" section).
7. Use β-blockers when there is a guideline-directed indication for their use (e.g., in patients with symptomatic angina, heart failure with reduced ejection fraction, or in patients with atrial fibrillation to facilitate rate control) (Fig. 37.3). The US guidance does not contain a formal treatment algorithm, but the guidance in the US and Europe is very consistent on the treatment strategy[8] (Table 37.9).

Initial Therapy With a Two-Drug Combination

The lower BP targets recommended in current guidelines makes two-drug combinations almost inevitable for the majority of patients as initial therapy, with the preferred combinations RAS blockade plus diuretic or RAS blockade plus CCB. This will often be a "low-dose" two-drug combination therapy. The recommendation of a two-drug

TABLE 37.9 US Guidance for Approach to Drug Therapy for Hypertension

Grade	LOE	Recommendation
Recommendation for Choice of Initial Medication		
I	A	For initiation of antihypertensive drug therapy, first-line agents include thiazide diuretics, CCBs, and ACE inhibitors or ARBs.
Recommendation for Choice of Initial Monotherapy Versus Initial Combination Drug Therapy		
I	C	Initiation of antihypertensive drug therapy with two first-line agents of different classes, either as separate agents or in a fixed-dose combination, recommended in adults with stage 2 hypertension and an average BP >20/10 mm Hg above their BP target.
IIa	C	Initiation of antihypertensive drug therapy with a single antihypertensive drug reasonable in adults with stage 1 hypertension and BP goal <130/80 mm Hg with dosage titration and sequential addition of other agents to achieve BP target.

ACE, Angiotensin-converting enzyme; *ARBs,* angiotensin receptor blockers; *LOE;* level of evidence.

From Whelton PK, Carey RM, Aronow WS, et al. ACC/AHA/AAPA/ABC/ACPM/AGS/APhA/ASH/ASPC/NMA/PCNA Guideline for the Prevention, Detection, Evaluation, and Management of High Blood Pressure in Adults: A Report of the American College of Cardiology/American Heart Association Task Force on Clinical Practice Guidelines. *J Am Coll Cardiol.* 2018;71(19):e127–e248. Erratum *J Am Coll Cardiol.* 2018;71(19):2275–2279.

combination is in part driven by concern that the upward titration of treatment in people at high risk may be too slow and leave them at risk for too long. A two-drug combination is also logical because the response to a single drug is often limited by counteractivation of pressor systems. This also explains why many BP-lowering drugs in monotherapy have a relatively flat dose-response curve. For example, sodium and water loss caused by diuretics or vasodilation with CCBs will activate the renin-angiotensin-aldosterone system, which limits the BP lowering. Thus, a two-drug combination as initial therapy (1) will produce much greater BP lowering than even the most effective monotherapy; indeed, studies have shown this approach is twice as effective as monotherapy at achieving BP control within 3 to 4 months[34]; (2) will reduce heterogeneity in the BP-lowering response, ensuring that all patients get a response because more than one mechanism is being targeted by a two-drug approach; and (3) will cause the dose-response to be steeper to upward titration of either component because counterregulatory mechanisms are blocked.

The main concern has been adverse events related to potentially large initial BP falls in treatment-naïve patients, but in practice this has not been a major problem, even in older patients, and guidelines already highlight the one group where there may be a need for a more cautious approach to lowering BP (i.e., frail older patients). Ironically, adverse effects may actually be minimized rather than enhanced by the recommended combinations of therapy (i.e., less CCB-mediated peripheral edema) or diuretic-induced hypokalemia when either is combined with RAS blockade.

Further advantages of combination therapy. Now that the major classes of antihypertensive therapy recommended by guidelines are available as generic agents, the costs have reduced substantially, and the same is true for single-pill combinations of two drugs as well

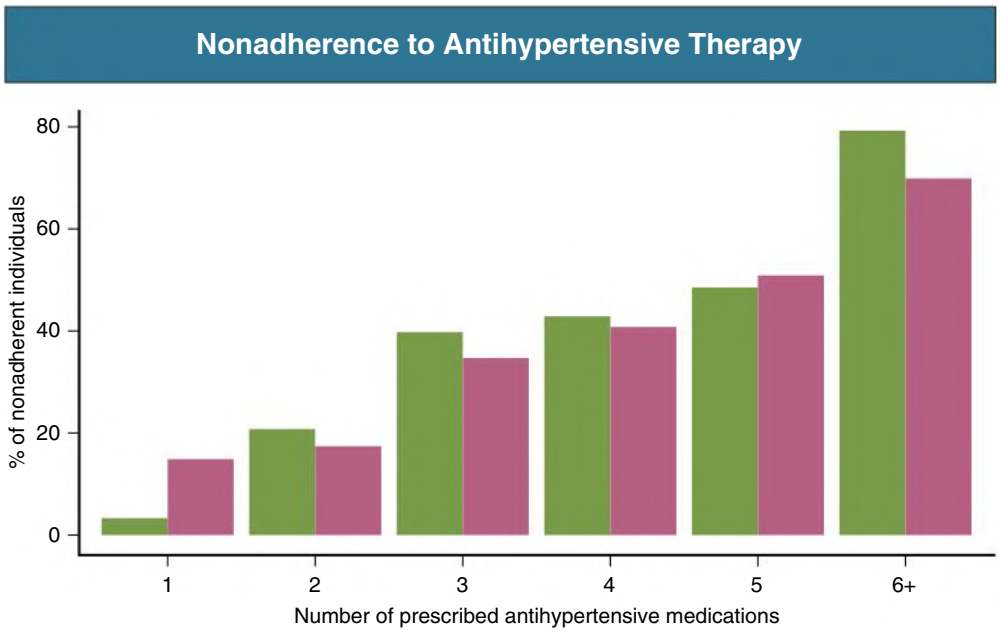

Fig. 37.4 Nonadherence to Antihypertensive Therapy According to Number of Antihypertensive Medications, as Detected by Urine Drug Testing. *Green bars* denote data from the United Kingdom; *red bars* denote data from the Czech Republic. (Modified from Gupta P, Patel P, Štrauch B. Risk factors for nonadherence to antihypertensive treatment. *Hypertension.* 2017;69[6]:1113–1120.)

as two drugs. This makes guideline implementation more feasible globally, especially for single-pill combinations, because the number of pills used to treat hypertension is inversely related to patient adherence[35] (Fig. 37.4). If a patient's BP is not controlled on three or more drugs, then poor adherence to at least some of the drugs should be considered and excluded as a likely cause of the poor treatment response. The converse is also true; that is, if the patient receives two or three drugs as a single-pill combination, then they are more likely to be adherent to their therapy and are more likely to achieve their BP treatment target.

Registry data shows that patients starting treatment with a two-drug combination are more likely to achieve BP control faster and more likely to escalate to a three-drug combination if needed compared with patients starting treatment with monotherapy and a traditional stepped care approach, many of whom remain on monotherapy despite inadequate BP control. This indicates that the two-drug initial therapy approach, especially with a single-pill combination, is effective at overcoming clinical inertia[36,37] (Fig. 37.5).

Finally, whereas no RCTs have compared initial combination therapy versus a standard stepped care approach, large-scale registry studies have suggested that initial combination therapy for hypertension is associated with improved CV outcomes compared with a standard initial monotherapy, stepped care approach, most likely due to faster and more effective BP control with the combination therapy[38] (Fig. 37.6).

Triple or quadruple low-dose combination therapy as initial therapy for hypertension. Enthusiasm for low-dose combinations of therapy involving multiple drugs is growing, fueled by the philosophy that targeting multiple pressor mechanisms simultaneously produces more effective BP lowering, and that most BP lowering and fewer side effects occur when drugs are used in low dose. Indeed, studies thus far have found that a pill containing four agents (quad pill) in low dose is more effective at lowering BP than standard dose monotherapy,[39] but what has not been studied is whether the quad pill would be more effective than low-dose dual therapy, which is now becoming the standard of care and is also much more effective than standard dose monotherapy. Thus, low-dose combination of three or four drugs is considered experimental and not currently recommended.

Combining Renin-Angiotensin System Blockade Is Not Recommended

The view that RAS blockade may help prevent or regress hypertension-mediated structural and functional damage led to the use of dual RAS blockers. However, data from numerous trials has demonstrated that dual RAS blockade was no more effective than RAS blocker monotherapy at preventing major CV events in high-risk populations, including those with diabetes,[6,7] but increased the risk for adverse events, especially kidney impairment. These findings have prompted all international guidelines to state that dual RAS blockade should not be used to treat hypertension.

Resistant Hypertension

Standardizing the routine treatment of hypertension has also helped refine the definition of resistant hypertension (RH). RH is defined as a BP that remains above target despite the concurrent use of three guideline recommended antihypertensive agents, usually a RAS blocker plus CCB plus thiazide/thiazide-like diuretic in optimal or maximum tolerated doses. The US guidance also includes patients with controlled BP when four different drugs have been required to achieve BP control. The definitions emphasize that causes of "pseudoresistant" or "apparent resistant" hypertension should be excluded. These include (1) ensuring proper measurement of office BP with an appropriately sized cuff (note that a cuff that is too small for the arm can lead to overestimation of BP); (2) the use of ABPM or home BP to exclude a significant white coat effect, which elevates BP only in the doctors' office setting; and (3) exclusion of nonadherence to therapy. Finally, secondary causes of hypertension, such as primary aldosteronism and renovascular disease, should be excluded. Other causes of resistant hypertension also should be considered (Table 37.10). Once this screen is complete, analysis of recruitment into clinical trials of patients with resistant hypertension has consistently shown that as many as 9 out of 10 patients originally considered to have resistant hypertension are excluded, principally because of suboptimal therapy, controlled BP on ABPM or home measurements, or nonadherence to their prescribed therapy. Most patients with resistant hypertension are older, obese, and/or have evidence of target organ damage.[40-42]

TABLE 37.10 Considerations in the Patient With Resistant Hypertension

Patient Factors	Secondary Causes of Resistant Hypertension	Concomitant Medications That May Raise BP	Causes of "Pseudoresistant Hypertension"
Demographics	Common causes	Prescription	Poor patient adherence to medications
Older age, especially >75 y	Primary hyperaldosteronism (Conn adenoma)	Oral contraceptives	Check BP response to directly observed medication
Obesity	Atherosclerotic renovascular disease	NSAIDs	Errors in BP Measurement
Women > men	Sleep apnea	Sympathomimetics (e.g., decongestants in cold remedies)	Including BP cuff too small for arm circumference
More common in Blacks	CKD	Cyclosporine	White coat hypertension
Excess dietary sodium	Uncommon Causes	Erythropoietin	Check BP with ABPM or home BP measurements
High baseline BP and chronicity of uncontrolled hypertension	Pheochromocytoma	Corticosteroids (e.g., prednisone, hydrocortisone)	
Concomitant Disease	Aortic coarctation	Nonprescription	
Target organ damage: LVH or CKD	Cushing disease	Drug abuse (e.g., cocaine, amphetamines)	
Diabetes	Hyperparathyroidism	Excess licorice ingestion	
Atherosclerotic vascular disease		Herbal remedies (e.g., ephedra, also known as ma huang)	
Aortic stiffening			

ABPM, Ambulatory blood pressure monitoring; *BP,* blood pressure; *CKD,* chronic kidney disease; *LVH,* left ventricular hypertrophy; *NSAIDs,* nonsteroidal antiinflammatory drugs.
Modified from Williams B. Resistant hypertension: an unmet treatment need. *Lancet*. 2009;374:1396–1398.

The PATHWAY-2 study of resistant hypertension showed resistant hypertension is most commonly a sodium-retaining state with an inappropriately suppressed plasma renin level, despite background treatment with diuretic therapy and other drugs (i.e., CCB and RAS blockade) that would be expected to raise plasma renin.[19] This has two important therapeutic implications: (1) there should be increased emphasis on dietary sodium restriction, and (2) treatment with further diuretic therapy is likely to be the most effective additional therapy as the fourth-line drug treatment for RH. This was tested and most convincingly proven in the PATHWAY-2 study, which showed that low-dose spironolactone (25 mg daily, titrated to 50 mg daily) was the most effective drug at lowering BP compared with placebo, a β-blocker (bisoprolol), or α-blocker (doxazosin).[17] This emphasizes a key point: although spironolactone is a relatively weak diuretic as a sole agent, when combined with other diuretics acting at a different site in the nephron (as in the treatment of resistant hypertension on a background of thiazide/thiazide-like diuretic), this multisegment nephron blockade can be highly effective at offloading sodium in sodium-resistant states. It is also conceivable that spironolactone was particularly effective because some of these patients may have undetected primary aldosteronism.

However, the PATHWAY-2 study was conducted in patients with normal GFR, and careful monitoring for hyperkalemia is required when using spironolactone, especially in patients with a baseline potassium level above 4.5 mmol/L or GFR less than 45 mL/min/1.73 m^2. shiftenterA more recent study in patients with advanced CKD (GFR 25 to ≤45 mL/min/1.73 m^2) and resistant hypertension (the AMBER study) evaluated whether coadministration of patiromer (as potassium-binding polymer) with spironolactone could facilitate the safer use of spironolactone in these patients.[43] The study showed that hyperkalemia with spironolactone occurred much less commonly (1%) in patients coadministered patiromer versus spironolactone (7%), and BP was lowered significantly after the addition of spironolactone in these patients. The PATHWAY-2 study showed that amiloride in higher doses that were usually administered (10–20 mg daily) was as effective at spironolactone at lowering BP in resistant hypertension,[19] but as with all potassium-sparing diuretics, similar caution is needed with respect to potassium levels. Other theoretical (but not proven) alternatives to spironolactone for treatment of resistant hypertension include eplerenone, higher doses of thiazide-type diuretics, loop diuretics in place of thiazide diuretics in patients with GFR less than 45 mL/min/1.73 m^2, the newer generation of nonsteroidal mineralocorticoid receptor antagonists, or even potentially newer drugs with multinephron segment diuretic actions such as ARNIs and SGLT2 inhibitors (see earlier).

Finally, treatments beyond further diuretic therapy may be effective for some patients with RH; for example, both doxazosin and bisoprolol did lower BP more effectively than placebo in the PATHWAY-2 study, though not as effectively as spironolactone. Alternatively, clonidine has also been shown to be effective at lowering BP in RH.[44] For patients where all else has failed, it may be necessary to resort to a combination of minoxidil, loop diuretic, and β-blocker to improve BP control.

Pharmacologic Treatment of Hypertension With Specific Comorbidities or in Specific Patient Groups

Hypertension With Diabetes, or Cerebrovascular Disease, Peripheral Vascular Disease, or Hypertension-Mediated Organ Damage

The core drug treatment algorithm in the European guidance (Fig. 37.3) is recommended for patients with uncomplicated hypertension, those with hypertension-mediated organ damage (e.g., LVH), or those with diabetes, cerebrovascular, or peripheral vascular disease.[7] The only caveat is that the core algorithm may need to be modified in those with other comorbidities such as coronary artery disease (CAD), heart failure, or significant CKD (see later). The US guidance[6] does not show a specific treatment algorithm but instead emphasizes which drug classes have compelling indications for specific clinical comorbidities—this generally leads to similar treatment as the European guidance for these conditions.

Hypertension in Patients With Coronary Artery Disease

All guidance acknowledges that in hypertensive patients with stable CAD, RAS blockers and β-blockers may improve outcomes post-MI, and that in patients with symptomatic angina, β-blockers and CCBs would be preferred components of the drug treatment strategy. Thus, combination therapy for patients with stable CAD differs little from the core treatment strategy, except for the addition of β-blockers as required.

Hypertension in Patients With Heart Failure

Heart failure with reduced ejection fraction (HFrEF) or preserved ejection fraction (HFpEF) are common consequences of long-standing

hypertension. Patients with HFrEF and hypertension should already be treated with guideline-directed therapy for their heart failure, including ACE inhibitors or ARBs, β-blockers, and mineralocorticoid receptor antagonists (e.g., spironolactone and eplerenone). If further BP lowering is required, thiazide/thiazide-like diuretics or DHP CCBs may be considered. ARNI therapy (sacubitril/valsartan) lowers BP (see earlier) and improves outcomes in patients with HFrEF, and it is indicated for the treatment of HFrEF as an alternative to ACE inhibitors or ARBs. In addition, SGLT2 inhibitors improve outcomes for patients with HFrEF (both diabetic and nondiabetic patients) and also more recently in HFpEF, and they may be considered for patients with heart failure to further reduce BP if required. Non-DHP CCBs (diltiazem and verapamil), α-blockers, and centrally acting agents, such as moxonidine, should not be used in patients with heart failure.

BP lowering is commonly required in patients with HFpEF. Effective treatments for HFpEF are less clearly defined, and in most patients, treatment will follow similar principles to the treatment of HFrEF. If volume overload is present, diuretics will be required.

Hypertension in Patients With Chronic Kidney Disease

There is consensus that RAS blockade should be part of drug treatment for hypertension in patients with CKD, especially when albuminuria or proteinuria are present.[6,7,9] This would usually be prescribed with a CCB or diuretic, the latter specifically required when volume overload is evident, but required in most patients with more advanced CKD when three or more drugs may be required to control BP. Other key considerations are that (1) thiazide/thiazide-like diuretics often become less effective when eGFR is less than 45 mL/min/1.73 m^2 and certainly when less than 30 mL/min/1.73 m^2, and will need to be replaced with a loop diuretic if a diuretic is required; and (2) hyperkalemia becomes more of a concern, especially with potassium-sparing diuretics when eGFR is less than 45 mL/min/1.73 m^2 or baseline potassium levels are greater than 4.5 mmol/L.

Hypertension in Women

For a detailed discussion of this topic, the reader is referred to the US and European guidance,[6,7] but it is important to highlight some specific considerations: (1) oral contraceptives (OCP), particularly those containing estrogen, may result in a significant rise in BP in about 5% of women, and thus BP should be carefully monitored and an alternative OCP formulation or form of contraception will usually be required in those who develop significant elevations of BP; (2) menopause is associated with an increased risk of hypertension, and the presence of hypertension is not a contraindication to hormone replacement therapy, provided that BP can be controlled; (3) in patients who are hypertensive and planning a pregnancy (i.e., prepregnancy hypertension), careful consideration should be given to whether BP medication is needed before consensus; when treatment is required, RAS blockers should be avoided, and the safest options are methyldopa, labetalol, or CCBs; there is controversy about whether diuretics should be used; and (4) postpregnancy, prescribers should refer to local formulary guidance regarding which drugs are safe to use when breastfeeding.

Hypertension in People of Black African Origin

Hypertension is more prevalent in Black patients, is associated with more target organ damage, and carries a worse prognosis, with a particularly high risk for stroke.[45] Black patients tend to respond better to diuretics, CCBs, and dietary salt restriction than White patients. ACE inhibitors, ARBs, and β-blockers are generally less effective as initial therapy in Black patients but become more effective in combination with diuretics or CCBs. When a RAS blocker is used as part of the treatment strategy, an ARB may be preferred because of the increased risk for angioedema with ACE inhibitors in Black patients.

Hypertension in Older People

If a BP of 140/90 mm Hg or higher is used to define hypertension, more than 70% of people older than 60 years will be hypertensive—most of these patients having isolated systolic hypertension (ISH). Surveys suggest that physicians consistently underestimate the risks and undertreat hypertension in older people. However, important considerations in treating older people include the following:

1. The arterial wall stiffening that gives rise to systolic hypertension and increased pulse pressure is also associated with impaired baroreflex sensitivity with increased risk for orthostatic hypotension. Thus, it is important to record lying and standing BP readings in elderly patients. However, contrary to popular perception, BP-lowering therapy has not been associated with increased risk of falls, even with lower BP goals now being advocated.
2. GFR declines with age, and older patients are more susceptible to reductions in GFR with BP lowering. In addition, they also often have impaired kidney conservation of sodium and fluid and may be more susceptible to volume depletion as a result of diuretic therapy.
3. Clearance of drugs and their active metabolites is decreased as a result of reduced hepatic and kidney function.
4. Cardiac function and reserve are often reduced, and patients are therefore much more likely to develop cardiac failure. Trials in elderly patients have consistently shown that treatment of hypertension reduces morbidity and mortality from cardiac failure.
5. Multiple comorbidities are much more common with advancing age, and this heterogeneity of patients means that actual age is a less important determinant of an individual patient's tolerability of BP lowering than their functional independence.
6. Communication and adherence with therapy may be more difficult with decline in cognitive function.

Despite these considerations, age should never be considered a contraindication to treatment, as most older patients will generally tolerate BP-lowering medications well, and BP reduction leads to substantial benefits, reducing the risk for stroke, coronary events, heart failure, and possibly dementia.[46] As a general rule, dosages should be increased more gradually and monotherapy initiation should be considered in older patients who are frail. Therapy needs to be tailored to individuals, remembering that elderly participants in clinical trials tend to be fitter and more independent than the many millions of elderly patients to whom guidelines are applied. However, it is reassuring for patients and families that the benefits are substantial if effective BP lowering can be achieved and is tolerated. Finally, there is a paucity of data with regard to treatment strategies for the most frail and dependent elderly patients, often with limited life expectancy, which in many cases is unlikely to be influenced by treatment of hypertension. Treatment decisions for such patients have to be individualized in consultation with the patient, family, and carers.

Concomitant Medication to Reduce Cardiovascular Risk

Treating hypertension should be considered part of a more comprehensive strategy to reduce CVD risk. Various tools to assess CVD risk, usually over a 10-year time frame, are available. The proposed level of CVD risk considered sufficient to warrant additional interventions has been progressively reduced toward 10% CVD risk over 10 years, and more recently, estimation of lifetime risk has been advocated.[47] Patients at high risk (i.e., with established CVD, organ damage, or diabetes or with a high calculated CVD risk) should be considered for additional interventions to reduce risk (i.e., reinforcement of lifestyle advice, especially smoking cessation). In addition, routine use of statins to reduce total cholesterol values by 40 mg/dL (~1 mmol/L) reduces the risk for coronary events by about one-third and for stroke by about one-fifth above the benefit already accrued from BP lowering.[48,49] Moreover, this risk reduction associated

with statin therapy is not dependent on a high baseline cholesterol value. Hypertensive patients should be considered for treatment with antiplatelet drugs once BP has been controlled for secondary prevention (i.e., in those with established CVD or cerebrovascular disease).

Follow-up

In the early stages of treatment, the frequency of monitoring will be determined by the patient's response to therapy, the comorbidities, and the complexity of the treatment regimen required to control the BP. After initiating therapy, patients should be reviewed frequently to adjust treatment, monitor for adverse effects, and establish BP control. Once BP is controlled, patients should be reevaluated at least annually for a formal review, and most will be reevaluated every 6 months. Patients are increasingly monitoring their own BP between appointments, and this trend is likely to increase.

Withdrawal of Therapy

Most patients with hypertension require lifelong therapy. Some with milder hypertension who make major adjustments to their lifestyle may obtain sufficient fall in their BP to warrant safe withdrawal of monotherapy. However, patients with target organ damage or those at high CVD risk usually should not have their therapy withdrawn unless there is a compelling clinical reason.[6,7] In patients with previously severe hypertension that has subsequently been well controlled, treatment withdrawal may not result in an immediate increase in BP, which can sometimes take many months to return to dangerously high values. Any patient who discontinues therapy must remain under review with regular BP monitoring. All but a very few will require treatment again.

Indications for Specialist Referral

Referral to a specialist center is sometimes indicated for the patient in management of hypertension. Indications include uncertainty about the decision to treat, investigations to exclude secondary hypertension, severe and complicated hypertension, and resistant hypertension (Box 37.1).

BOX 37.1 Patient Characteristics That Should Raise Suspicion of Secondary Hypertension, and/or Circumstances That Should Prompt Consideration of Patient Referral to a Specialist Center for Further Evaluation

- Younger patients (<40 years) with grade 2 hypertension or onset of any grade of hypertension in childhood
- Acute worsening of hypertension in patients with previously documented chronically stable normotension
- Resistant hypertension (BP uncontrolled despite treatment with optimal best-tolerated doses of three or more drugs including a diuretic, and confirmed by ABPM or HBPM)
- Severe (grade 3) hypertension or a hypertension emergency
- Presence of extensive HMOD
- Clinical or biochemical features suggestive of endocrine causes of hypertension or CKD
- Clinical features suggestive of an OSA
- Symptoms suggestive of pheochromocytoma or family history of pheochromocytoma

SELF-ASSESSMENT QUESTIONS

1. Which of the following statements is *true* about combination therapy for the treatment of hypertension?
   - **A.** Combination therapy with two drugs is recommended as initial therapy only for patients younger than 65 years.
   - **B.** There are three- or four-drug single-pill combinations now available, which are recommended as initial therapy for patients with hypertension.
   - **C.** The recommended combinations of drug therapy for most patients with hypertension usually involve a RAS blocker combined with a CCB or diuretic.
   - **D.** Single-pill combination therapy is associated with worse adherence with therapy than free combination of the same drugs.
   - **E.** Combinations of an angiotensin-converting enzyme inhibitor and ARB are recommended for some specific patient groups with hypertension.
2. Which of the following statements is *true* of recommended BP targets for treated hypertensive patients?
   - **A.** Lowering BP to at most 140/90 mm Hg in all treated patients, if tolerated, is recommended by all guidelines.
   - **B.** The US guideline recommends routinely lowering BP to less than 120/80 mm Hg in high-risk patients.
   - **C.** The evidence for optimal BP targets is stronger for diastolic versus systolic BP.
   - **D.** All guidelines recommend the routine use of ambulatory or home BP monitoring for checking BP control in all patients.
   - **E.** The BP targets are similar for office, home, and ambulatory BP measurements.
3. Which of the following statements is *true* of drugs used to treat hypertension?
   - **A.** Thiazide diuretics are more effective than thiazide-like diuretics at lowering BP.
   - **B.** RAS-blocking drugs are suitable treatment for women of childbearing potential, either alone or as part of combination treatment, as long as they are discontinued by the third trimester in pregnant women.
   - **C.** β-Blockers are only used for specific guideline-directed indications and are especially effective as part of combination therapy in reducing the risk for stroke in older patients.
   - **D.** CCBs are less likely to reduce BP variability compared with other drug classes, especially in older patients.
   - **E.** Angiotensin receptor-neprilysin inhibitors are significantly more effective at lowering BP than ARBs alone.
4. Which of the following statements is *true* for RH?
   - **A.** RH is common, affecting approximately 30% of treated patients.
   - **B.** When patients are thoroughly investigated, RH is usually found to be due to a secondary cause of hypertension.
   - **C.** RH is more common in younger patients.
   - **D.** It is only rarely possible to control BP in RH with additional drug therapy.
   - **E.** RH is most effectively treated with further diuretic therapy.

Evaluation and Treatment of Hypertensive Urgencies and Emergencies

Pantelis A. Sarafidis, George L. Bakris

Severe elevations in blood pressure (BP) can present as hypertensive emergencies or hypertensive urgencies.[1–3] A *hypertensive emergency* is defined as severe elevation in BP associated with evidence of new or worsening target-organ damage, such as coronary ischemia, dissecting aortic aneurysm, pulmonary edema, acute kidney failure, papilledema, hypertensive encephalopathy, cerebral hemorrhage, and eclampsia. In these cases, both the rate and magnitude of an increase in BP are at least as equally important to the absolute BP level in determining the magnitude of organ injury. As such, although in most of these cases BP is usually greater than 180/120 mm Hg,[1,2] there is no specific BP threshold to define hypertensive emergencies, and previously normotensive subjects can present with hypertension-mediated organ damage at lower BP levels.[3] Hypertensive emergencies require immediate and careful intervention to reduce BP (not necessarily to normal), preferably with intravenous (IV) drug therapy in an intensive care unit (ICU) to limit further target-organ damage.[1–3] A *hypertensive urgency* is the clinical situation of a patient who presents with severe BP elevation without acute or impending target organ dysfunction. These patients require a gradual BP reduction within hours with oral medications and do not normally require hospitalization.[1,2,4]

The term *malignant hypertension* first appeared in 1928 and described patients with extremely high BP values to emphasize that because of rapid target organ damage, their average prognosis was similar to that of most cancer patients.[5] Subsequently, malignant hypertension is used to describe patients with greatly elevated BP and vascular damage that manifests as the bilateral presence of retinal flame hemorrhages and/or papilledema, which can be accompanied by encephalopathy, acute kidney injury, or thrombotic microangiopathy.[2,3,6] Dramatic advances in both in-hospital and outpatient treatment have led to an improved prognosis of such cases and a decrease in 1-year mortality from 80% in 1928 to 50% in 1955 and to less than 10% after 1990.[5,7]

ETIOLOGY AND PATHOGENESIS

Hypertensive emergencies and urgencies can develop de novo in normotensive individuals but usually complicate underlying primary or secondary hypertension.[4,8] Box 38.1 shows the most common clinical situations identified as hypertensive emergencies, along with cases of severe BP elevation without target-organ damage. In some hypertensive emergencies, an underlying condition is the clear cause of acute BP elevation. For example, in acute glomerulonephritis, renal crisis in patients with systemic sclerosis, and renal artery stenosis, severe BP elevations usually result from increased activity of the renin-angiotensin system (RAS). In pheochromocytoma, cocaine intoxication, or spinal cord injury, acutely elevated BP is the result of excess catecholamine release. In other patients, acute sustained elevations in BP itself are the etiologic factor, resulting in conditions such as hypertensive encephalopathy or severe hypertension with acute left ventricular failure and pulmonary edema. In some cases, however, it may be difficult to differentiate whether BP elevation is the cause or the result of a hypertensive emergency. For example, in a patient with intracerebral hemorrhage, an acute marked BP increase may be the primary cause; alternatively, a hemorrhage of other etiology (i.e., coagulation deficit) may have occurred, followed by BP elevation to preserve cerebral tissue blood supply. Thus, a careful diagnostic evaluation of hypertensive emergencies and urgencies is essential to guide proper treatment.

The most common clinical setting for hypertensive urgency is a patient with chronic hypertension (often undiagnosed, untreated, or uncontrolled) whose usual BP is greater than 180/120 mm Hg. In many of these patients, chronically elevated BP does not affect target organ perfusion because of *autoregulation,* which is the ability of blood vessels to dilate or constrict in response to changes in perfusion pressure and thereby maintain normal organ perfusion.[9,10] In the brain, autoregulation primarily preserves blood flow, whereas in the kidney, it preserves glomerular hydrostatic pressure. Arteries from normotensive individuals can maintain flow over a wide range of mean arterial pressures (70–170 mm Hg, reflecting systolic blood pressure [SBP] of around 90–200 mm Hg). Chronic BP elevations cause compensatory functional and structural changes in the arteriolar circulation and shift the autoregulatory curve to the right, which allows hypertensive patients to maintain normal perfusion and avoid excessive blood flow at higher BP levels (Fig. 37.1).[9,10] As such, most patients with chronically elevated BP greater than 180/120 mm Hg visiting the emergency department (ED) have no evidence of acute target-organ damage, and thus have hypertensive urgencies rather than emergencies.

The factors that lead to the severe and rapid BP elevation causing a hypertensive emergency are poorly understood. In some cases, the rapidity of the onset suggests a triggering factor (i.e., release of a humoral vasoactive factor) superimposed or not on preexisting hypertension. Most often, the hypertensive emergency is likely again a nonspecific consequence of chronically elevated BP, as with time, further structural and functional changes in cerebral and renal arterioles can lead to a progressive inability of the arterioles to autoregulate properly.[9–12] Calcium channel blockers (CCBs) may also paradoxically increase glomerular pressure because of their ability to impair the renal autoregulatory response if systemic BP is not controlled. One way or another, target organ damage occurs when the autoregulatory mechanisms cannot maintain normal perfusion pressures in certain vascular beds (especially the retina, brain, and kidney) when systemic BP rises markedly.[11–13] This results in high-shear forces causing extensive endothelial injury, with detachment and exposure of subendothelium to blood, and with activation of platelets and the coagulation cascade, leading to fibrin formation, increased vascular wall permeability, and vascular smooth muscle cell proliferation culminating in vasculopathy, occasionally with fibrinoid necrosis. Thrombotic microangiopathy may result after formation of platelet-rich

BOX 38.1 Common Hypertensive Emergencies and Urgencies

Acceleration of Chronic Hypertension
- With papilledema ± encephalopathy ± kidney failure
- With features of thrombotic microangiopathy (thrombocytopenia, hemolytic anemia, renal failure, ± papilledema, ± encephalopathy)

Cardiovascular Conditions
- Acute myocardial ischemia/infarction caused by coronary artery disease
- Acute left ventricular failure/pulmonary edema
- Acute aortic dissection
- Severe hypertension after coronary bypass or other vascular surgery

Kidney Conditions
- Acute or rapidly progressive glomerulonephritis
- Renovascular hypertension
- Renal crises from scleroderma or collagen vascular disease
- Severe hypertension after kidney transplantation

Neurologic Conditions
- Hypertensive encephalopathy
- Intracerebral hemorrhage
- Subarachnoid hemorrhage
- Cerebral embolism or atherothrombotic cerebral infarction
- Severe hypertension after thrombolysis for atherothrombotic stroke
- Acute head trauma
- Guillain-Barré syndrome

Excess Circulating Catecholamine Conditions
- Pheochromocytoma crisis
- Interactions of tyramine-containing foods with monoamine oxidase inhibitors
- Rebound hypertension after sudden withdrawal of centrally acting α_2-agonists (clonidine, methyldopa, or other)
- Use of sympathomimetic drugs (phencyclidine, phenylpropanolamine, cocaine, or other)
- Automatic hyperreflexia after spinal cord injury

Pregnancy-Related Condition
- Severe preeclampsia/HELLP syndrome
- Eclampsia

Surgical Conditions
- Severe hypertension in patients requiring immediate surgery
- Perioperative hypertension
- Epistaxis unresponsive to anterior/posterior packing

Hypertension Associated With Severe Burns

HELLP, Hemolysis, elevated liver enzymes, and low platelets.

thrombi with obliteration of the microcirculation, platelet consumption, and intravascular hemolysis because of trapping and destruction of erythrocytes within the fibrin network. Activation of hormonal systems and release of vasoactive substances (RAS, catecholamines, endothelin, vasopressin) may create a vicious cycle in which elevated BP can both cause and result from vascular injury.[3,4,13,14] In patients with hypertensive emergency, the typical structural kidney changes are onion-skin appearances of small arteries and arteriolar and glomerular collapse (Fig. 38.2) with electron-lucent widening of the subendothelial zone and wrinkling of the glomerular capillary walls, whereas fibrinoid necrosis of small arteries is less common.[15]

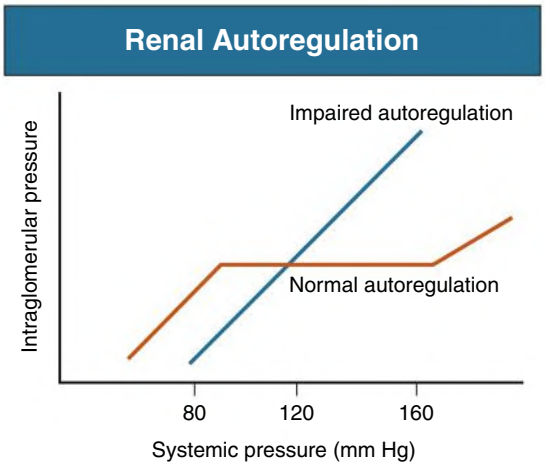

Fig. 38.1 Renal Autoregulation. Relationship of systemic to glomerular pressure in the setting of normal or abnormal renal autoregulation.

In normotensive or minimally hypertensive individuals, such as children or pregnant women, the symptoms and signs of a hypertensive emergency may occur at lower BP levels than in hypertensive patients because adaptive chronic microvascular changes are absent. In such cases, the rate and magnitude of BP increase are more important than the actual BP level, which may be lower than the commonly used threshold of 180/120 mm Hg.[12]

EPIDEMIOLOGY

The incidence of hypertensive emergencies and urgencies can be estimated from large observational studies of patients with hypertension. Among 333,407 patients visiting 10 EDs in Italy over a 1-year period, 1155 had a hypertensive urgency, defined as BP at or greater than 220/120 mm Hg (3.46/1000/year), and 391 patients had a hypertensive emergency (1.17/1000 visits/year).[16] The most common manifestations of hypertensive emergency were acute pulmonary edema (30.9%), stroke (22%), myocardial infarction (MI; 17.9%), acute aortic dissection (7.9%), acute kidney failure (5.9%), and hypertensive encephalopathy (4.9%). A systematic review of seven studies with variable definitions reported an incidence of hypertensive urgency between 1.64 and 24 patients/1000 ED visits/year and of hypertensive emergency between 1.17 and 7.6 patients/1000 ED visits/year.[17] Furthermore, a wide-scale retrospective analysis of the Nationwide Emergency Department Sample (NEDS), representing about 20% of all hospital-based ED visits in the United States, showed that both hypertensive emergencies and urgencies may be increasing. Between 2006 and 2013 the incidence of acute hypertension (diagnosed by International Classification of Diseases [ICD]-9 Clinical Modification [CM] coding) increased from 1.8 to 4.6/1000 ED visits/year, and the incidence of hypertensive emergencies increased from 0.7 to 1.7/1000 visits/year.[18] There is also evidence that hypertensive urgencies and emergencies are more common in middle- and low-income countries,[19,20] and in deprived urban populations and ethnic minorities of high-income countries,[21] that is, in patients who often have poor BP control.

People with a history of chronic kidney disease, coronary artery disease (CAD), or stroke also are at higher risk of hypertensive crises. Hypertensive emergency is more common in men, older individuals, and those with diabetes and hyperlipidemia.[22] Importantly, 24% of patients presenting with a hypertensive crisis are suggested to be completely nonadherent (none of the prescribed drugs detected

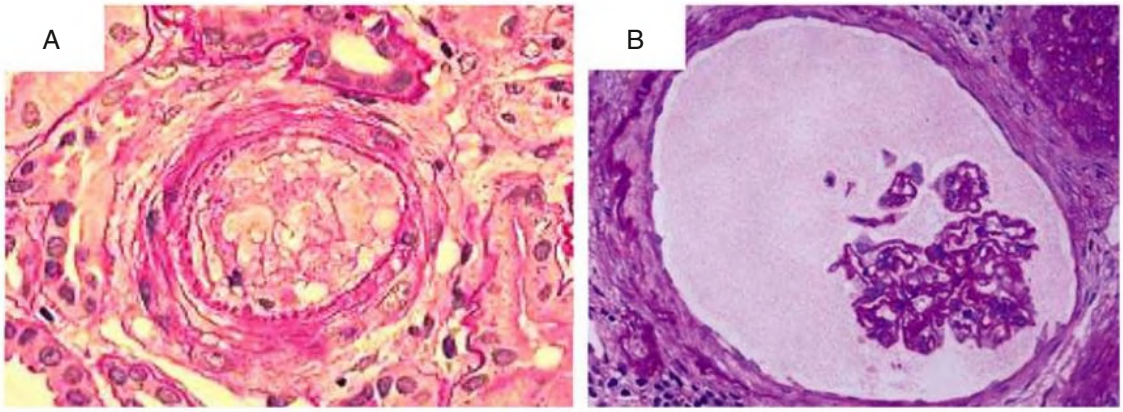

Fig. 38.2 Common Kidney Biopsy Findings in Patients With Hypertensive Emergency–Related Renal Dysfunction. (A) Concentric subendothelial edematous thickening ("onion skin" appearance) of an arteriole. (B) Collapsed glomerulus (PAS stain). (From Nonaka K, Ubara Y, Sumida K, et al. Clinical and pathological evaluation of hypertensive emergency-related nephropathy. *Intern Med*. 2013;52:45–53.)

in urine) and another 34% partially nonadherent to their prescribed treatment.[23] Another study in patients presenting with hypertensive urgency showed that 38% had skipped antihypertensive medications and 45% had pain of noncardiac origin.[24]

Hypertensive emergencies are associated with an increased risk for mortality, with an acute in-hospital mortality of 11% to 12.5% and a 1-year mortality of 38.9%. Mortality was greater in those who experienced neurologic or cardiovascular emergencies.[25,26] As expected, mortality associated with hypertensive urgency is lower (in-hospital mortality between 0.3%– and .8% and 1-year mortality of 8.9%).[25,26] With regards to kidney function, about 70% of patients with malignant hypertension have an estimated glomerular filtration rate (eGFR) of less than 60 mL/min/1.73m^2 at presentation; among these patients, 7% would need permanent kidney replacement therapy and another 20% to 25% would develop end-stage kidney disease (ESKD), requiring dialysis over long-term follow-up.[27,28]

DIAGNOSTIC EVALUATION

The primary goal of the diagnostic process is to differentiate a true hypertensive emergency from a hypertensive urgency because of the different therapeutic approaches. The second goal is rapid assessment of the type and severity of ongoing target-organ damage. In some hypertensive emergencies, the history (e.g., acute head trauma, preeclampsia, scleroderma) or overt symptoms and signs (e.g., chest/back pain, dyspnea, focal neurologic deficit, throbbing abdominal mass) may quickly guide the diagnosis; in patients with more general symptoms (headache, visual disturbances, dizziness, nausea, or altered mental status), however, the evaluation must be more comprehensive.

The diagnostic approach begins with the patient's history, with attention to duration, severity, and treatment of preexisting hypertension and associated conditions, and to adherence to prescribed agents and possible use of substances that increase BP[2–4,8] (Box 38.2). BP readings should be performed in both arms and a leg to detect BP differences caused by aortic dissection and, if possible, in both sitting and standing positions.[3] Repeated BP measurements should be performed at regular intervals because in one-third of patients with hypertensive urgencies, BP will fall considerably without antihypertensive drugs.[29] Physical examination of cardiac, pulmonary, peripheral vascular, and neurologic systems with assessment of mental status should follow. Funduscopic (ophthalmoscopic) examination should look for hemorrhages, exudates (cotton wool spots), and papilledema as a crucial part of the diagnostic process.[4,8,12]

BOX 38.2 Diagnostic Evaluation for Hypertensive Emergencies and Urgencies

History
- Previous diagnosis and treatment of hypertension
- Symptoms, previous diagnoses, and treatment of cardiac, cerebral, renal, and visual damage
- Intake of pressor agents: sympathomimetics, illicit substances

Blood pressure

Physical examination
- Cardiac
- Vascular
- Pulmonary
- Neurologic
- Optic fundi

Laboratory studies
- Complete blood count, creatinine, urea, electrolytes, urinalysis,
- Specific tests by indication: fibrinogen, LDH, schistocytes, urine microscopy for red blood cells and casts, urine albumin/creatinine ratio, troponin, CK-MB, NT-proBNP, pregnancy test
- Plasma renin activity, aldosterone, and catecholamines if secondary hypertension is suspected

12-Lead electrocardiogram

Chest radiograph

Further investigations (according to clinical presentation)
- Kidney ultrasound including assessment of renal artery flow with Doppler
- Brain CT scan or MRI
- Transthoracic echocardiography
- Thoracoabdominal CT scan or MRI

CK-MB, Creatinine kinase-MB fraction; *CT,* computed tomography; *LDH,* lactate dehydrogenase; *MRI,* magnetic resonance imaging; *NT-proBNP,* N-terminal pro-B natriuretic peptide.

This initial examination should not miss signs of secondary hypertension. An abdominal bruit may indicate renovascular hypertension; a pulsatile abdominal mass suggests abdominal aneurysm; palpable kidneys may be because of polycystic kidney disease; a radial-femoral pulse delay suggests aortic coarctation; abdominal striae and central obesity are observed with Cushing syndrome; and exophthalmos may indicate hyperthyroidism.

Initial laboratory studies in a hypertensive emergency include a complete blood count (CBC) with peripheral smear, urinalysis,

creatinine and urea concentrations, and electrolytes.[4,8,12] Comparison of kidney function with a patient's recent measurement is important. Further tests should be guided by clinical suspicion.[2] High troponin and creatine kinase-MB (CK-MB) or high N-terminal pro-hormone B-type natriuretic peptide (NT-proBNP) can guide the diagnosis of acute MI or decompensated heart failure (HF). Acute deterioration in kidney function, microscopic hematuria with red blood cell casts, or nephritic urine sediment suggest acute glomerulonephritis. Features of hemolytic anemia and thrombocytopenia characterize patients with malignant hypertension–associated TMA. Differentiating hypertension-induced TMA from thrombotic thrombocytopenic purpura (TTP) and hemolytic-uremic syndrome (HUS) can be difficult.[3,30] The coexistence of severe BP elevation and advanced retinopathy are helpful, along with the fact that malignant hypertension is usually accompanied by less pronounced thrombocytopenia and fewer schistocytes present in a peripheral blood smear than TTP and HUS; however, some cases would require measurement of ADAMTS13 and other tests.

If a secondary form of hypertension is suspected, samples for plasma renin activity, aldosterone concentration, and plasma-free catecholamines and metanephrines should also be drawn *before* initiation of treatment with the patient supine. If the patient is already receiving RAS inhibitors, diuretics, or β-blockers, the diagnostic accuracy of these tests changes considerably, and results should be interpreted with caution.

Electrocardiography to rule out myocardial ischemia and left ventricular strain or hypertrophy, as well as chest radiography, should be performed in every patient. Kidney ultrasound, with renal artery Doppler, if available, is also useful to rule out abnormalities such as differences in kidney size or perfusion,[31] especially in patients with reduced eGFR or with abnormalities on urinalysis.

Neurologic syndromes associated with hypertension, including subarachnoid hemorrhage, intracerebral hemorrhage, thrombotic stroke, and hypertensive encephalopathy, are difficult to distinguish from one another only by means of clinical examination. Computed tomography (CT) or magnetic resonance imaging (MRI) provides a definite diagnosis of a hemorrhagic or thrombotic stroke. Echocardiography, thoracoabdominal CT or MRI, or abdominal ultrasound may be needed in patients with suspected aortic dissection or pheochromocytoma.[2–4]

TREATMENT

General Principles and BP Treatment Thresholds for Hypertensive Emergencies

No randomized controlled trials (RCTs) examine the effect on hard outcomes of treatment strategies with different speed and degree of BP reduction for hypertensive emergencies, with the exception of acute stroke. Recommended strategies are based on consensus from clinical experience and observations on intermediate outcomes.[1–3] Nevertheless, clinical data document that lowering BP in hypertensive emergencies is beneficial: papilledema and exudates regress, hypertensive encephalopathy vanishes, pulmonary edema resolves, and kidney function improves. On the other hand, abrupt or excessive BP lowering may cause or contribute to cerebral, coronary, or renal ischemia. Oral loading of antihypertensive agents can have cumulative undesirable effects; the most typical example is use of sublingual nifedipine with potent but unpredictable decrease in BP that may shunt blood away from the cerebral penumbra, resulting in ischemic events.[32] Overall, understanding autoregulation and consideration of comorbidities, such as age and extent of vascular disease, are crucial for therapeutic decisions. Thus, the goal of therapy is not to normalize BP rapidly but rather to limit target-organ damage by gradually reducing BP, while minimizing the risk of tissue hypoperfusion.[11]

There are three major considerations before initiating treatment: (1) establishing whether there is a distinct cause of BP elevation (e.g., eclampsia, acute head trauma) or a distinct target-organ damage (acute MI, aortic dissection) that would require specific interventions in addition to BP lowering; (2) the timescale and magnitude of BP lowering required; and (3) the optimal type of drug treatment.[2] In hypertensive emergencies, IV treatment with a short-acting and easily titratable agent is recommended to allow tight control of BP response (Tables 38.1 and 38.2). This treatment may be initiated in the ED but should be continued in an ICU or a high dependency unit (HDU) to enable continuous BP/hemodynamic monitoring and continuous clinical surveillance.[1–3] A further consideration before initiation of IV therapy is assessment of the patient's volume status. With the obvious exceptions of patients presenting with volume overload and/or pulmonary edema, several patients with a hypertensive emergency may be volume depleted because of pressure natriuresis, and diuretics should not be used; rather, fluid administration may help restore organ perfusion and prevent a precipitous fall in BP.[4] Diuretics should be especially avoided in hypertensive emergencies caused by catecholamine excess states (pheochromocytoma, monoamine oxidase inhibitor crisis, cocaine intoxication) because these patients are usually volume depleted.

Current guidelines have minor differences with regards to the recommended timescale and magnitude of BP fall for major hypertensive emergencies.[1–3] The 2017 American College of Cardiology/American Heart Association (AHA/ACC) Guidelines recommend reducing BP by a maximum of 25% within the first hour to SBP/diastolic blood pressure [DBP] levels of 160/100 to 160/110 mm Hg over the next 2 to 6 hours and to normal over the next 24 to 48 hours in most patients. In patients with severe preeclampsia or eclampsia and those with pheochromocytoma crisis, SBP should be reduced to less than 140 mm Hg within an hour and in those with aortic dissection to less than 120 mm Hg in the same timeframe.[1]

The 2018 European Society of Cardiology/European Society of Hypertension (ESC/ESH) guidelines differ in recommending immediate BP reduction to less than 160/105 mm Hg in patients with severe preeclampsia or eclampsia and to SBP less than 140 mm Hg in those with acute coronary event and acute cardiogenic pulmonary edema.[2]

With regard to acute ischemic stroke, evidence from RCTs does not conclusively suggest a benefit from BP-lowering in short-term and midterm mortality risk and functional outcomes.[33] Therefore, current recommendations suggest that patients who are candidates for treatment with IV tissue plasminogen activator or mechanical thrombectomy should have their BP reduced to less than 185/110 before treatment.[1–3,34] For patients that are not candidates for such interventions and have BP greater than 220/120 mm Hg, most guidelines agree that the evidence is uncertain, but it is reasonable to reduce BP by 15% within the first 24 hours.[1,2,34] With regards to acute intracerebral hemorrhage (ICH), a previous RCT showed that lowering SBP to less than 140 mm Hg within an hour is safe and may improve functional outcome[35]; however, a subsequent RCT that examined BP lowering within 4.5 hours of an acute ICH found that treatment to SBP levels of 110 to 139 mm Hg did not lead to better outcomes compared with treatment to 140 to 179 mm Hg and was associated with more renal adverse effects.[36] Thus, in patients with acute ICH presenting with SBP levels greater than 220 mm Hg, BP should be lowered using IV drugs to goal levels of 140 to 180 mm Hg.[1,2]

After the BP has been controlled for a suitable period, typically 12 to 24 hours, which allows autoregulation to reestablish, the IV medication can gradually be reduced and replaced by oral agents. Typically, a dihydropyridine CCB, α- and β-blocker, or RAS blocker is used, depending on the suspected cause and possible ongoing investigations for secondary hypertension.[11]

Specific Aspects of Antihypertensive Drug Use for Hypertensive Emergencies

The need for gradual and tightly controlled BP reduction requires the use of IV drugs (see Table 38.1), the effects of which can be promptly reversed if the response is excessive. Previous systematic

TABLE 38.1 Pharmacologic Agents for Treatment of Hypertensive Emergencies

Drug	Mechanism of Action	Dose	Onset of Action	Duration of Action	Adverse Effects[a]	Special Indications
Vasodilators						
Nicardipine hydrochloride	Calcium channel blocker	Initial 5 mg/h IV; increase every 5 min up to 15 mg/h	5–15 min	15–30 min, may exceed 4 h	Tachycardia, headache, flushing, nausea, vomiting, local phlebitis	Most hypertensive emergencies except acute HF
Clevidipine butyrate	Calcium channel blocker	1–2 mg/h IV; increase every 5–10 min up to 16 mg/h	2–4 min	5–15 min	Tachycardia, headache, flushing, HF deterioration	Most hypertensive emergencies; caution with severe aortic stenosis
Isradipine	Calcium channel blocker	0.15 μg/kg/min IV, increase by 0.0025 μg/kg/min every 15 min Maintenance infusion 0.15 μg/kg/min	1–10 min	1–2 h	Headache, flushing, peripheral edema, dizziness, tachycardia	Perioperative, pregnancy
Fenoldopam mesylate	Dopamine-1 receptor agonist	Initial 0.1–0.3 μg/kg/min IV; increase by 0.05–0.1 μg/kg/min every 15 min up to 1.6 μg/kg/min	>5 min	30 min	Tachycardia, headache, nausea, flushing	Most hypertensive emergencies; caution with glaucoma
Sodium nitroprusside	↑ Cyclic GMP, blocks intracellular Ca^{2+} increase	Initial 0.25–0.5 μg/kg/min IV[b]; increase by 0.5 μg/kg/min up to 10 μg/kg/min	Immediate	1–2 min	Nausea, vomiting, muscle twitching, thiocyanate and cyanide intoxication, impaired cerebral autoregulation, coronary steal syndrome	Caution in situations associated with CNS manifestations, hepatic failure or renal failure; probably should be avoided if given other agents, especially fenoldopam
Nitroglycerin	↑ Nitrate receptors	Initial 5 μg/min IV; increase by 5 μg/min every 3–5 min up to 20 μg/min	2–5 min	5–10 min	Headache, vomiting, methemoglobinemia, tachyphylaxis, tolerance with prolonged use	Coronary ischemia, pulmonary edema
Enalaprilat	ACE inhibitor	Initial 1.25 mg over 5 min IV; increased up to5 mg every 6 h	15–30 min	6–12 h	Precipitous fall in BP in high-renin states, variable response, acute renal failure	Acute left ventricular failure; avoid in acute MI
Hydralazine hydrochloride	Opens K^+ channels	Initial 10–20 mg IV; repeat every 4–6 h	10–20 min	1–4 h	Tachycardia, flushing, headache, vomiting, aggravation of angina	Must be given with concomitant IV β-blockers to avoid precipitation of angina but *not* a preferred initial choice or treatment

Continued

TABLE 38.1 Pharmacologic Agents for Treatment of Hypertensive Emergencies—cont'd

Drug	Mechanism of Action	Dose	Onset of Action	Duration of Action	Adverse Effects[a]	Special Indications
Adrenergic Inhibitors						
Labetalol hydrochloride	α_1-, β-Blocker	Initial 0.3–1.0 mg/kg dose (maximum 80 mg) in slow IV injection and repeat after 10 min *or* 0.4–1.0 mg/kg/h IV infusion up to 3 mg/kg/h Maximum dose 300 mg; can be repeated every 4–6 h	5–10 min	3–6 h	Nausea, vomiting, scalp tingling, bronchoconstriction, dizziness, heart block, heart failure	Most hypertensive emergencies except acute HF
Esmolol hydrochloride	β_1-Blocker	0.5–2 mg/min IV infusion *or* 250–500 μg/kg/min IV bolus, then 50–100 μg/kg/min by infusion; may repeat bolus after 5 min or increase infusion to 300 μg/min	1–2 min	10–30 min	Nausea, asthma, first-degree heart block, HF, thrombophlebitis, COPD	Aortic dissection, perioperative, increased heart output or heart rate
Urapidil	α_1-Blocker, serotonin (5-HT_{1A}) receptor agonist	12.5–25 mg IV bolus followed by 5–40 mg/h IV infusion	3–5 min	4–6 h	Headache, dizziness	Perioperative
Phentolamine	α-Blocker	Initial 5–15 mg IV bolus; repeat after 10 min	1–2 min	10–30 min	Tachycardia, flushing, headache	Catecholamine excess

TABLE 38.2 Management of Specific Types of Hypertensive Emergencies

Type of Emergency	First-Choice Drug(s)	Second-Choice or Additional Drug(s)	Drugs to Avoid	Aim of BP Reduction
Cardiac				
Coronary ischemia/infarction	Nicardipine, clevidipine, labetalol, nitroglycerin	Sodium nitroprusside, esmolol if heart failure absent	Diazoxide, hydralazine	Improvement in cardiac perfusion
Heart failure, pulmonary edema	Clevidipine, nitroglycerin, fenoldopam,	Sodium nitroprusside, enalaprilat; loop diuretics	Diazoxide, hydralazine; β-blockers	Decrease in afterload
Aortic dissection	Labetalol or combination of esmolol with sodium nitroprusside or fenoldopam or nicardipine		Diazoxide, hydralazine	Decrease of aortic wall stress with systolic BP reduction <120 mm Hg in 1 hour
Renal				
Acute glomerulonephritis, collagen vascular renal disease, or renal artery stenosis	Fenoldopam	Nicardipine, labetalol, clevidipine; diuretics for volume overload	Sodium nitroprusside; ACE inhibitors and ARBs	Reduction in vascular resistance and volume overload without compromise of renal blood flow or glomerular filtration rate

TABLE 38.2 Management of Specific Types of Hypertensive Emergencies—cont'd

Type of Emergency	First-Choice Drug(s)	Second-Choice or Additional Drug(s)	Drugs to Avoid	Aim of BP Reduction
Scleroderma crisis	Enalaprilat or other ACE inhibitor	Angiotensin receptor blocker, fenoldopam	Corticosteroids,[a] diuretics	Decrease BP up to 25% over 1 hour
Neurologic				
Hypertensive encephalopathy	Nicardipine, fenoldopam, labetalol, clevidipine	Nitroprusside, esmolol, urapidil		Decrease BP up to 25% over 1 hour
Ischemic stroke	Nicardipine, labetalol, clevidipine	Nitroprusside, nimodipine, esmolol, urapidil		Reduction of BP if >220/120 mm Hg by up to 15% within first 24 hours to avoid impairing cerebral blood flow in penumbra Reduction of BP if >185/110 in candidates of thrombolysis
Intracerebral hemorrhage	Nicardipine, labetalol, clevidipine	Fenoldopam, nitroprusside, esmolol, urapidil, nimodipine for subarachnoid hemorrhage		For patients presenting with SBP >220 mm Hg, it is reasonable to reduce SBP to 140–180 mm Hg. For patients presenting with SBP 150–220 mm Hg, decreasing to <140 mm Hg is not of benefit.
Catecholamine Excess States				
Pheochromocytoma	Phentolamine or labetalol	β-Blocker in the presence of phentolamine, sodium nitroprusside	Diuretics, β-blockers alone	Control of BP paroxysms from sympathetic stimulation; reduce SBP <140 mm Hg over 1 hour
Ingestion of cocaine or other sympathomimetic	Phentolamine or labetalol	β-Blocker in the presence of phentolamine, sodium nitroprusside	Diuretics	Control of BP paroxysms from sympathetic stimulation
Perioperative/Postoperative Hypertension				
Coronary artery surgery	Nitroglycerin, nicardipine, clevidipine	Esmolol, labetalol, fenoldopam, isradipine, urapidil		Protection against target organ damage and surgical complications (keep BP <140/90 mm Hg)
Noncardiac surgery	Esmolol, labetalol, fenoldopam, nicardipine, clevidipine, urapidil, nitroglycerin			Protection against target organ damage and surgical complications
Pregnancy Related				
Eclampsia	Labetalol, urapidil	Isradipine, nicardipine, $MgSO_4$, methyldopa, hydralazine	Nitroprusside, ACE inhibitors, ARBs	Reduce BP <140–160/105 mm Hg over 1 hour and protect placental blood flow

[a]Corticosteroids may worsen hypertension in scleroderma renal crisis.
ACE, Angiotensin-converting enzyme; *ARBs,* angiotensin receptor blockers; *BP,* Blood pressure; *SBP,* systolic blood pressure.

reviews and meta-analyses showed minor differences in the degree of BP lowering and no differences in morbidity or mortality among these agents because of the relative paucity of large RCTs with appropriate follow-up.[37,38] Thus, treatment practices were mainly empiric. More recent evidence, however, suggests some benefits of novel agents.

Nicardipine is a dihydropyridine CCB with intermediate onset and duration of effect and strong cerebral and coronary vasodilatory activity. It is useful for most hypertensive emergencies, especially in patients with CAD. Nicardipine potentiates curare effects and interacts with inhalant anesthetics.[4,11,39,40] In an RCT of 226 patients with acute SBP of 180 mm Hg or higher, those receiving nicardipine reached physician-specified target range slightly more often (92% vs. 83%, $P = .039$) than those receiving labetalol.[41] A systematic review of studies comparing nicardipine with labetalol suggested that the two drugs had comparable efficacy and safety, but nicardipine showed more predictable and consistent BP response.[42] Nicardipine can be particularly useful in patients with acute coronary syndromes or hypertensive emergencies involving the brain because it reduces myocardial and cerebral ischemia.

Clevidipine butyrate is an ultrashort-acting (within 1–2 minutes) third-generation CCB that acts through inhibition of extracellular calcium influx and reduces peripheral vascular resistance without affecting venous vascular tone or cardiac filling pressure. Clevidipine is rapidly hydrolyzed by blood esterases, and thus its metabolism is not affected by renal or hepatic function.[4,39,40] In clinical studies, clevidipine was effective and safe for the control of perioperative hypertension and hypertensive emergencies. Three RCTs including more than 1500 patients with perioperative acute hypertension that compared clevidipine, nitroglycerin, sodium nitroprusside, and nicardipine found no difference between clevidipine, nitroglycerin, and nicardipine in the primary endpoint of death, MI, stroke, or reduced eGFR at 30 days, but clevidipine was more effective in maintaining BP within the prespecified range and was associated with lower mortality than nitroprusside.[43] A factor that has limited the widespread use of clevidipine is its relatively high cost.

Fenoldopam mesylate is a selective agonist of dopaminergic 1 receptors located mainly in the renal and splanchnic arteries, with lesser density in the coronary and cerebral arteries.[4,39,40] IV fenoldopam does not cross the blood-brain barrier and has no central nervous system activity because it is a poorly lipid-soluble molecule and, unlike dopamine, it lowers rather than raises BP. In clinical studies, compared with sodium nitroprusside, fenoldopam demonstrated similar BP-lowering efficacy and beneficial renal effects (increased diuresis, natriuresis, creatinine clearance).[44] Thus, fenoldopam is mostly useful for BP reduction in patients with renal impairment, those with HF, and those undergoing vascular surgery. Fenoldopam must be administered with caution, if at all, to patients with glaucoma because it increases intraocular pressures.[4,11,39,40]

For several years, *sodium nitroprusside* was considered the first-choice drug for almost all hypertensive emergencies. It is easily titrated, inexpensive, and has a long record of effectiveness.[4,11] However, sodium nitroprusside has several drawbacks, including accumulation of toxic metabolites (thiocyanate and cyanide) when used for more than 48 hours, especially in patients with renal or hepatic dysfunction, and the need for invasive BP monitoring and an administration system that protects it from light. High-dose nitroprusside also increases intracranial pressure, obliterates cerebral autoregulation, and reduces regional coronary blood flow. These attributes limit its usefulness in patients with neurologic complications or acute coronary syndromes.[4,11]

Labetalol is a nonselective α_1- and β-blocker (in 1:7 ratio) that can be used in many hypertensive emergencies because when given intravenously it has rapid onset of action, potent and sustained effect, and low toxicity. Labetalol reduces peripheral vascular resistance without a reflex increase in systolic volume, and cerebral, renal, and coronary blood flow are maintained. Its main indications are for hypertension associated with aortic dissection, acute coronary syndromes, hypertensive encephalopathy, and adrenergic crisis.[4,39,40] Labetalol can be used in pregnancy-induced hypertensive crisis because little placental transfer occurs as a result of its negligible lipid solubility.[4] Labetalol may be used in chronic obstructive pulmonary disease if the patient has no history of an asthmatic component.[45] *Esmolol* is a β_1-blocker with an immediate onset and a short duration of action, whose metabolism is not dependent on kidney or hepatic function. Esmolol is used particularly in patients with severe postoperative hypertension, and it can be useful in those with increased cardiac output and heart rate.[4,39,40]

Table 38.1 provides pharmacologic characteristics and adverse effects of the aforementioned agents, as well as other agents that have been used in the treatment of hypertensive emergencies. Table 38.2 includes a general guide for use of these drugs according to the type of hypertensive emergency.[4,8,12,39,40]

Treatment of Hypertensive Urgencies

Although hypertensive urgencies are particularly common, high-quality studies on the value of extensive diagnostic testing for target-organ damage, the need for hospitalization, the type of treatment, and the optimal follow-up in asymptomatic patients with BP elevation are missing.[46,47] A retrospective cohort study with propensity matching that included all patients presenting with hypertensive urgency (BP > 180/110 mm Hg) to an office in a large health care system in the United States showed that patients sent home compared with those sent to the ED had an equally low risk of major cardiovascular events (0.9%) and equal chance to have uncontrolled hypertension (65% vs. 67%) at 6 months.[48]

Because there is no proven benefit from rapid BP reduction in asymptomatic patients without evidence of acute target-organ damage, current guidelines agree that BP lowering should occur over a longer time than for a hypertensive emergency, and no hospitalization is necessary.[1,2] BP reduction to less than 160/100 mm Hg may be accomplished within 2 to 4 hours in the ED with resting and oral agents. This may be particularly important for patients without ongoing target-organ damage, who are judged to be at high risk for CV events over the next days because of severe hypertension (e.g., those with known history of aortic aneurysm or repeated episodes of pulmonary edema). However, there are many different types of patients who may present as a hypertensive urgency, the most common of which is the hypertensive patient with low treatment compliance and chronically elevated BP levels. Thus, less aggressive lowering of BP (over several hours to days) is also proposed by some, using strategies such as resumption of antihypertensive therapy (in nonadherent patients), initiation of antihypertensive therapy with long-acting agents (if patients are treatment naive), and treatment modification or addition of another antihypertensive drug (in patients who are already treated). In short, the most important aspect of treatment of hypertensive urgency is not achieving a BP goal but rather ensuring adequate follow-up, generally within 1 week, to an appropriate site of care for chronic hypertension to optimize care and improve chronic BP control.[1,2,4,11]

Patients with hypertensive urgency should be provided a quiet room in which to rest. An uncontrolled study showed this maneuver resulted in a BP fall of at least 20/10 mm Hg in one-third of these individuals,[49] and a recent RCT showed that resting produced identical BP reductions to 40 mg of telmisartan over a 2-hour period.[24] A large observational study showed that there were no differences in 1-week ED revisit rate and BP control between patients with hypertensive urgencies treated or not with oral medications.[50] The importance of relaxation is further supported by data suggesting that techniques such as pursed-lip breathing combined with number counting or anxiolytic treatment are associated with greater BP reductions than usual care alone.[51,52] Another major factor to consider before prescribing antihypertensive medication is assessment of pain. Patients with severe pain not of cardiac or cerebral origin should be given analgesics first to improve it because if they are given acute-acting medications, they could become hypotensive once pain is alleviated.

The choice of drugs for treatment of hypertensive urgencies is much broader than for emergencies because almost all antihypertensives lower BP effectively given sufficient time. Captopril, clonidine, labetalol, and other short-acting drugs have been used most often (Table 38.3).[4,40,53] A careful history to assess chronic antihypertensive treatment and patient adherence to medication is critical for drug and dose selection, and clinical surveillance is always advisable during the first few hours after drug administration. If a pheochromocytoma is suspected, it is advisable to avoid β-blockers because they can increase BP because of unopposed α-adrenergic activity; this included labetalol because its α-blocking effect is very small. An α-blocker such as doxazosin or prazosin is preferred. Overall, if the patient admits to missing one or more doses of their usual antihypertensive agents, reinstituting these medications in an appropriate order is a reasonable option.

Oral captopril is typically given in a 12.5- to 25-mg dose; angiotensin-converting enzyme (ACE) inhibitors must be used with caution because they can cause or exacerbate renal impairment in the occasional patient

TABLE 38.3 Pharmacologic Agents for Treatment of Hypertensive Urgencies

Drug	Mechanism of Action	Dose	Onset of Action	Duration of Action	Adverse Effects
Captopril	ACE inhibitor	12.5–25 mg PO every 1–2 h	15–30 min	4–6 h	Angioedema, cough, acute renal failure
Clonidine	Central α_2-agonist	0.1–0.2 mg PO every 1–2 h	30–60 min	6–8 h	Sedation, dry mouth, bradycardia, rebound hypertension after withdrawal
Labetalol	α_1-, β-Blocker	200–400 mg PO every 2–3 h	30–120 min	6–8 h	Bronchoconstriction, heart block, congestive heart failure
Furosemide	Loop diuretic	20–40 mg PO every 2–3 h	30–60 min	8–12 h	Volume depletion, hyponatremia, hypokalemia
Isradipine	Calcium channel blocker	5–10 mg PO every 4–6 h	30–90 min	8–16 h	Headache, tachycardia, flushing, peripheral edema

PO, By mouth.
Shown are short-acting agents commonly used in the emergency room setting. However, as noted in the text, sometimes longer-acting drugs can be used.

with critical renal artery stenosis.[53] Sublingual captopril has a more pronounced BP lowering effect than oral captopril at 10 and 30 minutes but similar at 60 minutes after dosing.[54] Oral clonidine, 0.1 to 0.2 mg, is one of the most common agents used in this setting. However, patients should not be discharged on clonidine if they have a history of nonadherence to drug regimens because of the risk for rebound hypertension if clonidine is abruptly stopped. Furosemide also can effectively lower BP if elevated pressure is related to volume overload, especially if renal dysfunction is present. However, a common physiologic response of the kidney to elevated BP is natriuresis, so many patients, especially those with normal renal function, are volume depleted, as previously discussed.[4,53] Further, furosemide is not considered appropriate for treating primary hypertension because of its short duration of action and a rebound in sodium reabsorption if dosed once daily.

Sublingual short-acting nifedipine, although once frequently used, is now contraindicated secondary to a higher incidence of stroke, MI, and death related to precipitous hypotensive episodes after ED release.[32] Intermediate-acting dihydropyridine CCBs, such as isradipine and nicardipine, may be used, because their onset of action is between 30 and 90 minutes. Longer-acting CCBs, such as once-daily nifedipine, sustained-release isradipine, and amlodipine do not have a role in reducing BP in the ED. However, these and long-acting agents from other major antihypertensive classes are valuable tools for long-term BP control, which, as mentioned previously, is the most important aspect of management in these patients.

Despite existing recommendations,[1,2] a substantial proportion of patients with hypertensive urgency are still treated with IV medications in everyday clinical practice, an intervention that produces similar BP reduction, readmission rates, and adverse outcomes with oral dosing.[55,56] There are also data suggesting that most of these patients do not receive proper instructions in the ED as proposed in the literature, and providers overestimate how often they refer patients for follow-up, resulting in questionable improvement in long-term outpatient BP control.[46] Finally, there is a justified concern on the optimal treatment of patients with severe BP elevation and unclear symptoms while they are undergoing workup in the ED to determine whether they have target-organ damage, especially as health system practices and available ED resources vary considerably across the globe.[57] Further research is needed to clarify these issues and inform decisions for short- and long-term management of patients with hypertensive urgencies.

SELF-ASSESSMENT QUESTIONS

1. A patient being evaluated for a routine history and physical is noted to have a BP of 220/130 mm Hg. He states he feels fine except for nightly reflux. Examination shows fundi with atrioventricular nipping and normal heart sounds. Chest radiograph is normal; serum creatinine is 1.3 mg/dL, and urinalysis shows rare red blood cells (RBCs). Management should include which of the following?
   - **A.** Immediate hospitalization to the intensive care unit with administration of intravenous labetalol
   - **B.** Stat electrocardiogram, cardiac enzymes, and admission to the cardiac care unit
   - **C.** Start oral isradipine 5 mg, let the patient rest in a quiet room, and observe for some hours
   - **D.** Perform a full workup for secondary causes with plasma metanephrines and catecholamines and aldosterone-renin ratio. Start clonidine, 0.4 mg twice daily.
2. A patient presents with an acute hemorrhagic stroke and has a BP of 180/120 mm Hg. You are asked to consult on the patient. Which of the following is the *best* strategy?
   - **A.** Give hydralazine (10 mg IV) to bring the BP down as rapidly as possible.
   - **B.** Initiate nitroprusside therapy and titrate BP down to 140/90 mm Hg over a 1-hour period.
   - **C.** Start nicardipine infusion and reduce BP to 160/90 mm Hg within an hour.
   - **D.** Do not treat the hypertension because it may worsen the stroke.
3. A patient presents with acute chest pain. On examination, BP in the right arm is 190/120 mm Hg but in the left arm is only 160/90 mm Hg. The chest radiograph shows a widened mediastinum. What is the *best* initial treatment to lower the BP?
   - **A.** Start a nitroprusside infusion, targeting BP of 140/90 mm Hg in the right arm.
   - **B.** Start a labetalol infusion, targeting BP of 120 mm Hg systolic in the right arm.
   - **C.** Start an esmolol infusion, targeting BP of 120 mm Hg systolic in the left arm.
   - **D.** Do not treat the BP because it is important to preserve cerebral perfusion.

Endocrine Causes of Hypertension: Aldosterone

I. David Weiner, Charles S. Wingo

INTRODUCTION

Aldosterone is a steroid hormone produced in the adrenal glands that has critical roles in blood pressure (BP), plasma volume, and potassium homeostasis. Its production is normally under feedback regulation such that hypertension, intravascular volume expansion, and hypokalemia decrease its expression. When this feedback regulation is impaired, autonomous and inappropriate aldosterone production can lead to severe hypertension that is often refractory to treatment and to hypokalemia. Autonomous aldosterone production is also associated with an increased risk of major cardiovascular events, such as myocardial infarction, congestive heart failure, atrial fibrillation, and stroke, such that the rate of these complications is substantially greater than expected solely from the associated hypertension. Recent advances in the diagnosis of aldosterone-induced hypertension have led to the recognition that primary aldosteronism is surprisingly common. Effective diagnostic strategies are available, and treatment regimens are highly efficacious.

ETIOLOGY AND PATHOGENESIS

Aldosterone is produced under normal conditions in the zona glomerulosa of the adrenal glands (Fig. 39.1). The enzyme, aldosterone synthase, is encoded by the gene *CYP11B2,* and it is generally accepted as the rate-limiting enzyme for aldosterone production. Box 39.1 summarizes factors known to stimulate or inhibit aldosterone synthesis. The physiologically most important regulators of aldosterone production are angiotensin II (Ang II), which stimulates aldosterone production through activation of the AT_1 receptor; adrenocorticotropic hormone (ACTH), which acutely stimulates aldosterone secretion; atrial natriuretic peptide (ANP), which is inhibitory; and extracellular potassium concentration (hyperkalemia is stimulatory and hypokalemia is inhibitory).[1,2] A high NaCl (salt) diet suppresses aldosterone production; this likely occurs through changes in ANP and renin-dependent Ang II production. Finally, there is a significant circadian variation, with serum levels greatest in the late morning with peak values about 50% greater than the average concentration.

Aldosterone mediates its effects almost exclusively through activation of the mineralocorticoid receptor (MR). MR is a classic steroid hormone receptor, which upon activation translocates to the nucleus where it functions as a transcription factor altering the expression of many genes. The endogenous glucocorticoid hormone cortisol can also activate MR. However, in most MR-expressing cells, there is concomitant expression of 11β-hydroxysteroid dehydrogenase type 2 (11β-HSD2), an enzyme that converts cortisol to cortisone, which does not activate MR. MR is expressed in a wide variety of tissues, including the kidney, endothelial cells, vascular smooth muscle cells, cardiomyocytes, fibroblasts, and macrophages and in the central nervous system (CNS).[3] In the kidney, MR is found in the aldosterone-sensitive distal nephron (ASDN), in glomerular mesangial cells and podocytes, and in interstitial fibroblasts.

Pathogenesis of Aldosterone-Dependent Hypertension

Aldosterone increases BP through several mechanisms. Its effects on renal NaCl retention, leading to intravascular volume expansion, are well known but are not the only mechanism. Extrarenal MR activation leads to effects on the vasculature, CNS, peripheral nervous system, and other hormones (Fig. 39.2). It also has nonhemodynamic effects, such as activation of interstitial fibroblasts, that can contribute to development of hypertension and to progression of chronic kidney disease (CKD).[4] These multiple effects help explain why primary aldosteronism can cause refractory hypertension.

In the kidney, aldosterone stimulates renal sodium chloride retention by increasing expression of the amiloride-sensitive epithelial sodium channel (ENaC) in the collecting duct and the chloride-reabsorbing protein pendrin in the cortical collecting duct.[5,6] Through nongenomic mechanisms, aldosterone also acutely stimulates sodium reabsorption in these segments.[7] Furthermore, aldosterone-induced hypokalemia increases expression of the Na^+Cl^- cotransport protein (NCC), the sodium-chloride cotransporter present in the distal convoluted tubule. Together, these effects on multiple Na^+ and Cl^- transporters lead to NaCl retention, intravascular volume expansion, and volume-dependent hypertension.

A second renal-mediated mechanism through which aldosterone increases BP involves its generation of hypokalemia. Aldosterone increases extrarenal cellular potassium uptake by stimulating the ubiquitous Na^+,K^+-ATPase pump. As discussed in Chapter 10, potassium depletion raises BP through a variety of mechanisms, including increased expression of NCC in the distal convoluted tubule, induction of renal interstitial injury, and direct vascular effects.

In addition, aldosterone has multiple direct effects on the vasculature. Aldosterone increases both basal vascular tone and vascular reactivity to circulating vasoconstrictors, including norepinephrine, epinephrine, Ang II, and vasopressin.[8] Aldosterone decreases flow-mediated vasodilation, in part by decreasing nitric oxide production as a result of decreased endothelial nitric oxide synthase expression.[9] In addition, aldosterone leads to vascular inflammation and fibrosis, vascular stiffness, increased expression of proteins involved in atherosclerosis, and endothelial oxidative stress.[10]

The CNS control of BP is another mechanism through which aldosterone regulates BP. Aldosterone, through activation of CNS MR, stimulates CNS-mediated sympathetic nervous tone, which further increases BP.[11] CNS MR activation may also contribute to salt-sensitive hypertension and to effects of peripheral aldosterone on BP.

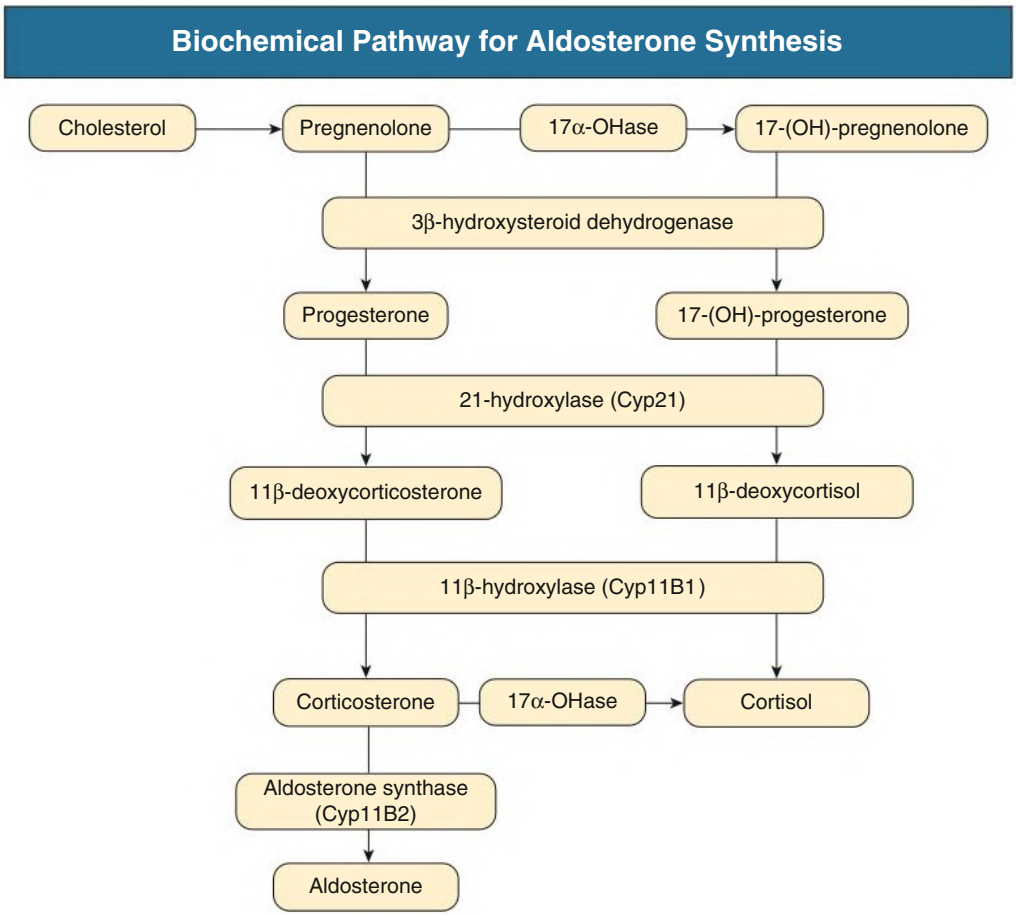

Fig. 39.1 Biochemical pathway for aldosterone synthesis.

BOX 39.1 Factors That Regulate Aldosterone Release

Stimulatory

Angiotensin II
Adrenocorticotropic hormone[a]
Potassium
Serotonin
Vasopressin
Endothelin-1
Estrogen (via GPER-1 receptor)
Parathyroid hormone
Leptin

Inhibitory

Atrial natriuretic peptide
Dopamine
Somatostatin
Estrogen (via ERβ receptor)

Both extracellular potassium and numerous hormones exert significant effects on aldosterone release. The primary effectors under most clinical circumstances are noted in italics.
[a]Only acutely.

Primary aldosteronism: Changing definitions and new concepts of physiology and pathophysiology both inside and outside the kidney. *Physiol Rev*. 2016;96:1327–1384.

Aldosterone-Independent Mineralocorticoid Receptor Activation

MR can also be activated through mechanisms not involving aldosterone. As previously noted, cortisol, a naturally synthesized glucocorticoid, has an affinity for MR that is similar to that of aldosterone but has plasma levels about 100-fold greater than aldosterone. The enzyme 11β-hydroxysteroid dehydrogenase type 2 (11β-HSD2), which is expressed in the aldosterone-sensitive distal nephron, metabolizes cortisol to cortisone, which does not effectively bind to MR, thereby preventing glucocorticoid-dependent MR activation. Either the genetic deficiency of 11β-HSD2 or the ingestion of inhibitors of this enzyme can result in excessive activation of the MR and development of severe hypertension (see Chapters 40 and 49).[12]

A second aldosterone-independent mechanism that can activate MR involves Ang II. In the vasculature, in smooth muscle cells, Ang II acting through the angiotensin receptor blocker (ARB)-sensitive Ang II type 1 receptor activates MR through mechanisms that may involve post-translation modifications, such as phosphorylation.[10,13]

Another aldosterone-independent mechanism involves the Rho family small guanosine triphosphatase, Rac1. Rac1 activation increases MR expression, and its expression is increased by increased dietary NaCl intake.[10] This effect can lead to Rac1-dependent dietary salt–evoked paradoxical MR activation that can lead to increased renal NaCl reabsorption through reduced oxidative stress and direct regulation of Na transporters.[14]

Lastly, the concept of differential aldosterone sensitivity is being increasingly recognized. This concept in based on the observation that similar levels of aldosterone lead to highly different BP responses in

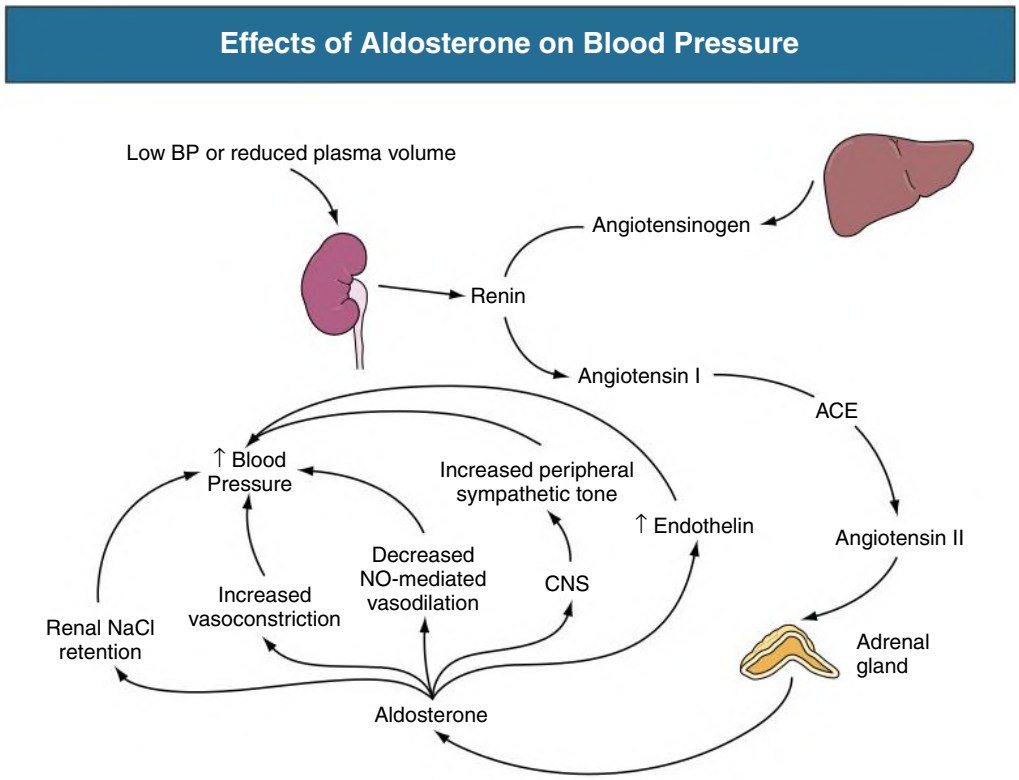

Fig. 39.2 Summary of aldosterone's effects on blood pressure (BP) regulation. *ACE,* Angiotensin-converting enzyme; *CNS,* central nervous system; *NO,* nitric oxide.

different individuals and that MR blocker (MRB) medications exert profound effects on BP in some patients, particularly those with suppressed plasma renin levels, whereas it has substantially less effect in others.[15] The mechanism of this differential sensitivity is incompletely understood at present, but it is possible that differences in tissue MR expression and/or downstream signaling pathways mediate these differences.

Types of Primary Aldosteronism

Primary aldosteronism can result either from unilateral or bilateral autonomous aldosterone production (Fig. 39.3). Typically, unilateral disease results from an aldosterone-producing adenoma (APA) and bilateral disease from hyperplasia. This association is not absolute, and about 10% of patients with primary aldosteronism have either bilateral adenoma, which may be microscopic, or unilateral hyperplasia. In general, an APA causes more severe primary aldosteronism than does adrenal hyperplasia, but this distinction is not sufficient to solely guide clinical decision making.

Most APAs are unilateral and are large enough (≥10 mm) to be seen with thin-slice computed tomography (CT) (Fig. 39.4). However, APAs may also be microscopic, and they may be bilateral. Hyperplasia is typically bilateral but occasionally is unilateral, and it may develop asynchronously in the two adrenal glands. Because unilateral adrenal hyperplasia is potentially curable with adrenalectomy, the absence of an identifiable adrenal adenoma on CT or magnetic resonance imaging (MRI) does not exclude the possibility of surgically treatable primary aldosteronism.

Familial Hyperaldosteronism

Recognizing the presence of familial forms of primary aldosteronism is important for both case detection in affected family members and because it may result in changes in management for selected forms.

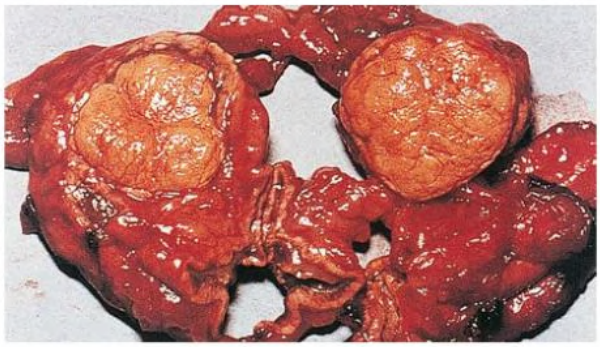

Fig. 39.3 Adrenal Adenoma. An aldosterone-producing adrenal adenoma with typical cholesterol-rich yellow appearance.

Although identification of familial hyperaldosteronism (FH) was previously based on an arbitrary definition of the presence of two or more family members, improved understanding of the genetic causes has led to a classification system based on genomic DNA sequencing findings. Table 39.1 summarizes the different forms of FH. In some cases, the clinical presentation suggests the presence of a familial etiology, and in some the presentation is indistinguishable from sporadic forms. Except for familial hyperaldosteronism type I, identification of these familial forms, beyond allowing specific genetic testing of family members of affected individuals, does not alter treatment decisions at this time.

The first identified was *familial hypertension type I* (FH-I), which is also known as *glucocorticoid-remediable aldosteronism* (GRA). In FH-I there is crossover between the *CYP11B1* and *CYP11B2* genes. This leads to a chimeric aldosterone synthase gene whose expression is regulated by ACTH, leading to excessive aldosterone release.[16,17] FH-I is transmitted in an autosomal dominant pattern and should be considered in children or young adults with refractory hypertension or

who have a family history of hypertension at a young age or history of premature hemorrhagic stroke.[18] If suspected, genetic testing is the preferred diagnostic approach because this offers improved sensitivity and specificity over measurement of steroid metabolites or dexamethasone suppression testing.[18] When FH-I is found, administering corticosteroids at the lowest dose necessary to suppress ACTH release often dramatically improves BP control (see Chapter 49). Concomitant MRB and/or anti-ENaC therapy may be necessary to avoid high doses of glucocorticoids with their associated side effects.

Familial hyperaldosteronism type II. In the past several years, there has been a fundamental change in our understanding of FH type II (FH-II). Previously, FH-II was based on the presence of at least two family members with primary aldosteronism after excluding a diagnosis of FH-I. This definition almost certainly overestimated the frequency of FH because of misclassification of sporadic primary aldosteronism in multiple family members as FH-II. FH-II is now known to result from germline mutations in the gene, *CLCN2,* which encodes the chloride channel, ClC-2.[19,20] These mutations lead to gain-of-function, increasing cellular Cl^- exit, which causes membrane depolarization. Membrane depolarization increases Ca^{2+} entry through voltage-sensitive calcium channels. Increases in intracellular Ca^{2+} lead to cellular proliferation and increased *CYP11B2* expression, which increases aldosterone production and secretion. FH-II appears to present in childhood with severe primary aldosteronism.

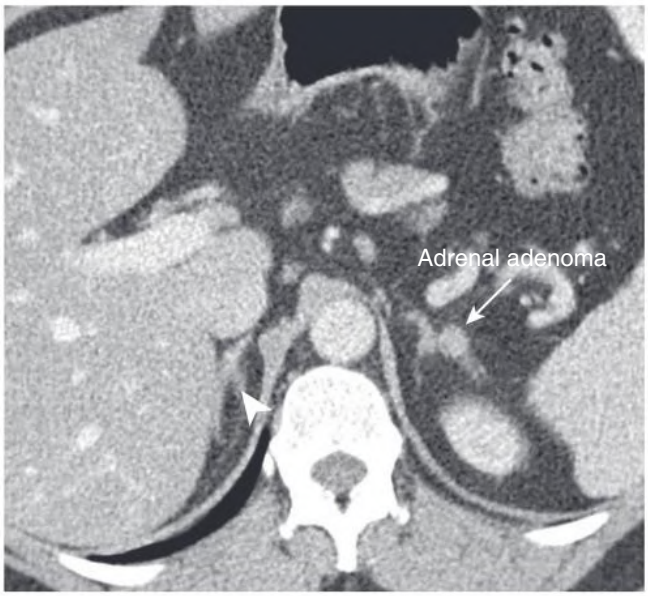

Fig. 39.4 Adrenal Adenoma by Computed Tomography Scan. A normal linear image of the right adrenal gland *(arrowhead)* and expansion of the left adrenal with aldosterone-producing adenoma (~1 cm) *(arrow).*

Familial hyperaldosteronism type III. FH type III (FH-III) is the result of germline mutations in the *KCNJ5* gene.[21–23] The *KCNJ5* gene encodes a K^+-channel that is a major determinant of adrenal cortical cell membrane voltage. Mutations observed in FH-III result in loss of K^+ selectivity, leading to Na^+ influx and membrane depolarization. Consequently, there is voltage-gated Ca^{2+} channel activation, increased cytosolic calcium, and stimulation of aldosterone production and adrenal cell proliferation. Although initial studies characterized FH-3 as having severe, often childhood-onset of hypertension, subsequent studies suggest the presentation is more variable.[24]

Familial hyperaldosteronism type IV. FH type IV (FH-IV) results from mutations in the *CACNA1H* gene, which encodes for a T-type calcium channel ($Ca_V3.2$).[25] These mutations appear to lead to increased Ca^{+2} entry, increased cytosolic calcium, and stimulation of aldosterone production and adrenal cell proliferation. Clinical penetrance of the mutation is incomplete.

Sporadic Forms

Our understanding of the factors that lead to sporadic forms of primary aldosteronism has advanced substantially. This is true for both unilateral autonomous aldosterone production associated with an APA and for bilateral autonomous aldosterone production. DNA sequencing,

TABLE 39.1 Familial Hyperaldosteronism (FH)

Form	Affected Gene	Pathogenic Effect	Classic Presentation	Targeted Treatment
FH-I	Crossover of *CYP11B1* promoter with *CYP11B2* coding sequence	Aldosterone synthase expression under control of ACTH-sensitive promoter	Severe hyperaldosteronism in childhood or young adults with autosomal dominant inheritance	Low-dose glucocorticoids, to suppress endogenous ACTH production. May need concomitant ARB and/or ENaC inhibitor therapy.
FH-II	*CLCN2*	Gain-of-function mutation in the Cl^- channel ClC-2, leading to increased Cl^- efflux and subsequent membrane depolarization Membrane depolarization increases Ca^{2+} entry, which leads to hyperplasia and increased *CYP11B2* expression	Early-onset hypertension	None available
FH-III	*KCNJ5*	Loss of Na^+ selectivity of K^+ channel, GIRK4, leading to membrane depolarization, which increases Ca^{2+} entry and subsequent hyperplasia and increased *CYP11B2* expression	Severe early-onset hypertension associated with profound hypokalemia	None currently available at present Macrolide antibiotics are effective in vitro, but in vivo effects have not been well characterized
FH-IV	*CACNA1H*	Mutation in the pore-forming α1 subunit of the voltage-sensitive calcium channel Cav3.2, leading to increased Ca^{2+} entry and subsequent hyperplasia and increased *CYP11B2* expression	Early-onset primary aldosteronism May be associated with developmental delay or attention deficit disorder	None currently available

ACTH, Adrenocorticotropic hormone; *ARB,* angiotensin receptor blocker; *ENaC,* epithelial sodium channel.

either "classic" Sanger sequencing, or immunohistochemistry-guided next-generation sequencing, shows that acquired somatic mutations lead to many cases of sporadic primary aldosteronism.[19,26] Unilateral autonomous aldosterone production associated with an APA is frequently associated with *KCNJ5* mutation in the APA and is found in as many as 80% of APA, with a higher frequency in Asian populations.[19,27] In African Americans, somatic *CACNA1D* mutations appear to be the most frequently acquired mutation.[28] Other genes in which somatic mutations have been found frequently include ATP1A1 and ATP2B3. Less frequently, mutations in *CTNNB1* and *PRKACA* have been identified.[19,27]

Recent advances have also been made in understanding the pathogenesis of primary aldosteronism from bilateral adrenal hyperplasia. Activating autoantibodies directed against the angiotensin II type 1 (AT1) receptor may activate the AT1 receptor, both directly stimulating adrenal aldosterone secretion and contributing to the hypertension through an aldosterone-independent mechanism involving AT1 receptor activation in vascular tissue.[29,30] To date, the presence of these antibodies has been examined in only a limited number of patients. Additional studies are needed to examine how widespread this mechanism is and what proportion of cases of bilateral adrenal hyperplasia results from this mechanism.

EPIDEMIOLOGY

The apparent incidence of primary aldosteronism varies with the patient population and the diagnostic criteria used. Early studies, which only recognized severe cases, suggested that primary aldosteronism was rare, with an incidence of less than 1% to 2%. More sensitive diagnostic criteria have now led to the recognition that primary aldosteronism is relatively common.[31] Patients with treatment-resistant hypertension—inadequately controlled hypertension despite treatment with three medications at appropriate dosages, including a diuretic—are quite likely to have primary aldosteronism, with rates typically of 20% to 40% and as high as 67% in some studies.[32]

Primary aldosteronism causes adverse effects that are independent of hypertension and hypokalemia. This includes an increased risk of cardiac arrhythmias, both atrial and ventricular, cerebrovascular events, and coronary heart disease.[33] Diagnosing and treating the primary aldosteronism, whether with adrenalectomy or with MRBs, as clinically appropriate, substantially reduces, and may even fully correct, this increased risk.[34,35] Finally, primary aldosteronism is associated with a variety of neuropsychiatric disorders, ranging from depression and anxiety to lethargy, fatigue, and difficulties with concentration. Appropriate treatment of the primary aldosteronism may improve these symptoms.[24]

CLINICAL MANIFESTATIONS

Identifying patients with primary aldosteronism purely on clinical characteristics is difficult. Some patients with primary aldosteronism have features suggestive of secondary hypertension, such as early onset of hypertension or the need for multiple drugs for BP control. Others present with either frank or easily provoked hypokalemia. In hypertensive patients with atrial fibrillation without a known cause of atrial fibrillation, primary aldosteronism may be present in as many as 42%.[36] Many, however, have no distinguishing characteristics that differentiate them from individuals with essential hypertension. The incidence of primary aldosteronism in a hypertensive population parallels the severity of hypertension, although 1% to 2%, and possibly as many as 13%, of normotensive individuals show evidence of autonomous aldosterone production (Fig. 39.5).[31,37]

EVALUATION AND DIFFERENTIAL DIAGNOSIS

Who to Evaluate for Primary Aldosteronism

We recommend a liberal policy for testing patients for primary aldosteronism. This involves testing patients who have early-onset hypertension, baseline or easily provoked hypokalemia, or hypertension not effectively controlled with routine antihypertensive therapy. Some evidence suggests patients with hypertension and atrial fibrillation should be screened for primary aldosteronism.[36] Patients with hypertension and a known adrenal adenoma should also undergo testing. Finally, hypertensive patients with a family history of primary aldosteronism should be tested. It is important to recognize that the absence of hypokalemia or metabolic alkalosis does not exclude the diagnosis of primary aldosteronism.

Evaluation of Suspected Primary Aldosteronism

Evaluation of patients with suspected primary aldosteronism is directed at identifying those who have autonomous aldosterone release, followed by determining whether treatment should be based on a pharmacologic or a surgical approach (Fig. 39.6).

The diagnosis of primary aldosteronism requires evidence of autonomous aldosterone production. As previously detailed, the major factors that stimulate aldosterone production involve Ang II-dependent and hyperkalemia-dependent stimulation of the adrenal gland. Thus, autonomous aldosterone production is identified by inappropriate aldosterone production in view of Ang II and serum/plasma K^+. Hyperkalemia, if present, should be corrected before screening to eliminate this possible stimulus for aldosterone production. Because Ang II cannot be assayed with routine clinical tests, plasma renin is used as a surrogate. A random blood sample is used to measure plasma aldosterone and renin. This test should be obtained in early morning because of diurnal variations in plasma aldosterone and plasma renin activity. The question as to whether to hold medications that can alter the renin-angiotensin-aldosterone system and, if so, for how long before testing is complex and is discussed in detail later. If the aldosterone/renin ratio (ARR) is elevated, this suggests there is significant Ang II–independent aldosterone release, providing presumptive evidence of autonomous aldosterone production consistent with primary aldosteronism.

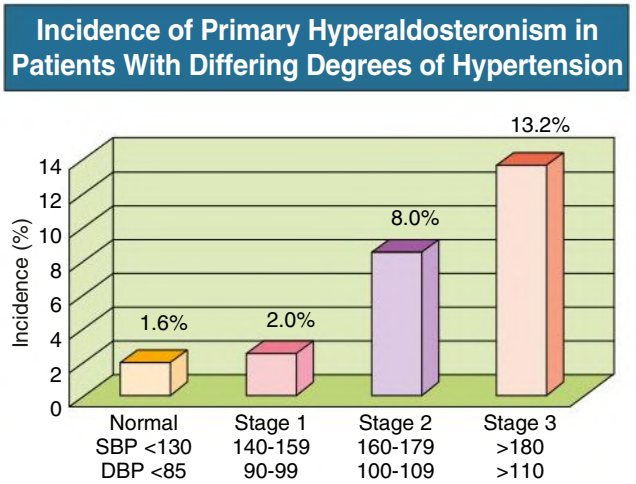

Fig. 39.5 Incidence of primary aldosteronism in patients with differing degrees of hypertension. *DBP,* Diastolic blood pressure; *SBP,* systolic blood pressure. (From Mosso L, Carvajal C, Gonzalez A, Barraza A, Avila F, Montero J, et al. Primary aldosteronism and hypertensive disease. *Hypertension.* 2003;42:161–165.)

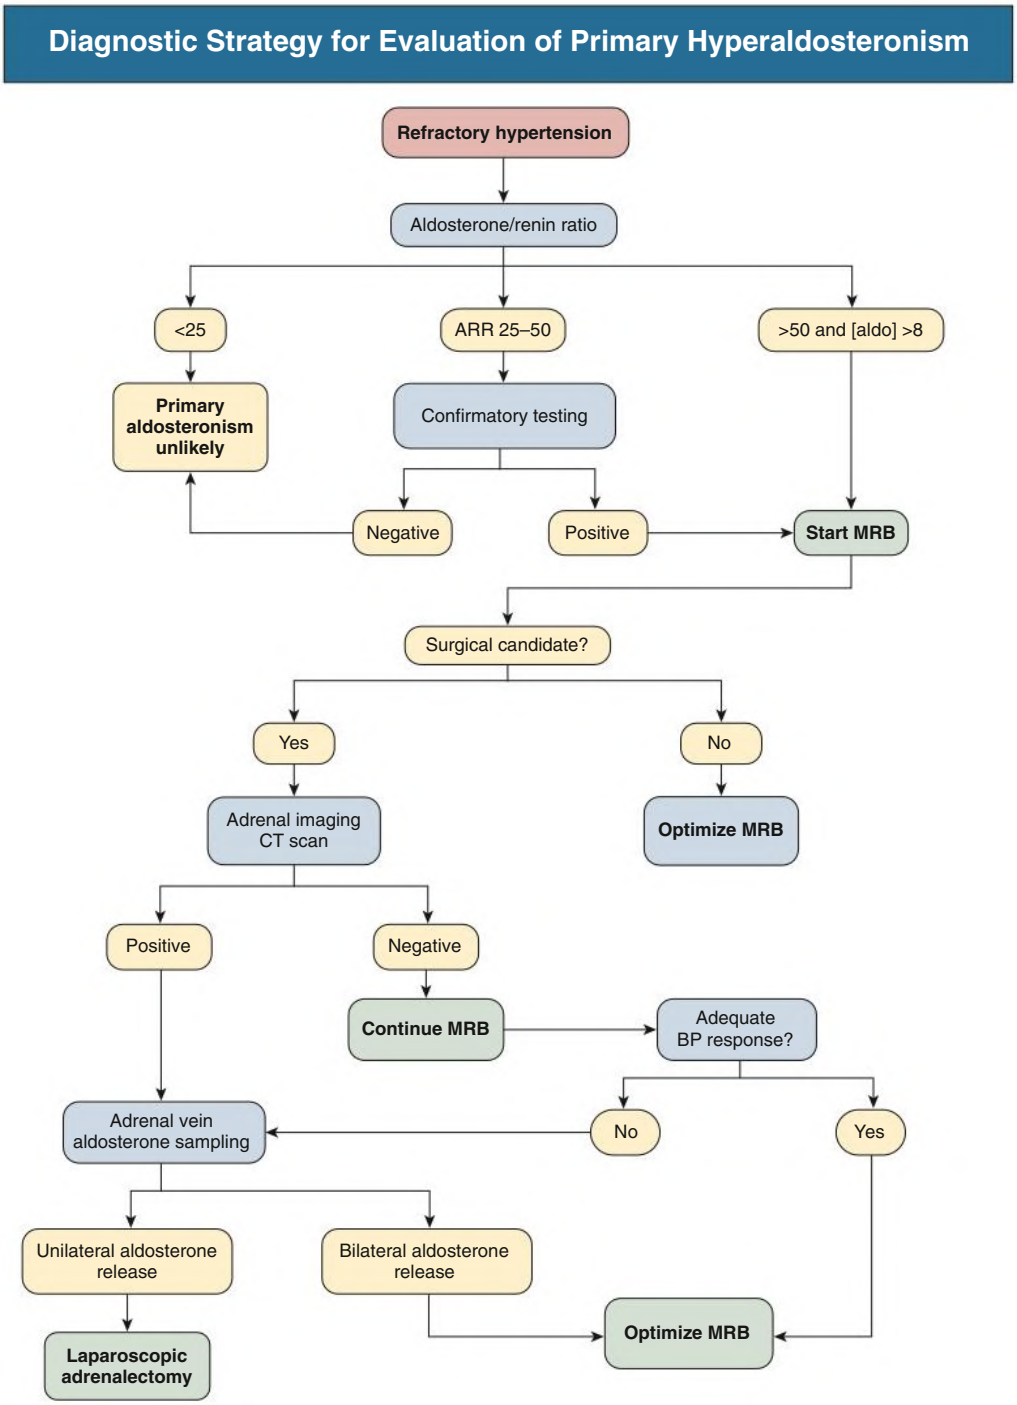

Fig. 39.6 Diagnostic Strategy for Evaluation of Primary Aldosteronism. Aldosterone-renin ratio (ARR) is calculated using measurement of plasma renin activity. If direct renin immunoassay is used, the resulting ARR calculation should be multiplied by approximately 8 for use with this diagnostic algorithm. *BP,* Blood pressure; *CT,* computed tomography; *MRB,* mineralocorticoid receptor blocker.

Currently, two types of renin assays are in routine clinical use. One measures renin activity, assayed as the rate of conversion of angiotensinogen to angiotensin I (Ang I), and the second measures the amount of immunoreactive renin. These two techniques yield results that correlate well with each other, but the units and numerical values obtained differ. For the plasma renin activity, the normal range is 1.9 to 3.7 ng Ang I/mL/hr, and the lower level of detectability is approximately 0.1 ng Ang I/mL/hr in most clinical laboratories. For the direct renin assay, the normal range is typically 13 to 44 IU/mL and the lower level of detectability is approximately 28 IU/mL. Therefore, the typical ARR, for a patient with primary hypertension not receiving drugs that alter the renin-angiotensin system (RAS), is about 10:1 when using the plasma renin activity, and 1:1 with the direct renin assay. Currently, an ARR greater than 25 ng/dL per ng/(mL/h) or 650 pmol per μg/(L/h), depending on the units used for aldosterone measurement, is considered elevated. If using direct renin measurements, the cut-off is 2.3 ng/dL per mIU/L or 60 pmol per mIU/L.

TABLE 39.2 Confirmatory Testing for Primary Aldosteronism

Test	Method	Evaluation	Limitations
Oral salt loading	Oral NaCl intake >200 mmol/d for 3 days, with oral KCl as needed to prevent hypokalemia, with subsequent 24-hr urine aldosterone measurement	Urine aldosterone <10 μg/d, diagnosis unlikely; >12 μg/d, primary aldosteronism likely	Avoid if severe uncontrolled hypertension, CKD, CHF, cardiac arrhythmias, or severe hypokalemia
Saline infusion test	Patient in recumbent position for 1 hr before testing and then throughout entire test Begin test between 8 and 9:30 AM; measure plasma aldosterone, plasma renin activity, cortisol, and potassium at beginning of test and then after infusing 2 l NS IV over 4 hr	Plasma aldosterone at end of infusion <5 ng/dL, primary aldosteronism unlikely; >10 ng/dL, diagnosis likely; 5–10 ng/dL, indeterminate	Avoid if severe uncontrolled hypertension, CKD, CHF, cardiac arrhythmias, or severe hypokalemia
Fludrocortisone suppression test	Oral fludrocortisone, 0.1 mg every 6 hr for 4 d, plus oral NaCl, 30 mmol 3×/d, and high-salt diet combined with sufficient KCl to avoid hypokalemia	Upright plasma aldosterone on day 4 >6 ng/dL and plasma renin activity <1 ng/mL/hr, primary aldosteronism likely	Requires very close follow-up to monitor blood pressure and potassium
Captopril challenge test	Plasma aldosterone and plasma renin activity obtained immediately before oral captopril, 25–50 mg, is given and then 1–2 hr afterward, with patient seated throughout test	Plasma aldosterone decrease >30%, primary aldosteronism unlikely	Probably more false-positive and false-negative results than other tests

CHF, congestive heart failure; *CKD,* chronic kidney disease; *IV,* intravenously; *NS,* normal saline.

Although an elevated aldosterone in combination with an elevated ARR strongly suggests primary aldosteronism, the ARR may be elevated even with suppressed plasma aldosterone production if plasma renin activity (or concentration) is substantially suppressed. In this event, the elevated ARR may represent a false-positive screening test. We recommend that a combination of an elevated ARR and a "nonsuppressed" aldosterone level should be used for case-screening for primary aldosteronism. The minimal plasma aldosterone level that may be associated with aldosteronism is unclear. We recommend using a minimal value of 8 ng/dL to make a diagnosis of primary aldosteronism.[38] Others recommend using a cutoff of 15 or even 20 ng/dL.[39,40] We recommend the lower cutoff because about 40% of patients with primary aldosteronism have plasma aldosterone levels between 9 and 16 ng/dL,[37,41] and about 20% of those with unilateral autonomous adrenal aldosterone production have levels less than 15 ng/dL.[41]

Effect of Medications on Screening for Primary Aldosteronism

Many medicines commonly used for the treatment of hypertension can alter either plasma aldosterone or renin release and thereby alter the ARR.[40,42] β-Adrenergic receptor antagonists (β-blockers) suppress renin but generally do not cause the nearly complete renin suppression typically seen in primary aldosteronism. Angiotensin-converting enzyme (ACE) inhibitors (ACE-I) and ARBs, along with diuretics, can increase renin release in normal individuals, which theoretically might decrease the sensitivity of ARR measurement. However, the effect of ACE-Is and ARBs to increase renin release can also be an advantage. In patients using either an ACE-I or an ARB, a suppressed renin in combination with a nonsuppressed aldosterone (>8 ng/dL) is highly specific for primary aldosteronism. MRBs such as spironolactone and eplerenone can elevate the plasma renin activity and impair the sensitivity of testing. Direct renin inhibitors have been reported to both increase and decrease plasma renin activity in patients who presumably have essential hypertension and to decrease plasma aldosterone. Their effect on plasma renin activity and ARR in patients with primary aldosteronism is presently not known.

When to Hold Medications That Affect the RAS System Before Screening

The decision whether to hold medications that affect the renin-angiotensin-aldosterone system requires the clinician to balance competing priorities. Holding these medications, which includes diuretics, ACE-Is, ARBs, direct renin inhibitors, and β-blockers, improves the diagnostic accuracy of the plasma aldosterone and plasma renal activity. However, in the patient with poorly controlled hypertension, discontinuing these medications and attempting to control the blood pressure solely with calcium channel blockers, α-adrenergic blockers, and direct vasodilators can be problematic. In one study, as many as 38% of patients with difficult-to-control hypertension experienced one or more related adverse effects.[43] Moreover, the amount of time drugs should be stopped to completely reverse their effects on the adrenal gland is not clear.

The observation that patients with refractory hypertension who do not have primary aldosteronism respond similarly well to MRB therapy as those who do[44,45] suggests that accurate diagnosis may only be needed to guide whether to pursue evaluation of unilateral autonomous aldosterone production. If medications are to be withheld, it should be done carefully using standardized protocols with extensive safety monitoring.

In patients being evaluated because they have an adrenal adenoma and who do not have resistant hypertension or substantial hypokalemia, the risk/benefit balance may differ. In this latter group, the clinical difficulty and the risks to the patient from changing medications are less substantial, and the utility of accurately identifying clinical milder forms of primary aldosteronism may be greater.

Confirmatory Testing

If the diagnosis of primary aldosteronism is in doubt, several confirmatory tests can be used. Table 39.2 summarizes the various confirmatory testing methods in routine use. Recent studies suggest that confirmatory testing may not be needed in patients with spontaneous hypokalemia, plasma aldosterone greater than 20 ng/dL, and completely suppressed renin[46] or in patients with plasma aldosterone greater than 30 ng/dL with a suppressed renin.[47] Both the risks and the benefits of confirmatory testing must be considered.[38] No confirmatory test has 100% sensitivity or specificity. Moreover, confirmatory testing has complicating issues associated with its performance. Salt loading, if used for testing, can raise BP and worsen hypokalemia and is problematic in the patient who already has poorly controlled hypertension. Testing also requires the patient not use any medications that interact with the RAS, which means discontinuing β-blockers, ACE-Is,

ARBs, MRBs, direct renin inhibitors, and diuretics; this can lead to significant worsening of hypertension control.[38] How long these medications should be held is not clear. Acute effects will dissipate within days as the medications are metabolized, but chronic effects on expression of proteins involved in adrenal aldosterone metabolism may persist longer.

Confirmatory testing should be considered if the diagnosis is in doubt and if it will substantially alter management. In general, patients with resistant hypertension respond to MRBs with significant BP improvement regardless of whether they have primary aldosteronism.[44,45] Because of this, confirmatory testing may not alter the decision as to whether to use MRB therapy in this population. We generally reserve confirmatory tests for patients with an adrenal adenoma found for unrelated reasons who have mild hypertension and are under evaluation for possible adrenalectomy. In this latter patient population, the benefits of MRB therapy are less clear, and the clinical risks associated with holding RAS blockers are substantially less.

Unilateral Versus Bilateral Differentiation

Selection of Patients for Further Testing

Once primary aldosteronism is diagnosed, the clinician should consider the possibility that the patient has unilateral aldosterone release, in which case adrenalectomy may be curative. However, this step is important only if the patient is both an appropriate surgical candidate and the patient desires possible surgical intervention. If either condition is not met, then further evaluation is not necessary, and the patient can be treated with MRB therapy.

Imaging Approaches

Adrenal imaging is typically the next step in evaluation. Unilateral autonomous aldosterone production is often the result of an aldosterone-producing adenoma (see Fig. 39.3), which is frequently sufficiently large to be identified by thin-slice (1 mm) CT (see Fig. 39.4). However, in some cases, microadenoma that are not detectable with current imaging approaches are the cause of unilateral autonomous aldosterone release. Bilateral autonomous aldosterone production is typically not associated with the presence of a detectable functional adenoma, but nonfunctional adrenal adenomas are frequent, and their incidence increases with age. Consequently, the presence of an adenoma on imaging studies does not necessarily indicate unilateral disease, and its absence does not necessarily indicate bilateral aldosterone production. Overall, an adrenal adenoma in a patient with primary aldosteronism has an approximately 70% to 80% chance that it is functional (i.e., an APA is present) and a 20% to 30% chance that it is a nonfunctional adenoma.[48] In patients younger than 40 years old, the likelihood of a nonfunctional adenoma is less, and the likelihood of an APA is greater. The absence of a detectable adenoma indicates bilateral aldosterone production in 70% to 80% of cases, but there is a 20% to 30% chance of unilateral aldosterone production.

Adrenal Vein Sampling

Adrenal vein sampling is the definitive test for determining whether autonomous aldosterone release is unilateral or bilateral. This is a technically difficult procedure and should be performed in a specialized center experienced with it. When interpreting adrenal vein sampling results, the first step is to confirm sampling of both the right and left adrenal veins. The right adrenal vein is short and may have a common insertion into the inferior vena cava (IVC) as the inferior accessory hepatic vein, making successful cannulation difficult. Accordingly, biochemical confirmation of successful adrenal vein sampling should be employed. This is done by measuring the concentration of a hormone produced in the adrenal gland and showing that the observed concentration is significantly greater than in the IVC. To quantitatively evaluate whether the adrenal veins were successfully cannulated, a selectivity index is calculated from the adrenal vein and IVC cortisol concentrations (Table 39.3). The higher the selectivity index, particularly if it is greater than 2 in unstimulated and greater than 5 in stimulated samples, the greater the confidence that the sample accurately reflects adrenal origin.[49] Cortisol is the most frequently measured analyte, but metanephrine or androstenedione can also be used.[50,51] Stimulation of cortisol production with cosyntropin can facilitate confirmation of adrenal vein cannulation by increasing adrenal cortisol production, which increases adrenal vein cortisol levels acutely with minimal effects on IVC cortisol. However, cosyntropin can also stimulate aldosterone secretion, which can lead to differing conclusions as to whether aldosterone production is unilateral or bilateral in as many as 25% of cases.[52]

TABLE 39.3 Formulas Used to Interpret Adrenal Vein Sampling Results

Name	Formula	Comment
Selectivity index (SI)	$SI_X = [Cortisol_X]/[Cortisol_{IVC}]$	Metanephrine or androstenedione measurements may be substituted for cortisol.
Lateralization index (LI)	$LI = \frac{[Aldo_A]/[Cortisol_A]}{[Aldo_B]/[Cortisol_B]}$	Calculate using the adrenal vein sample with the higher aldosterone concentration as sample A and the contralateral samples as sample B.

The lateralization index (LI) is then determined to assess aldosterone lateralization. After confirming successful adrenal vein sampling, the ratio of adrenal vein aldosterone to adrenal vein cortisol is calculated for each adrenal vein (see Table 39.2). The LI is calculated by dividing the greater adrenal vein ratio by the lesser adrenal vein ratio. An LI greater than 2.0 supports a diagnosis of an aldosterone-producing adenoma, but this cutoff is not 100% specific. Our practice is to use an LI greater than 2.0 to indicate an aldosterone-producing adenoma if this is concordant with imaging findings. If the LI finding is discordant with imaging, we consider a LI between 2 and 4 an indeterminant finding. The importance of interpreting adrenal vein sampling in context of the clinical situation is exemplified by the finding that adrenal vein sampling performed twice within 5 minutes had a discordance rate of 13% for the selectivity index and 10% for the LI.[53]

Other Testing Options

Many other diagnostic tests have been suggested in the evaluation of primary aldosteronism to differentiate unilateral from bilateral disease, but none has widespread acceptance. Noninvasive physiologic tests, such as saline suppression test and postural stimulation tests, rely on the association that APA-mediated aldosterone release is typically not stimulated by Ang II, whereas in hyperplastic lesions, Ang II-dependent stimulation is generally retained. All medicines that affect the RAS, including diuretics, β-blockers, ACE-Is, and ARBs, must be stopped before testing, but the difficulty in controlling BP in these patients without these medicines often limits the utility of this test. In addition, the association of Ang II-stimulated aldosterone production is discordant with whether aldosterone release is unilateral or bilateral in as many as 20% of cases, leaving this test result insufficiently accurate to determine whether surgical therapy is appropriate in most

cases. Its main role may be in the evaluation of the patient with an adrenal adenoma and unsuccessful adrenal vein sampling.[54]

Aldosterone Breakthrough

Approximately 30% to 40% of patients treated with an ACE-I or ARB respond with an initial decrease in the plasma aldosterone levels, which is then followed by a return of their aldosterone level to baseline, or even above baseline, levels. This is termed *aldosterone breakthrough*.[55] Mechanisms that have been proposed to explain this include ACE-independent Ang II generation, Ang II–independent stimulation of aldosterone generation, possibly via either ACTH or ANP, and alterations in endothelial nitric oxide formation.[55,56] Aldosterone breakthrough likely contributes to the development of resistant hypertension in patients being treated with an ACE-I or ARB and likely contributes to progressive kidney disease in CKD.

Metabolic Syndrome

The metabolic syndrome is associated with elevated plasma aldosterone levels,[57] which may contribute to the associated, and often resistant, hypertension. However, it does not appear to be associated with changes in plasma renin activity.[57] The mechanism of the increased plasma aldosterone may involve adipocyte production of cytokines that stimulate adrenal sensitivity to Ang II.[58] It may also involve fructose, a common pathogenic factor in the metabolic syndrome, stimulating vasopressin release, which stimulates ACTH release[59] and thereby increases aldosterone production. Vasopressin may also directly increase adrenal aldosterone secretion.[60]

NATURAL HISTORY

The natural history of untreated primary aldosteronism leads to a variety of significant complications. Clearly, it is a major cause of worsening hypertension, and it also increases the incidence of hypokalemia, with its adverse chronic effects. In addition, it leads to a wide variety of end-organ complications. These end-organ effects include increased risks of coronary heart disease, atherosclerotic peripheral vascular disease, cardiac arrhythmias, left ventricular hypertrophy, low bone mineral density, and development of CKD.[33,61] The incidence of these complications appears to be twofold greater than in patients with essential hypertension of the same magnitude. These effects appear to be related to excessive activation of mineralocorticoid receptors in these end-organ tissues and therefore reflect a direct, and blood pressure-independent, disease association. Effective treatment of primary aldosteronism appears to substantially improve these risks. Therefore, treatment either with MRBs or with adrenalectomy is recommended for all patients with primary aldosteronism.

TREATMENT

Adrenalectomy

Patients with unilateral autonomous aldosterone production, typically from an APA, who are acceptable surgical candidates, can have a dramatic response to adrenalectomy. Patients with an APA who undergo adrenalectomy have a greater than 95% likelihood of biochemical cure and a 30% to 60% chance of hypertension cure.[62,63] Patients most likely to have their hypertension cured are female, younger than 50 years, and have shorter duration of hypertension, lower body mass index, and few family members with primary hypertension. Those not cured have a greater than 95% chance of BP improvement.[62,63] The lack of complete cure may reflect microvascular disease that developed because of the poorly controlled hypertension and/or hypokalemia. Adrenalectomy performed using a laparoscopic approach is associated with a relatively short hospital stay, low postoperative morbidity, and a rather quick return to normal health, at least compared with a nonlaparoscopic surgical approach. Adrenalectomy should not be performed in patients with bilateral autonomous aldosterone production because unilateral adrenalectomy is not curative and bilateral adrenalectomy is associated with unacceptable long-term complications because of the induction of deficiency of other adrenal hormones, such as glucocorticoids and catecholamines.

Mineralocorticoid Receptor Blocker Therapy

Patients who are not candidates for surgical adrenalectomy or who have bilateral aldosterone production should be treated with MRBs. Current MRB treatment options are spironolactone and eplerenone. Many patients will find that their responses are delayed, and monthly dose adjustments are often needed until an optimal dose is identified. It is possible that some of the effects of MRB therapy may also be mediated through effects on pannexin.[64]

The choice of which MRB to use involves consideration of effectiveness and side effects. Importantly, the treatment efficacy of these two agents is quite different. Spironolactone is more effective than eplerenone at improving BP, yielding almost twice as great a BP reduction and a substantially greater proportion of patients experiencing a significant BP improvement.[65] Spironolactone also has off-target effects on sex-steroid hormone receptors, which can lead to breast enlargement (gynecomastia) in men and breast tenderness (gynecodynia) and menstrual irregularities in women. These side effects are dose-dependent and are typically mild or absent at doses of 100 mg per day or less. Eplerenone is more selective than spironolactone for the mineralocorticoid receptor, and the risk of these side effects is less, but its efficacy is also less.

Based on its greater treatment efficacy, we recommend spironolactone as the preferred initial agent for medical treatment of primary aldosteronism. Treatment with an MRB usually results in dramatically improved BP control. Many patients will respond to a low dose of spironolactone (25–50 mg daily) as initial therapy. Both systolic BP and diastolic BP often decrease by about 25 mm Hg over a few weeks to months. Dosage of the MRBs can be increased as necessary but generally should not be changed more than every 2 to 4 weeks. If present, hypokalemia and metabolic alkalosis typically improve. Potassium supplements can often be stopped when MR therapy is initiated; if not, the dose can often be tapered rapidly. Because there is significant interpatient variability in the serum K^+ response after initiating MRB therapy, close follow-up is needed.

With time, BP can be controlled in many patients with an MRB and a single alternative agent. We typically use ACE-Is or ARBs because renin activity, which is suppressed initially, typically increases after starting MRB therapy. Synergistic use of an ACE-I or ARB may prevent development of a renin-stimulated, Ang II–dependent component of hypertension. However, many antihypertensive combinations can be used successfully with the MRB.

Many of the side effects of MRBs can be easily managed. Muscle cramps occur with both spironolactone and eplerenone. Changing from one MRB to the other often allows resolution of the muscle cramps. MRBs can cause neuropsychiatric side effects that are often nonspecific and can include symptoms of feeling out of touch with reality, difficulty thinking, and decreased attention and performance in various memory tasks.[65,66] In general, these effects are temporary and resolve within a few weeks.

Other MRBs are in development and may become available for use soon. Finerenone is a novel, selective, nonsteroidal MRB that may have less effect on serum potassium and slows the progression of diabetic nephropathy.[67] This may make this medication useful in selected patients. Multiple other nonsteroidal MRBs are also in development.[68]

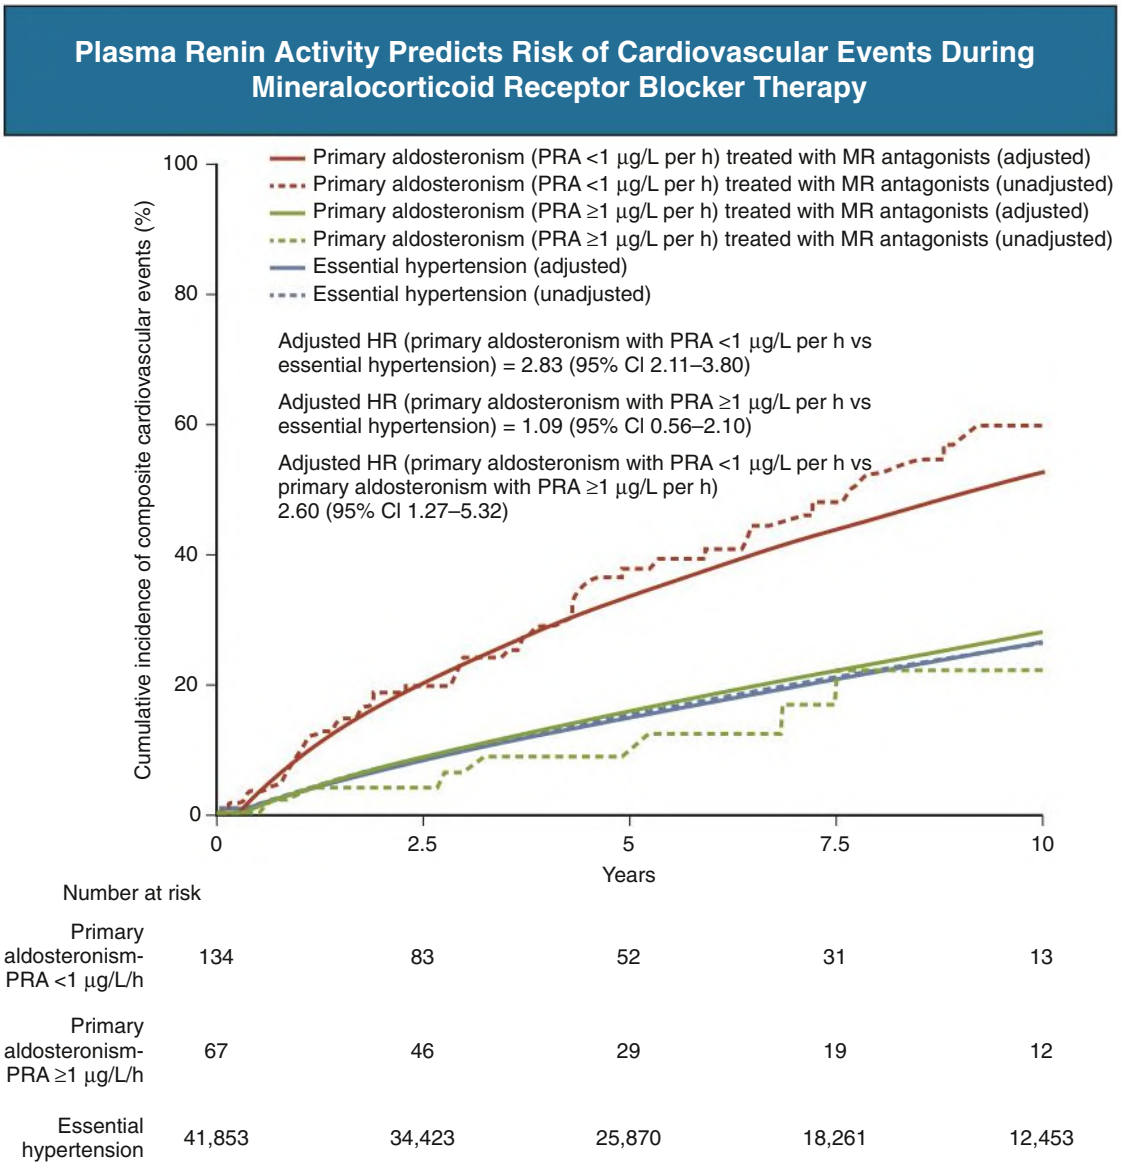

Fig. 39.7 Plasma Renin Activity Predicts Risk of Cardiovascular Events During Mineralocorticoid Receptor Blocker (MRB) Therapy of Primary Aldosteronism. Patients with primary aldosteronism treated with MRBs that have plasma renin activity of at least 1 ng/mL/hr have a composite risk of cardiovascular events not significantly different from matched patients with essential hypertension. Those patients with plasma renin activity less than 1 ng/mL/hr have a significantly increased hazard ratio (HR) for composite cardiovascular events 2.83-fold greater. *CI,* Confidence interval; *PRA,* plasma renin activity; *MR,* mineralocorticoid receptor. (From Hundemer GL, Curhan GC, Yozamp N, Wang M, Vaidya A. Cardiometabolic outcomes and mortality in medically treated primary aldosteronism: a retrospective cohort study. *Lancet Diabetes Endocrinol.* 2018;6:51–59.)

Monitoring Mineralocorticoid Receptor Blocker Therapy With Plasma Renin Measurements

Primary aldosteronism is associated with end-organ complications, particularly affecting the cardiovascular system, whose frequency is greater than that expected from the associated hypertension. This suggests that treatment of primary aldosteronism directed solely at controlling BP may not fully reverse the adverse consequences of primary aldosteronism. Assessment of the plasma renin activity response during therapy may be helpful (Fig. 39.7). Recent studies show that MRB therapy that results in reversal of the plasma renin suppression, to greater than 1 ng/mL/hr, is associated with major cardiovascular events, mortality, and atrial fibrillation rates similar to matched patients with essential hypertension.[34,35] In contrast, in those treated with MRB therapy who continue to have suppressed plasma renin activity, less than 1 ng/mL/hr, these rates remain approximately two-fold elevated.[34,35] Although alternative explanations other than therapy effectiveness are possible, we recommend using a plasma renin-guided therapeutic approach, adjusting the MRB dose on a 1- to 2-month basis targeting a plasma renin activity greater than 1 ng/mL/hr.

Choice of Adrenalectomy Versus MRB Therapy

The choice of adrenalectomy versus MRB therapy for the patient with unilateral autonomous aldosterone production is often not easy. Adrenalectomy is associated with a greater than 95% biochemical cure, and with clinical cure (normotension and normokalemia without medications) of 30% to 60%. Studies comparing outcomes in patients with unilateral primary aldosteronism treated with adrenalectomy versus medical therapy have suggested benefits from adrenalectomy in terms of lower all-cause mortality, reduced risk of stroke and atrial fibrillation,

and regression of left ventricular hypertrophy in patients treated with adrenalectomy rather than MRB therapy.[19,69] However, whether the patients treated with MRB therapy had normalization of the plasma renin is unknown, and if they did not, whether renin-guided medical therapy would have resulted in equivalent outcomes as adrenalectomy is also unknown. Finally, many patients are elderly, have significant comorbid medical conditions that make adrenalectomy relatively contraindicated, or prefer not to undergo elective surgery.

Nonmineralocorticoid Receptor Blocker Therapy

In occasional patients, high doses of MRBs will not be sufficient to block the effects of aldosterone on BP, potassium, and plasma renin. In this case, addition of a medication that specifically blocks aldosterone's effect on renal NaCl reabsorption can be helpful. Aldosterone specifically stimulates the distal epithelial cell Na^+ transporter, ENaC, which contributes to the volume expansion and resultant hypertension. Use of ENaC inhibitors, such as amiloride or triamterene, in combination with MRBs may be helpful. We typically use amiloride, starting at 5 mg by mouth daily and titrating as needed.

Aldosterone synthase inhibitors are a new treatment option under development.[70] These medications directly inhibit adrenal aldosterone synthesis, leading to decreased plasma aldosterone levels and improvements in BP control. Because they do not target MR, their side effect profile is likely to differ from that seen with MRBs, although the development of hyperkalemia is not likely to differ.

Considerations in the Treatment of Patients With Chronic Kidney Disease

CKD is common in patients with primary aldosteronism,[71,72] which leads to several concerns regarding changes in serum/plasma K^+ and GFR. This frequency may be because of direct effects of aldosterone to stimulate renal fibrosis and glomerular injury, manifested initially as albuminuria, and to indirect effects resulting from the associated hypertension and, if present, hypokalemia. Because aldosterone also stimulates glomerular hyperfiltration, which may contribute to renal injury, the full extent of renal injury may not be evident until the primary aldosteronism is adequately treated. Anticipating and then appropriately responding to these effects is helpful for the management of the patient with CKD and primary aldosteronism.

Patients with CKD who are treated with an MRB may be more likely to develop clinically significant hyperkalemia during treatment. Treatment with a K^+-binding polymer, such as patiromer or sodium zirconium cyclosilicate, can facilitate treatment, enabling continued MRB use with less risk of hyperkalemia,[73] and the beneficial effect is maintained even if eGFR is between 25 and less than 30 mL/min/1.73 m^2.[74] Our recommendation is to follow closely patients who have CKD who are started on MRB therapy for the development of hyperkalemia. If it occurs, we then start therapy with a K^+-binding resin (see above), dosed as needed to control the serum/plasma K^+. Although this approach is supported by the benefit of MRB treatment to improve BP and to slow the progression of CKD, whether correcting the hyperkalemia by addition of a K^+ binder versus discontinuation of MRB deserves further study.

Second, initiation of MRB therapy can be associated with an acute decrease in eGFR in patients with CKD. However, patients with a greater acute decrease had a slower long-term eGFR decline.[75] Acute decreases in eGFR after initiating therapy with an MRB does not need to be an indication to discontinue therapy.

SELF-ASSESSMENT QUESTIONS

1. The most common genetic cause of primary aldosteronism because of an APA is related to a mutation in which protein?
   - **A.** Aldosterone synthase
   - **B.** Mineralocorticoid receptor
   - **C.** AT1 receptor
   - **D.** Potassium channel (KCNJ5)
   - **E.** Sodium channel (ENaC)
2. Based on recent comparative studies, which of the following MR antagonists for primary aldosteronism is preferred and for what reason?
   - **A.** Eplerenone because of greater efficacy
   - **B.** Eplerenone because of fewer side effects and less drug discontinuation
   - **C.** Spironolactone because of greater efficacy
   - **D.** Spironolactone because of fewer side effects and less drug discontinuation
3. Which of the following is the preferred first-line test for identification of primary aldosteronism?
   - **A.** Serum potassium
   - **B.** Plasma aldosterone
   - **C.** Plasma renin activity
   - **D.** ARR in combination with absolute level of plasma aldosterone
   - **E.** Urinary sodium and potassium excretion rate

Other Endocrine Causes of Hypertension

A. Lauren Fishbein, Mark Richards, Debbie L. Cohen

Endocrine causes of hypertension often are undiagnosed. Some studies suggest endocrine causes make up over 20% of all secondary hypertension cases, of which primary aldosteronism is most common.[1]

Endocrine hypertension frequently occurs in the absence of readily observed signs and symptoms, but certain features should trigger consideration (Fig. 40.1). Chapter 39 discusses primary aldosteronism; this chapter describes the other causes of endocrine-related hypertension.

CUSHING SYNDROME

Definition

Cushing syndrome is defined by sustained glucocorticoid excess that does not follow a circadian rhythm. Cushing syndrome can be caused by overproduction of adrenocorticotropic hormone (ACTH) by a pituitary adenoma (i.e., Cushing disease); by cortisol overproduction from an adrenal adenoma, adrenal nodular hyperplasia, or adrenal cortical carcinoma; or rarely as secondary to ectopic ACTH (corticotrophin) secretion from neuroendocrine tumors.[2-4] Approximately 0.5% of patients with bronchogenic carcinoma (more common in men than women) develop ectopic ACTH syndrome. Even more rare, ectopic corticotropin-releasing hormone (CRH) from tumors can cause hypercortisolism. Another rare cause of Cushing syndrome is Carney complex, an autosomal dominant disorder featuring cardiac myxomas and pigmented skin/mucosal lesions and Cushing syndrome. The most common cause of Cushing syndrome is exogenous corticosteroid administration, including from steroids present in joint injections, creams, inhalers, nasal sprays, and oral steroids. The incidence of endogenous Cushing syndrome is 5 to 10 cases per 1 million population per year. Cushing disease and cortisol-secreting adrenal tumors are four times more common in women than in men.

Etiology, Pathogenesis, and Epidemiology

Hypertension is present in 80% of patients with Cushing syndrome (less often when caused by exogenous synthetic corticosteroid administration) and results from an increase in both cardiac output and total peripheral resistance.[5]

In some patients, Cushing syndrome may be caused by concurrent overproduction of mineralocorticoids such as aldosterone, 11-deoxycorticosterone, and corticosterone. Although cortisol can bind to the mineralocorticoid receptor (MR) in the kidney, it usually does not because 11β-hydroxysteroid dehydrogenase type 2 (11β-HSD2) inactivates cortisol to cortisone, thereby preventing its binding to the MR. However, in patients with extremely high cortisol levels (e.g., severe Cushing syndrome as in ectopic ACTH syndrome), 11β-HSD is overwhelmed, and excess cortisol can bind the MR and lead to a pseudohyperaldosterone state.

Cardiac and vascular MR activation may foster cardiovascular inflammatory, hypertrophic, and fibrotic changes. Inhibition of the vasodilator nitric oxide (NO) by cortisol may contribute to the hypertension, along with enhanced pressor responsiveness to catecholamines and angiotensin II (Ang II), heightened cardiac inotropic sensitivity to β-adrenergic stimulation, and increased plasma volume.[5] The sympathetic nervous system and renin-angiotensin system (RAS) may be suppressed, even though circulating levels of renin substrate are increased. Adipokines, including leptin and resistin, plus release of proinflammatory cytokines (tumor necrosis factor-α, interleukin-6), also may contribute to the increased cardiovascular (CV) risk observed in Cushing syndrome.[2–4,6–8]

Successful treatment of Cushing disease or removal of an underlying adrenal adenoma usually results in blood pressure (BP) reduction and partial return of the previously impaired nocturnal fall in arterial pressure, although hypertension persists in some patients.[8]

Clinical Manifestations

Clinical features in Cushing disease result from elevated circulating levels of hormones, including ACTH (increased pigmentation) and cortisol (central adiposity, insulin resistance or diabetes, muscle wasting/weakness, plethoric facies, purple striae [Fig. 40.2], easy bruising, osteoporosis, psychological problems). In some patients, androgen effects are observed (hirsutism, acne, virilization) and may be striking in those with adrenal adenoma or adrenal cortical carcinoma. Ectopic ACTH syndrome caused by small cell lung carcinoma or other tumors (e.g., bronchial or thymic neuroendocrine tumors) manifests typically as a wasting disease, often with hyperpigmentation (from the very high ACTH levels) and hypokalemia (from the MR binding in very high cortisol states). Hypertension is often associated with left ventricular hypertrophy, which can be disproportionate to the blood pressure, and frank cardiac failure is occasionally the presenting feature.[2,5]

Differential Diagnosis

Pseudo-Cushing syndrome can occur with a sustained high intake of alcohol by inducing augmented cortisol secretion and reduced cortisol metabolism caused by hepatic damage. Routine diagnostic tests are unable to distinguish alcoholic pseudo-Cushing syndrome from true Cushing syndrome, and reassessment after alcohol withdrawal may be required.[9] Depression is associated with an increased cortisol level. Careful psychological and physical evaluation will usually differentiate these patients from those with Cushing syndrome.

Diagnosis

Initial evaluation should test for one or more of the following: (1) an elevated 24-hour urinary free cortisol excretion (at least two collections), (2) increased late night salivary cortisol (at least three samples), (3) absence of suppression of 7 to 8 AM serum cortisol after a 1 mg dose of dexamethasone taken at midnight the night before the morning blood draw (1 mg dexamethasone suppression test), and (4) failure

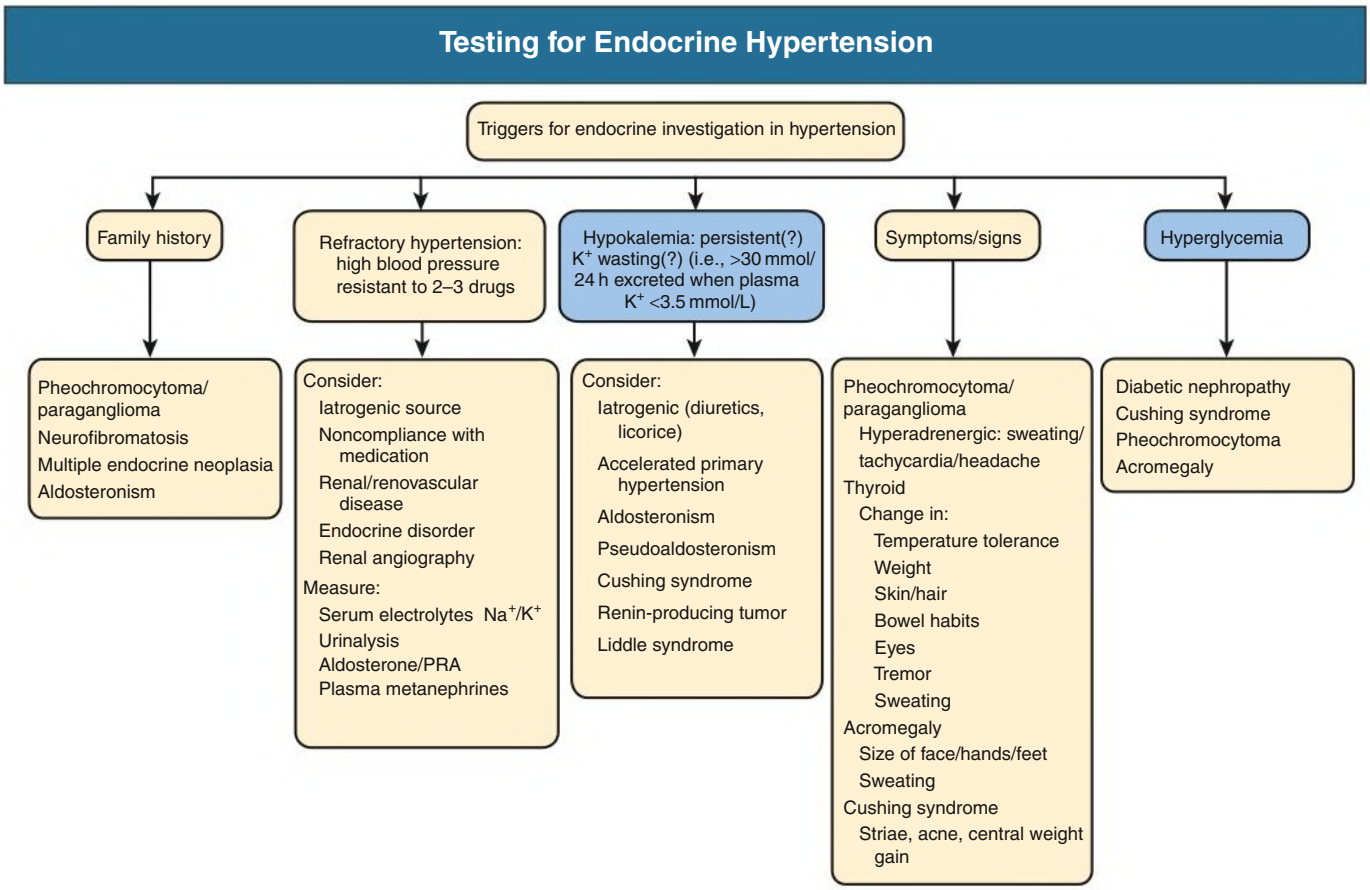

Fig. 40.1 Testing for Endocrine Hypertension. Clinical observations suggesting investigation into endocrine causes of hypertension in hypertensive patients.

Fig. 40.2 Striae and central obesity in a patient with Cushing syndrome.

of suppression of serum cortisol on low-dose dexamethasone (0.5 mg four times daily) for 48 hours. Random blood cortisol measurements are not reliable.

A positive screening test result should trigger involvement of an endocrinologist. Once the screening tests suggest hypercortisolism, early morning cortisol, ACTH, and dehydroepiandrosterone sulfate (DHEAS) can be measured; high levels of ACTH suggest ACTH-dependent causes of hypercortisolism (pituitary adenoma or ectopic ACTH), whereas low ACTH suggests ACTH-independent causes (adrenal adenomas or adrenal cortical carcinoma). Magnetic resonance imaging (MRI) of the pituitary is recommended for ACTH-dependent causes, and computed tomography (CT) of the adrenal glands is recommended for ACTH-independent causes. ACTH-producing pituitary adenomas, corticotroph adenomas, are often small and may not be well visualized on MRI. For ACTH-dependent cases, further tests may include a high-dose dexamethasone suppression test (8 mg dexamethasone suppression test) that partially suppresses ACTH (at least 50% reduction) in patients with pituitary tumors but not with ectopic ACTH. The response of plasma ACTH to a dose of corticotrophin-releasing hormone (≥20% rise in response to CRH points to a pituitary source) may help distinguish pituitary from adrenal or ectopic tumors. The gold standard to differentiate Cushing disease from ectopic ACTH production is bilateral inferior petrosal sinus sampling (IPSS) for ACTH measurements performed by experienced interventional radiologists. IPSS will show higher ACTH from the petrosal sinus sampling compared with the peripheral blood levels if the source is from the pituitary; no gradient will be seen between the petrosal sinus and the peripheral blood if the source is ectopic. If an ectopic source is suspected, imaging of the thorax/abdomen/pelvis is indicated to detect the most common sources of ectopic ACTH (e.g., lung cancer, pancreatic neuroendocrine tumors, pheochromocytomas/paragangliomas, medullary thyroid cancers). If cross-sectional imaging is unhelpful, ^{68}Ga-DOTATATE positron emission tomography (PET)/CT may be used to highlight tissues with somatostatin receptors and identify the location of ectopic ACTH production.[10]

Treatment and Prognosis

Untreated patients with Cushing syndrome have 50% 5-year mortality because of CV risk from hypertension, along with glucose intolerance, insulin resistance, hyperlipidemia, and obesity.[4,5]

Surgical removal of a pituitary microadenoma in Cushing disease results in 80% to 90% cure rates, whereas 50% cure rates occur for

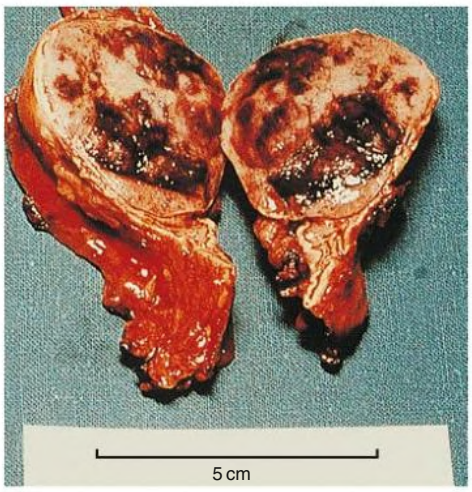

Fig. 40.3 Large adrenal pheochromocytoma with areas of hemorrhagic necrosis.

pituitary macroadenomas. Cushing syndrome due to adrenal adenoma is almost always cured by unilateral adrenalectomy. However, prognosis is poor when Cushing syndrome is from adrenocortical carcinoma or ectopic causes such as small cell lung cancer. If the ectopic ACTH-producing tumor can be located, and complete removal occurs, there is a substantial reduction of mortality. After cure of Cushing syndrome, approximately 30% of patients have persistent hypertension.[11]

No evidence supports the use of any antihypertensive class over another. Potassium-losing diuretics can exacerbate both hypokalemia and glucose intolerance, whereas potassium-sparing diuretics, usually in combination with other antihypertensive agents, may correct hypokalemia and reduce edema while lowering BP.

PHEOCHROMOCYTOMA/PARAGANGLIOMA

Definition

Pheochromocytoma and paraganglioma (PPGLs) can mimic a wide spectrum of other disorders, and the diagnosis is frequently delayed or missed.[12] PPGLs are tumors of the autonomic nervous system that arise from chromaffin tissue in the adrenal medulla (Fig. 40.3) and from sympathetic extra-adrenal ganglia, which secretes catecholamines and metanephrines, or the parasympathetic ganglia, which are nonsecretory, especially those in the head and neck (Fig. 40.4).

PPGLs occur in 2 to 8 per million people and are a rare cause of hypertension (0.2%–0.6% of all patients with hypertension),[13] yet pheochromocytomas make up 4% to 7% of adrenal incidentalomas.[14] Making the diagnosis is key because, when undiagnosed, these tumors are associated with high morbidity and mortality secondary to the uncontrolled catecholamine levels leading to hypertension, heart disease, stroke, and death. Although most tumors are localized, up to 25% can be metastatic and associated with a poor prognosis.[15] There are no good predictors of metastatic disease, and histologic features are not a reliable predictor for aggressive behavior. Large tumor size, extra-adrenal location, *SDHB* germline pathogenic variant, and very high dopamine/methoxytyramine secretion are associated with metastatic disease but are not specific.

Prevalence and Genetic Association With Pheochromocytoma and Paraganglioma

The prevalence of diagnosed pheochromocytoma in patients with hypertension in general medical outpatient clinics is 0.1% to 0.6%[16]; the true prevalence may be considerably higher.[12,16] PPGLs can be sporadic or familial. Up to 40% of patients with PPGLs will have a germline pathogenic variant in one of over 14 genes known to increase risk of PPGL[12,15] (Table 40.1). Guidelines recommend that all patients with these tumors be referred for clinical genetic testing because of the high rate of hereditary predisposition[12] and the screening implications for both the patient and family members. The classic tumor suppressor syndromes of neurofibromatosis type 1 (NF1), multiple endocrine neoplasia type 2 (MEN2), and von Hippel–Lindau disease (vHL) were the first discovered to be associated with increased risk of pheochromocytomas, often bilateral, and all are autosomal dominant syndromes (see Table 40.1). The hereditary paraganglioma-pheochromocytoma syndromes are caused by germline pathogenic variants in the *Succinate Dehydrogenase Subunit (SDH)* genes, which make up complex II of the mitochondrial respiratory chain and convert succinate to fumarate in the Krebs cycle. Germline pathogenic variants in any of the four genes *SDHA, SDHB, SDHC,* or *SDHC* and a cofactor, *SDHAF2,* increase risk for PPGLs. Table 40.1 describes more information. *SDHB* is associated with a higher risk of metastatic disease (~25%) compared with the other *SDHx* genes (<5%).[17] *SDHD* and *SDHAF2* germline pathogenic variants are paternally expressed, meaning a carrier will only develop PPGL if the variant was inherited from their father, with extremely rare exception.[18] Carriers of *SDHx* pathogenic variants are at risk for multiple primary PPGLs, clear cell renal cell carcinoma, gastrointestinal stromal tumors, and pituitary adenomas.[15] *SDHx* carriers must undergo lifelong screening, starting between 6 and 10 years of age with annual biochemistry panels and full-body imaging every 2 to 3 years,[19] usually with MRI rather than CT to minimize radiation exposure.

Clinical Manifestations

Classic symptoms from overproduction of catecholamines include headache, sweating, palpitations, anxiety, and pallor; however, patients may be asymptomatic or present with a variety of symptoms; therefore a high level of suspicion is required to make the diagnosis.[20] Although less than 1% of resistant hypertension cases are because of pheochromocytoma/paraganglioma, new or worsening hypertension or diabetes mellitus, with or without symptoms, may be the presenting manifestation. PPGL also may present with symptoms of mass effect because of enlarging tumors. On occasion, a metastatic lesion may be the presenting sign. Physical examination may reveal labile (66%) or persistent (33%) hypertension, and some patients may be normotensive or even hypotensive if epinephrine is the predominant catecholamine secreted. Patients may also present with catecholamine (takutsubo) cardiomyopathy. Hypertensive crisis with or without heart failure may be precipitated by surgery, general anesthesia, pregnancy, or rarely on exposure to radiocontrast material. This also may occur after minor or major trauma and from sudden spontaneous release of catecholamines from the tumor or on hemorrhage into it.

Diagnosis

Diagnosis of pheochromocytoma is based on clinical suspicion and biochemical confirmation. Measurement of plasma-free metanephrines or urinary fractionated metanephrines is used for diagnosis or exclusion of pheochromocytoma. Both plasma and urine metanephrine tests have over 90% sensitivity for PPGLs. Plasma metanephrines are favored because of their ease of collection and higher specificity compared with the 24-hour urine tests (ranging from 79%–98% vs. 69%–95%, respectively).[12] Catecholamine and metanephrine measurements are susceptible to false-positive elevations for many reasons. Interfering medications (Box 40.1) are the most common cause. Plasma tests should ideally be performed with the patient resting for 20

TABLE 40.1 Genetic Syndromes and Clinical Features Associated With PPGL

Gene	Syndrome	Primary PPGL location	Mode of inheritance	Clinical Features	Risk of Malignancy	Clinical Pearls
NF1	Neurofibromatosis type 1 (NF1)	Adrenal pheochromocytoma Can be bilateral	Autosomal dominant 1:3000	≥2 of the following clinical criteria: • 6 or more café-au-lait spots • Lisch nodules (benign iris hamartomas) • ≥2 cutaneous neurofibromas • Plexiform neurofibroma • Axillary or inguinal freckling • Optic glioma • Sphenoid dysplasia (thinning of the long bones) • First-degree relative with NF1	Up to 12%	All patients with NF1 and HTN must be screened for pheochromocytoma
RET	Multiple endocrine neoplasia type 2 (MEN2)	Adrenal pheochromocytoma Bilateral pheochromocytoma 50% (synchronous or metachronous)	Autosomal dominant 1:30 000	MEN2A (90%): • Medullary thyroid carcinoma • Pheochromocytoma • Primary hyperparathyroidism MEN2B (10%): • Medullary thyroid carcinoma • Pheochromocytoma • Mucosal neuromas • GI ganglioneuromas • Marfanoid habitus	<5%	Annual biochemical screening for pheochromocytoma • Age 11 in patients with high-risk mutations (including those in codons 634 and 918) • Age 16 for those with moderate risk mutations
VHL	von Hippel–Lindau	Adrenal pheochromocytoma in 10%–20% Bilateral pheochromocytomas	Autosomal dominant 1:36 000	Multiple different tumors and cysts • Pheochromocytoma • Hemangioblastomas of the central nervous system, including retina • Renal cysts • Clear cell renal cell carcinoma • Pancreatic cysts • Pancreatic neuroendocrine tumors • Endolymphatic sac tumors • Epididymal cysts	5%	Annual biochemical screening for pheochromocytoma should begin at age 5 y
Hereditary Paraganglioma-Pheochromocytoma Syndromes						
SDHA		Any location but more commonly in head and neck region	Autosomal dominant	PPGL GIST	May be high at ~12%	Most experts recommend screening starting between age 6 and 10 y with annual biochemistries and full body imaging (MRI preferred) every 3 y
SDHB		Any location but commonly extraadrenal and HNPGL	Autosomal dominant	PPGL Renal cell carcinoma GIST	23%–50%	
SDHC		Any location but commonly HNPGL or thoracic PGL	Autosomal dominant		<5%	
SDHD		Any location but commonly multifocal and often HNPGL	Autosomal dominant and paternal inheritance		<5%	
Other Germline Susceptibility Genes						
TMEM127	Familial PPGL syndrome	Adrenal pheochromocytoma Can be extraadrenal or HNPGL	Autosomal dominant	PPGL Renal cell carcinoma	<5%	Rare cause of PPGL
MAX	Familial PPGL syndrome	Adrenal pheochromocytoma Can be bilateral	Autosomal dominant		Unknown; may be high	Rare cause of PPGL

TABLE 40.1 Genetic Syndromes and Clinical Features Associated With PPGL—cont'd

Gene	Syndrome	Primary PPGL location	Mode of inheritance	Clinical Features	Risk of Malignancy	Clinical Pearls
FH	HLRCC syndrome	Any location	Autosomal dominant	Leiomyomas of the uterus and skin; renal cell carcinoma	May be high	Rare cause of PPGL
MDH2	Familial PPGL syndrome	Any location	Autosomal dominant			Rare cause of PPGL
EPAS1	Polycythemia paraganglioma syndrome	Any location	Somatic mosaic	Can have polycythemia and/or somatostatinomas		Rare cause of PPGL

GI, Gastrointestinal; *GIST,* gastrointestinal stromal tumors; *HLRCC,* hereditary leiomyomatosis and renal cell carcinoma; *HNPGL,* head and neck paraganglioma; *HTN,* hypertension; *MRI,* magnetic resonance imaging; *PPGL,* pheochromocytoma and paraganglioma.

BOX 40.1 Medications That Interfere With Screening Tests for Pheochromocytomas and Paragangliomas

- Acetaminophen
- Levodopa
- Monoamine oxidase inhibitors
- Selective serotonin reuptake inhibitors
- Sympathomimetics
- Tricyclic antidepressants
- Some β-blockers (especially nonselective)
- Some α-blockers (i.e., phenoxybenzamine)
- Cyclobenzaprine
- Cocaine

minutes in the supine position,[12] although this is not always practical. Most laboratories have different reference ranges for tests drawn in the supine and upright positions to help when interpreting the results. In patients with advanced chronic kidney disease (CKD), there are additional challenges with interpreting test results because catecholamines and their metabolites are renally cleared[21] and patients with advanced CKD or kidney failure have sympathetic hyperactivity.[22] Plasma-free metanephrines appear to be the least dependent on kidney function relative to plasma catecholamines and deconjugated metanephrines but remain higher in patients with kidney disease than hypertensive controls.[21] Different cutoffs for plasma metanephrine concentration have been suggested based on the severity of CKD, which would reduce false-positive screening results from 7.6% to 5% in patients with CKD stage 3 and from 21.9% to 4.1% in patients with CKD stage 4 or higher.[23] Another study suggested that 24-hour urine normetanephrine measurements can be used to detect PPGLs in people with CKD provided that the glomerular filtration rate (GFR) is greater than 15 mL/min/m^2.[24] End-stage kidney disease patients are often anuric; urinary measurements are not possible, and plasma metanephrines have been found to be approximately twofold higher than hypertensive controls.[21]

Imaging

Once the biochemical diagnosis is secured, the lesion must be localized. Cross-sectional imaging with MRI or CT scan (with contrast) of the abdomen and pelvis is recommended first because most lesions will be within the abdomen and pelvis. For patients with known susceptibility gene mutations, imaging of other anatomic locations may be necessary. Paragangliomas, particularly of the head and neck, that are derived from the parasympathetic chain are often nonsecretory; therefore, if suspected, imaging should be performed regardless of biochemical testing results. If patients with a known head and neck paraganglioma have elevated metanephrines, abdominal/pelvic imaging studies must be performed to evaluate for additional sympathetic-derived primary PPGLs.

Imaging with ^{123}I-metaiodobenzylguanidine (MIBG) should be reserved for patients in whom cross-sectional imaging did not reveal a tumor despite markedly abnormal biochemical testing or patients with metastatic disease to assess if the lesions are amenable to treatment with ^{131}I-MIBG.[12] ^{68}GA DOTATATE PET/CT or ^{18}F-FDG PET/CT scanning is preferred (particularly in patients with *SDHB* germline pathogenic variants) over ^{123}I-MIBG imaging for diagnosis of metastatic disease because of higher sensitivity and specificity.[25–28]

Treatment

Once a PPGL has been localized, the patient should be prepared for surgery with a collaborative team approach by the surgeon, anesthesiologist, and physician. Perioperative blockade is important to reduce the morbidity and mortality associated with tumor resection (down to 0%–2%[29]) and should be used before other surgical procedures and biopsies and considered before treatment for metastatic disease such as chemotherapy, radiation, and ^{131}I-MIBG therapy, particularly when catecholamine levels are very elevated. Independent of medication regimen, treatment should also include a high-sodium diet and increased fluid intake. The typical drugs and dosing regimens are shown in Table 40.2.

Medications

α-Blockers

Secretory PPGLs cause α-receptor activation in response to excess catecholamine secretion leading to severe vasoconstriction, which can result in hypertension, arrhythmias, and myocardial ischemia. Therefore, selective or nonselective α-blockers are recommended as first-line therapy in perioperative management.[12] A prospective randomized controlled trial suggested no major differences in using phenoxybenzamine (nonselective) versus doxazosin (α-1 selective) α blockade.[30] The nonselective α-blocker phenoxybenzamine is a noncompetitive inhibitor that covalently (irreversibly) binds to α-1 and α-2 receptors and provides more complete blockade of α receptors. This significantly lowers the risk of an intraoperative hypertensive crisis but can also cause hypotension once the tumor is resected, so vasopressors and IV fluids may be required for 24 to 48 hours postoperatively.

Selective α-1 receptor blockers include doxazosin, terazosin, and prazosin. These competitive inhibitors are relatively short-acting, and their effects can be overcome by the excess catecholamine released during surgery, potentially causing an intraoperative hypertensive crisis. However, their shorter half-life results in less postoperative hypotension.

TABLE 40.2 Common Medications for Perioperative Blockade of Patients With Pheochromocytoma and Paraganglioma

Drug	Mechanism of Action	Common Dosing	Common Side Effects
Nonselective α-Blocker			
Phenoxybenzamine	Noncompetitive antagonist	10 mg 2–3 times daily (maximum 60–100 mg/d)	Orthostasis, nasal congestion
Selective α-Blockers			
Doxazosin	Competitive antagonist	4–8 mg twice daily	Orthostasis, dizziness
Prazosin	Competitive antagonist	5 mg three times daily	Orthostasis, dizziness
Terazosin	Competitive antagonist	1–4 mg once daily	Orthostasis, dizziness
Calcium Channel Blockers			
Nicardipine	Dihydropyridine long acting	30 mg twice daily	Headache, edema, vasodilation
Amlodipine	Dihydropyridine long acting	5–10 mg daily	Headache, edema, palpitations
Tyrosine Hydroxylase Inhibitor			
Metyrosine	Decreases catecholamine production	250–500 mg 4 times daily (dose escalated every 2 days)	Severe lethargy, extrapyramidal neurologic side effects and gastrointestinal upset
β-Blockers			
Metoprolol tartrate (selective β-1 blocker)	Used to treat reflex tachycardia only after full α-blockade achieved	25–50 mg 1–2 times daily	Fatigue, dizziness
Atenolol (nonselective β-1 blocker)	Used to treat reflex tachycardia only after full α-blockade achieved	25–100 mg/d	Fatigue, dizziness

β-Blockers

Preoperative coadministration of β-adrenergic receptor blockers is indicated to control reflex tachycardia only after administration of α-adrenergic receptor blockers and sufficient volume expansion to avoid the potential for hypertensive crisis because of unopposed stimulation of α-adrenergic receptors. This tachyarrhythmia is a desired side effect indicating complete α-blockade has been achieved.

Calcium Channel Blockers

Calcium channel blockers are second-line therapy or add-on therapy.[12] No prospective studies compare α-blockade and calcium channel blockers for preoperative blockade.

Metyrosine

Methyl-paratyrosine (metyrosine) inhibits catecholamine synthesis and may be used in combination with α-adrenergic receptor blockers for a short period before surgery to further stabilize BP or to help control symptoms related to catecholamine excess in those with metastatic PPGL. Metyrosine is infrequently used because it is expensive, its efficacy is controversial, it is not readily available, and it has significant side effects.

Acute Hypertensive Crisis

Acute hypertensive crisis can be the presenting sign in patients with an undiagnosed PPGL and can occur in patients with a known tumor. Intravenous (IV) α-blockade with phentolamine can be used to control BP, with or without other IV vasodilators such as sodium nitroprusside or nicardipine.

Surgery

Surgical resection is the treatment of choice for PPGLs. Laparoscopic surgery for PPGL is associated with better outcomes than open adrenalectomy[31] for small PPGLs. Cortical-sparing surgery should be attempted in patients with or without genetic predisposition for bilateral adrenal pheochromocytomas (MEN2 and vHL) because it may avoid the need for lifelong glucocorticoid and mineralocorticoid replacement. However, there is a risk of recurrence with cortical-sparing surgery. Continuous hemodynamic and cardiovascular monitoring is required during surgery and perioperatively. Postoperatively, patients may require BP support with fluids, colloids, and sometimes α-adrenergic agonists for 24 to 48 hours. BP usually returns to normal within a few days of surgery, but patients may remain hypertensive, particularly if they have chronic underlying hypertension or widespread metastatic disease.

Follow-up

All patients should have plasma metanephrines checked about 4 to 6 weeks after surgery; if levels remain elevated, this may indicate residual or metastatic disease. All patients should have annual plasma metanephrines levels checked for life because recurrence or metastatic disease can occur even 20 years later, and patients also can develop additional primary tumors. All patients with PPGL should be referred for genetic testing because of the high rate of inherited disease (up to 40%).[12] Follow-up imaging is not required for most patients with complete sympathetic PPGL resection unless they have a known germline susceptibility gene mutation. Imaging also should be considered if catecholamines remain elevated or if metastatic disease is suspected.

Pheochromocytoma and Paraganglioma in Pregnancy

PPGL in pregnancy can be dangerous, even fatal, for both the mother and fetus. Perioperative blockade is the same as for nonpregnant patients; however, timing of surgery is often tricky. It is usually recommended to proceed with surgical resection around 18 to 22 weeks of pregnancy. If diagnosis is not made until the third trimester, it is recommended to perform a cesarean section and surgical resection of the PPGL at the same surgery. Spontaneous labor and delivery should be avoided. In patients with genetic predisposition, screening with plasma metanephrine levels is recommended when contemplating conception and/or when pregnancy is confirmed to avoid morbidity from an undetected PPGL. If patients develop a hypertensive crisis during pregnancy, treatment is

the same as for nonpregnant patients except nitroprusside should be avoided because of the risk of cyanide toxicity in the fetus. A recent large multicenter, retrospective study of patients with PPGL and pregnancy included 249 pregnancies in 232 patients with PPGL, and 66% had an underlying germline mutation.[32] Adverse outcomes were associated with unrecognized PPGL during pregnancy, abdominal or pelvic tumor location, and very high catecholamine levels at least 10 times the upper limit of the normal range. For patients diagnosed during pregnancy, α-adrenergic blockade therapy was associated with fewer adverse outcomes, and the outcome was similar if surgery was performed during pregnancy or delayed until after pregnancy.

Metastatic Pheochromocytoma and Paraganglioma

PPGLs should be described as metastatic or nonmetastatic PPGL rather than malignant or benign.[13] Common metastatic sites include lymph nodes, liver, bones including the skull, lung, and peritoneum. Metastases occur in approximately 10% of pheochromocytomas and 20% of paraganglioma and are more likely to occur in large tumors, extra-adrenal paragangliomas, and patients with *SDHB* mutations.[33] Metastases can be detected at the time of primary tumor diagnosis or even 20 years later and are associated with 5-year survival of 50%.[33] Unfortunately, there are no reliable histopathologic markers to predict metastatic disease.

Treatment Options

Treatments for metastatic disease can slow disease progression, but none are curative. Surgical debulking is still the best option when tumor burden is low. If the tumor is MIBG avid, ^{131}I-MIBG therapy can be used. Recently high-specific-activity ^{131}I-MIBG was US Food and Drug Administration (FDA) approved for treatment of patients with metastatic PPGL. Peptide receptor radionuclide therapy (PRRT) using radiolabeled somatostatin analogs is FDA approved for gastrointestinal and pancreatic neuroendocrine tumors and is in clinical trials for PPGL. External beam radiation therapy and proton therapy often are used for bone metastases and control of unresectable head and neck paragangliomas. Cytotoxic chemotherapy with cyclophosphamide, vincristine, and dacarbazine (CVD) can control disease but is not curative.

ADRENAL INCIDENTALOMA

Definition and Epidemiology

Adrenal incidentaloma refers to the incidental discovery of an adrenal mass in the absence of any prior suspicion of adrenal disease.[34,35] The prevalence of unsuspected adrenal masses of adults undergoing high-resolution CT or MRI abdominal studies is approximately 1% in those younger than 30 years, rising to 10% in the elderly.[34]

Hypertension is more common in those with incidentalomas (40%) than in the general population. About 75% prove to be nonsecretory benign adenomas. However, an important minority show hormone secretion, including aldosterone-producing adenomas (2.5%, frequently normokalemic), pheochromocytoma (7%, often normotensive), and, most often, cortisol-secreting tumors (12%).[34]

Subclinical Cushing syndrome (SCS), now referred to as mild autonomous cortisol secretion (MACS) without clinical manifestations of Cushing syndrome, is the most frequent hormonal abnormality detected in patients with adrenal incidentalomas. Cortisol excess should be ruled out by performing a 1-mg overnight dexamethasone suppression test (DST). If the 8 AM serum cortisol concentration after 1 mg of dexamethasone given at midnight the evening before is greater than 1.8 μg/dL, this suggests hypercortisolism. Typically, a level greater than 5 μg/dL is considered overt hypercortisolism, whereas levels between 1.8 and 5 μg/dL are considered MACS. In addition, DHEAS is low in adrenal cortisol excess. A baseline morning ACTH and cortisol can confirm if this hypercortisolism is ACTH independent (ACTH should be low) and from an adrenal nodule. Hypercortisolism, even mild hypercortisolism, is frequently complicated by hypertension (~65% of cases), diabetes (~33%), obesity, and osteoporosis and carries increased risk for CV events and related mortality.[36,37] A recent retrospective study of 632 patients with either MACS (n = 212) or nonsecreting adenomas (n = 420) demonstrated a higher prevalence of atrial fibrillation in those with MACS (8.5%) compared with the nonsecreting group (3.1%).[38]

Adrenal cortical carcinoma (ACC) is rare, affecting 1 to 2 per million people[39] and accounts for a very small percentage of adrenal tumors, but is deadly with 5-year survival of less than 30%. Most ACC are greater than 4 cm on imaging and may or may not be functional (e.g., with evidence of Cushing syndrome, primary aldosteronism, and/or virilization).

Management

Investigation of adrenal incidentalomas should address two key issues: whether the tumor is malignant and whether it is hormonally active. Every adrenal incidentaloma should be evaluated for pheochromocytoma (plasma-free metanephrines or 24-hour urine fractionated metanephrines), glucocorticoid excess (early-morning plasma cortisol concentration after 1 mg dexamethasone given the night before), and, if the patient has hypertension, also evaluated for primary aldosteronism (plasma renin and serum aldosterone levels), as outlined here and in Chapter 39. Tumors with an appearance that is worrisome for malignancy (e.g., noncontrast Hounsfield units [HU] >10), tumors that are growing, tumors more than 4 to 6 cm in diameter, and those that are functional should be surgically resected.[34,35] Adrenal incidentaloma guidelines suggest benign-appearing (HU < 10), small adenomas (less than 4–6 cm) that are nonfunctional no longer need imaging or biochemical follow-up,[34] although some experts suggest even nonfunctional nodules may have long-term cardiometabolic consequences and should have some subsequent follow-up.

RENIN-SECRETING TUMOR

Definition

Primary renin-secreting tumors are rare, and less than 200 cases have been reported.[40] Diagnostic criteria include an elevated plasma renin or prorenin level, which decreases on removal of the tumor, and demonstration of renin within the tumor. Most renin-secreting tumors are caused by benign renal juxtaglomerular cell tumors (JGCT) ranging from 5 mm to 6 cm in diameter (typically 2–4 cm). These tumors occasionally occur with nephroblastomas, renal cell carcinomas, and extrarenal neoplasms (bronchial or pancreatic carcinoma, ovarian tumors, carcinoma of ileum or colon, soft tissue sarcomas, orbital hemangiopericytoma).

Etiology and Pathogenesis

Autonomous hypersecretion of renin results in high circulating levels of Ang II that increase arterial pressure. Secondary hyperaldosteronism and hypokalemia result from stimulation of the adrenal glomerulosa by Ang II. High Ang II levels also induce hyponatremia in a minority of patients, by stimulation of thirst and arginine vasopressin (AVP) secretion, together with a direct renal water-retaining action of the peptide.[40]

Clinical Manifestations

Cases show female predominance; 75% of patients are aged less than 30 years, presenting usually with severe, occasionally paroxysmal

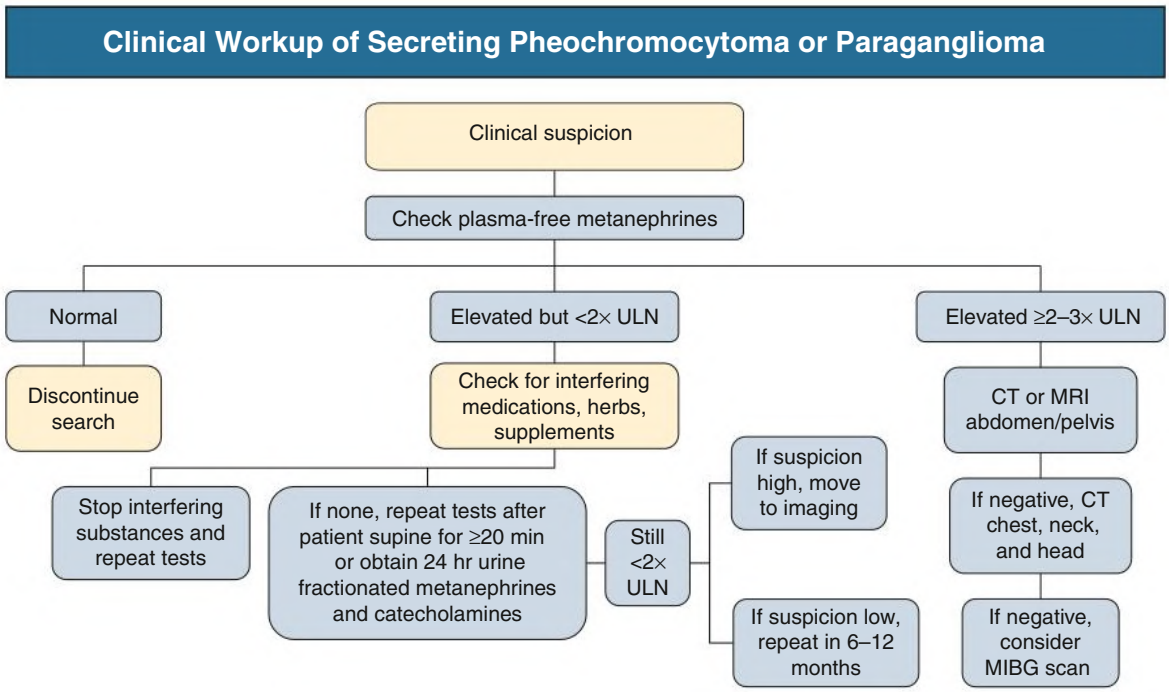

Fig. 40.5 Clinical workup of secreting pheochromocytoma or paraganglioma. *CT*, Computed tomography; *MIBG*, metaiodobenzylguanidine; *MRI*, magnetic resonance imaging; *ULN*, upper limit of normal.

hypertension (average 206/131 mm Hg), hypokalemia (<3.0 mmol/L in ~70% of cases), proteinuria (>0.4 g/day in ~50% of patients), and, in a minority, hyponatremia.[41] GFR is normal or high. BP may decrease substantially with the first dose of angiotensin-converting enzyme (ACE) inhibitor or angiotensin receptor blocker (ARB).

Pathology

Renin-secreting tumors are encapsulated and tan or grayish yellow, with scattered hemorrhages. These masses consist largely of polygonal or spindle cells in close contact with capillary and sinusoidal vessels and contain cytoplasmic renin granules.[40]

Diagnosis and Differential Diagnosis

Patients presenting with hypertension and hypokalemia together with elevated renin (and prorenin) and aldosterone levels may harbor a renin-secreting tumor, most often a JGCT.

CT or MRI angiography or renal arteriography typically identify JGCTs as radiolucent, expansile, homogeneous, solid renal cortical neoplasms, usually 2 to 4 cm in diameter (Fig. 40.5).[41] CT and MRI scans showing an isodense or hypodense lesion with little or no enhancement after injection of contrast material have proved helpful in the provisional localization of these tumors. Bilateral, simultaneous renal vein sampling may enable lateralization of the tumor. Because renal blood flow to the culprit kidney is not impaired, however, a renin ratio of more than 1.2:1 between the two renal veins may not be present, in contrast to unilateral renal artery stenosis, in which reduced blood flow to the stenosed kidney and renin oversecretion often lead to an elevated renal vein renin ratio. Selective segmental renal vein renin sampling may help localize the tumor. When no renal lesion can be visualized and lateralization of renin secretion is not evident, an extrarenal renin-secreting lesion must be considered and sought by appropriate radiographic investigations and venous sampling for renin measurements.

Apart from renal artery stenosis or occlusion, it may be necessary to exclude other renin-producing lesions, including Wilms tumor, renal carcinoma, neuroblastoma, hepatocellular carcinoma, and pheochromocytoma, which can either secrete renin or stimulate renal renin production.

Treatment

Preoperative BP control is achieved using an ACE inhibitor or ARB, introduced cautiously to avoid first-dose hypotension. For JGCTs, local excision is advisable, if possible, to preserve nephrons. When doubt exists, an intraoperative frozen section will differentiate a benign JGCT from malignant lesions and guide surgery. Removal of a JGCT results in the return of renin and aldosterone levels to normal. BP decreases rapidly but not always to normal if there is a history of primary hypertension.[42]

ACROMEGALY

Definition and Epidemiology

Acromegaly is caused by excessive circulating growth hormone (GH) originating from a somatotroph (or somatomammotroph) adenoma of the pituitary in more than 95% of cases.[43] Rare causes include hypothalamic or neuroendocrine tumors secreting GH-releasing factor (GHRH) and, even more rarely, hemopoietic, breast, bronchial, and abdominal tumors may secrete GH. Multiple endocrine neoplasia type 1 is associated with pituitary adenomas, with somatotroph adenomas being the second-most common of the secreting tumors. Acromegaly may appear in other familial settings (e.g., McCune-Albright syndrome, Carney complex) or as an isolated disorder in familial isolated pituitary adenoma.

Acromegaly is rare, with an incidence of 6 to 8 cases per million population per year.[44] The median age of diagnosis is 47 years. Hypertension is more common (~40%) in persons with acromegaly than in the general population, especially in female and older patients.[45] Patients with acromegaly who have additional hypopituitarism or advanced cardiomyopathy may have BP reduction masking before hypertension. Most somatotroph adenomas are macroadenomas resulting in compression of the normal pituitary and hypopituitarism in 75% of cases.

Fig. 40.6 Facial features of acromegaly with enlargement of brow, nose, and jaw.

Fig. 40.7 Radiograph of the Hand in Acromegaly. "Arrowhead" distal phalanges, expanded joint spaces, and increased soft tissue can be seen.

The pathogenesis of hypertension in acromegaly is complex but reflects sodium retention and volume expansion associated with an inappropriate compensatory response. Total exchangeable sodium, total body water, and extracellular fluid volume are increased. Volume expansion should suppress plasma renin levels, but although levels are low, they are not consistent with the sodium status. Aldosterone levels are also normal or only slightly suppressed. The kidneys are enlarged and GFR is increased, but sodium balance is not corrected unless the acromegaly is cured.

Clinical Manifestations

Excess circulating GH stimulates production of insulin-like growth factor 1 (IGF-1) from the liver. IGF-1 mediates the biologic effects of GH. Acromegaly is characterized by enlargement of the jaw (macrognathia), skull (Fig. 40.6), hands (Fig. 40.7), and feet because of bone and soft tissue overgrowth. Other symptoms result from local effects of an expanding pituitary tumor and include visual field defects and headache. The manifestations of disease are gradual, slowly progressing over many years, and diagnosis may be delayed until dysmorphic features are well developed, typically in the fourth to fifth decade. Other signs and symptoms include headache (40%), excessive sweating (50%), loss of libido (35%), amenorrhea (45%), carpal tunnel syndrome (25%), diabetes mellitus (19%), and visual field defects (5%).[43] Thyroid enlargement occurs in 50% of patients and thyrotoxicosis in 6%; hirsutism occurs in 24% of women and galactorrhea in 10%. Other complications of acromegaly include cardiac hypertrophy, systolic and diastolic dysfunction, heart failure, arrhythmia, sleep apnea, osteoarthritis and osteopenia, and disturbed calcium metabolism.[46] Acromegaly is associated with increased risk of malignancy, including a twofold increase in colorectal cancer.

Diagnosis

Clinical suspicion should be raised by symptoms and signs. Box 40.2 lists appropriate tests for acromegaly. Elevated levels of IGF-1 and GH, especially with lack of suppression of GH on oral glucose tolerance testing, are strongly suggestive of the diagnosis. MRI of the pituitary and visual field testing for those with macroadenomas are necessary to define the tumor extension.

Treatment

Treatment aims to lower IGF1 (GH) levels so that symptoms and signs resolve and metabolic abnormalities improve. However, bony overgrowth generally does not reverse. Resection of the pituitary adenoma by transsphenoidal surgery is the treatment of choice. Surgical cure (defined by normalization of plasma IGF-1 and a nadir oral glucose tolerance test GH of < 2 μg/L) is achieved in 81% to 100% of microadenomas and 45% to 68% of macroadenomas.[43] Irradiation and drug therapy are valuable when complete removal of tumor tissue is not possible (approximately one-third of acromegalic cases overall) and when surgery is contraindicated. Somatostatin analogs are first-line medical therapy because they can decrease the size of the residual tumor in addition to lowering GH secretion. If IGF1 levels have not normalized, pegvisomant, a GH receptor antagonist, can be added or may be used as first-line therapy.[43,47] Pegvisomant does not shrink the tumor. Dopaminergic agents, such as bromocriptine and cabergoline, may be helpful to reduce GH levels in mild cases but are not strongly effective. Radiotherapy is used in cases with persistent active disease despite all other treatments but may not exert its full effect for months or years. Patients must be monitored regularly for pituitary function because hypopituitarism may occur late after treatment (even 10 years out) and necessitate hormone replacement in about 40% of patients.[48]

BOX 40.2 Diagnostic Tests for Acromegaly

- Screen with serum insulin-like growth factor-1. If elevated:
  - Serum growth hormone responses to glucose tolerance test to confirm
  - Assessement of full pituitary function (thyroid-stimulating hormone, T4 [thyroxine], prolactin, adrenocorticotropic hormone, cortisol, luteinizing hormone, follicle-stimulating hormone, estradiol/testosterone)
  - Magnetic resonance imaging of pituitary fossa; if macroadenoma, visual field testing

Management of Hypertension in Acromegaly

Surgical removal of the pituitary adenoma with normalization of GH levels may reduce BP, but most patients with acromegaly will continue to require antihypertensive therapy. Antihypertensive treatment

requires a diuretic, given the volume-expanded state. Additional antihypertensive agents are frequently required, and both calcium channel blockers and ACE inhibitors may be effective. β-Blockers also may be used, although theoretically such agents may increase GH concentration.

HYPOTHYROIDISM

Definition and Epidemiology

Hypertension is more common in hypothyroid patients than in the general population. The pathogenesis of the hypertension is multifactorial and associated with both increased total body sodium and increased peripheral vascular resistance.

Hypothyroidism is associated with increased aortic stiffness, loss of sensitivity to vasoconstrictors, and impaired endothelial function with loss of endothelial-dependent vasodilation plus reduced vasodilatory responses to NO donors.[49] Hypothyroidism is associated with increases in arterial pressure, plasma catecholamines, aldosterone, and cortisol.[50-52] The relationship between plasma catecholamine levels and BP is enhanced in hypothyroidism.[53] Hypertension develops despite a low cardiac output.

Thyroid replacement therapy corrects the electrolyte, hemodynamic, and hormone changes and cures the hypertension in most patients.

Clinical Features

Bradycardia, mild hypertension with narrowed pulse pressure, and muffled heart sounds are the most frequent signs in overt hypothyroidism. Other features include weakness, dry skin, lethargy, slow slurred speech, cold intolerance, thick tongue, facial puffiness, coarse and thinning hair, failing memory, constipation, and weight gain with reduced appetite. In extreme cases, myxedema and coma ensue. Coronary heart disease is common, with dyslipidemia and hypertension accelerating atherogenesis.

Diagnosis

Hypothyroidism should be considered in any patient with hypertension. Because the clinical manifestations of hypothyroidism are often difficult to elicit, especially in elderly patients, thyroid function tests, including thyroid stimulating hormone (TSH), should be performed. In patients with primary hypothyroidism who remain hypertensive despite full thyroxine replacement therapy, primary hypertension is likely also present. For those patients with known heart failure or angina who have overt or long-standing hypothyroidism, replacement thyroxine therapy should be given initially with low doses and increased slowly over time to minimize the chance of precipitating myocardial ischemia.

HYPERTHYROIDISM

Definition and Epidemiology

Hypertension is common in hyperthyroidism, with a prevalence of 60% in toxic adenoma and approximately 30% in Graves disease.[2]

Clinical Features

The clinical features depend on the underlying cause of the hyperthyroidism, the severity of the disorder, rapidity of onset, age of the patient, and concomitant disease. Abnormalities may be evident in the CV system (tachyarrhythmias, heart failure), skin (increased sweating, increasing pigmentation with vitiligo), eyes (lid lag, exophthalmos), nervous system (hypertension, nervousness), gastrointestinal system (increased appetite yet weight loss, diarrhea), and muscles (proximal weakness).

Hypertension in hyperthyroidism is associated with an increased pulse pressure and elevated systolic BP with normal or low diastolic BP.[54] It may be observed in both postpartum thyrotoxicosis and neonatal thyrotoxicosis. Elevation of diastolic BP is unusual unless there is concomitant primary hypertension.

The hemodynamic characteristics in hypertension of thyrotoxicosis are an increased cardiac output (by 50%–300%), increased myocardial contractility, tachycardia, decreased peripheral vascular resistance, and expanded blood volume. These indices return to normal in most patients on achieving the euthyroid state. Interestingly, catecholamine levels tend to be low (inversely to hypothyroid hypertension), and there is no sympathetic overactivity. The RAS tends to be activated and the aldosterone levels increased in hyperthyroidism, which may contribute to the development of systolic hypertension. Suspicion of hyperthyroidism should be high in the elderly patient with hypertension and a high pulse pressure, particularly if there is also atrial fibrillation. Such patients are prone to developing cardiac failure, in which case the increased systolic arterial pressure will diminish, masking previous hypertension. Hypertension with a high pulse pressure, although typical of hyperthyroidism, is observed in many elderly patients with primary hypertension because of the loss of compliance of the aorta with aging.

Diagnosis and Treatment

The diagnosis is confirmed by thyroid function tests, including measurement of TSH, and when suppressed, adding a T4 and T3. β-Blockers are effective first-line therapy for hyperthyroidism-associated hypertension because they prevent hyperthyroidism-associated arrhythmias, such as tachycardia and atrial fibrillation. Treatment of hyperthyroidism, whether by antithyroid drugs, surgery, or radioiodine, often will promptly normalize the increased systolic arterial pressure, unless concomitant primary hypertension is present.

PRIMARY HYPERPARATHYROIDISM

The incidence of primary hyperparathyroidism (PHPT) is approximately 20 per 100,000 person-years.[2,55] Full-blown PHPT may feature severe hypercalcemia, nephrolithiasis, acute and chronic kidney disease, and fractures, but patients are usually asymptomatic. The prevalence of hypertension in PHPT approaches 50% with an independent association between plasma ionized calcium levels and the presence of hypertension. In those with MEN2, the hypertension could be a sign of coincident pheochromocytoma.

Indications for surgery in PHPT include serum calcium at least 1 mg/dL above the upper limit of normal, presence of renal stones, decreased renal function with creatinine clearance less than 60 mL/min, elevated urinary calcium greater than 400 mg/day, osteoporosis or vertebral fracture, or age less than 50 years.[56] Generally, mild PHPT in those aged older than 50 years is not an indication for parathyroidectomy, and management involves serial follow-up with monitoring of plasma calcium, renal function, and bone density. Coincident hypertension is not an accepted indication for parathyroidectomy and is managed according to standard guidelines with the notable difference that thiazide diuretics (which may increase plasma calcium) should be avoided. There is some evidence that surgical cure of PHPT and restoration of eucalcemia restores vascular function and BP toward normal.[55]

SELF-ASSESSMENT QUESTIONS

1. Each form of endocrine hypertension:
   A. always manifests typical signs and symptoms.
   B. can always be cured if correct specific therapies are applied.
   C. is usually familial.
   D. may present as hypertension resistant to multiple drugs.
2. Initial screening tests for Cushing syndrome include which of the following?
   A. CT or MRI of pituitary and adrenal glands
   B. 1 mg dexamethasone suppression test
   C. High-dose dexamethasone suppression test
   D. Bilateral inferior petrosal sinus sampling for ACTH
3. Pheochromocytomas/paragangliomas are hereditary in what percent of cases?
   A. <5%
   B. 10% to 15%
   C. 30% to 40%
   D. >70%

Neurogenic Hypertension, Including Hypertension Associated With Stroke or Spinal Cord Injury

Venkatesh Aiyagari, Philip B. Gorelick

An intimate relationship exists between the nervous system and blood pressure (BP).[1] It is well recognized that the elevated BP response to stressors is mediated by the sympathetic nervous system (SNS). However, the role of the SNS in long-term regulation of BP and the initiation and maintenance of hypertension is now better delineated. Several studies of serum catecholamine levels, renal norepinephrine spillover, microneurography, and heart rate variability suggest that sympathetic activation plays a major role in hypertensive patients.[2] The SNS also has an important role in hypertension after neurologic injury. This chapter discusses the physiology and management of hypertension in such injury.

PHYSIOLOGY AND PATHOPHYSIOLOGY

Neural Control of Blood Pressure

The brainstem, especially the ventral medulla, has a key role in the maintenance of BP (Fig. 41.1). BP is controlled by the nucleus tractus solitarius, which receives inhibitory baroreceptor afferents, and the rostral ventrolateral medulla and rostral ventromedial medulla, which are the source of excitatory descending bulbospinal pressor pathways. In addition, a depressor center in the caudal ventrolateral medulla composed of γ-aminobutyric acid (GABA)-containing neurons receives afferents from the nucleus tractus solitarius and projects to the rostral ventral medulla. These inhibitory GABA-containing neurons are tonically active, and reduced activity of these neurons leads to hypertension.[3–5]

The ultimate effector units are the sympathetic neurons located in the intermediolateral cell column of the spinal cord and the parasympathetic neurons found in the dorsal motor nucleus of the vagus and nucleus ambiguus located in the medulla. In addition, impulses from the limbic system, cerebral cortex, and hypothalamus directly or indirectly project to the intermediolateral cell column of the spinal cord and influence BP regulation.

The factors that lead to increased sympathetic activation in hypertension are poorly understood. However, there is strong evidence linking hypertension with increased levels of circulating inflammatory markers, such as tumor necrosis factor-α, interleukin-6, C-reactive protein, monocyte chemoattractant protein 1, and adhesion molecules such as P-selectin and intercellular adhesion molecule 1. Angiotensin II (Ang II) and aldosterone also play a crucial role in vascular inflammation, and treatment with both candesartan and mineralocorticoid antagonists decrease the levels of inflammatory markers. In addition, Ang II–mediated hypertension is associated with brain microglial activation and increased brain levels of inflammatory cytokines and reactive oxygen species. An increase in reactive oxygen species may directly activate or sensitize sympathetic neurons and scavenge nitric oxide, the latter of which tonically inhibits sympathetic outflow. Thus, a dysfunction of the neural-immune-vascular triad leading to an increase in central oxidative stress may drive sympathetic activation, which then increases Ang II and promotes further inflammation and vascular dysfunction.[6] Another matter for debate is whether the kidney or the central nervous system (CNS) is the main driver for increased sympathetic tone in patients with neurogenic hypertension. The role of the afferent and efferent renal nerves in mediating neurogenic hypertension is being researched, and renal denervation procedures are being explored as possible therapeutic options to treat hypertension.

Cerebrovascular Autoregulation

Under normal conditions, cerebral blood flow (CBF) of the adult brain is approximately 50 mL/100 g/min. CBF is regulated by the relationship between cerebral perfusion pressure (CPP) and cerebrovascular resistance (CVR):

$$CBF = CPP/CVR$$

CPP is the difference between the mean arterial blood pressure (MAP) and the intracranial pressure (ICP). If ICP is increased, systemic BP must also increase to maintain CPP and CBF.

Cerebrovascular autoregulation maintains a constant blood flow over a wide range of CPP. Normally, changes in CPP have little effect on CBF because of compensatory changes in CVR. An increase in CPP produces vasoconstriction and a decrease produces vasodilation, thus keeping the CBF constant (Fig. 41.2). Autoregulation is effective for a range of CPP from about 60 to 150 mm Hg. In chronically hypertensive individuals, the cerebral arterioles develop medial hypertrophy and lose the ability to dilate effectively at lower pressures. This leads to a shift of the autoregulatory curve to the right.[7] In these individuals, a rapid reduction of BP may lead to a drop in CBF even though the BP might still be "normal." With effective control of hypertension for several months, the normal range for autoregulation can be reestablished.[8]

Above the upper limit of autoregulation, there is breakthrough vasodilation leading to damage of the blood-brain barrier, cerebral edema, and possibly cerebral hemorrhage. Below the lower limit of autoregulation, decreases in CPP lead to a decrease in CBF. Under these circumstances, increased extraction of oxygen and glucose maintains normal cerebral metabolism and brain function. When the CBF decreases to less than 20 mL/100 g/min, increases in oxygen extraction are no longer able to supply the metabolic needs of the brain, leading to impairment of brain function.

NEUROGENIC HYPERTENSION

It is challenging to identify patients in whom neurogenic mechanisms are the main driver of hypertension. There are no readily available

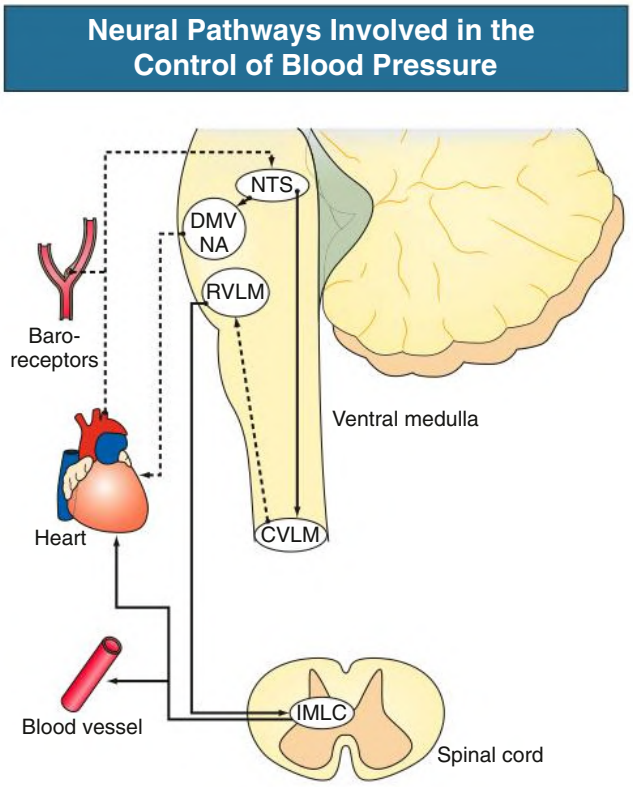

Fig. 41.1 Neural Pathways Involved in the Control of Blood Pressure. The ventral medulla has a key role in generating both excitatory *(solid line)* and inhibitory *(dotted line)* pathways, largely through the rostral ventrolateral medullary neurons (RVLM) and nucleus tractus solitarius (NTS), respectively. Ultimate effector control is provided by sympathetic activation originating in the intermediolateral cell column (IMLC) and parasympathetic action through the nucleus ambiguus (NA) and dorsal motor nucleus of the vagus nerve (DMV). *CVLM,* Caudal ventrolateral medullary neurons.

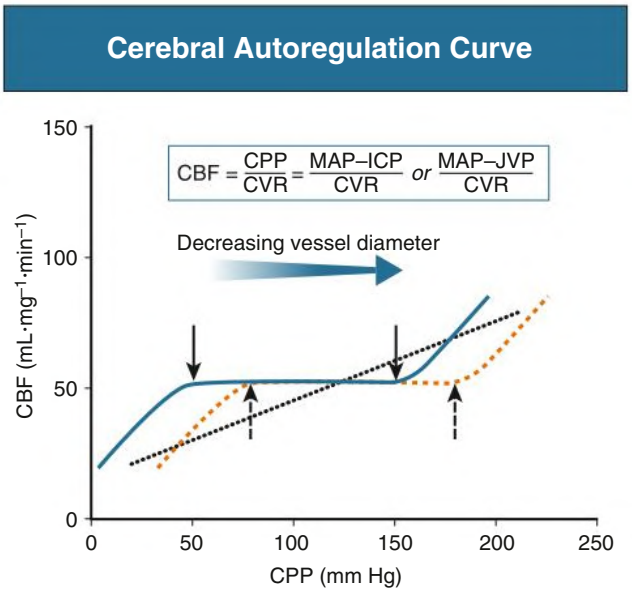

Fig. 41.2 Cerebral Autoregulation Curve. In the normal state *(solid line),* the cerebral blood flow (CBF) is held constant across a wide range of cerebral perfusion pressure (CPP) (60–150 mm Hg). In chronic hypertension *(dashed line),* the autoregulation curve shifts to the right. In the presence of acute cerebral ischemia *(dotted line),* cerebral autoregulation may be impaired, and the CBF becomes dependent on the CPP. *CVR,* Cerebral venous resistance; *ICP,* intracranial pressure; *JVP,* jugular venous pressure; *MAP,* mean arterial pressure. (From Testai FD, Aiyagari V. Acute hemorrhagic stroke pathophysiology and medical interventions: blood pressure control, management of anticoagulant-associated brain hemorrhage and general management principles. *Neurol Clin.* 2008;26:963–985.)

clinical tests to evaluate increased sympathetic activity and differentiate neurogenic hypertension from nonneurogenic hypertension. Nonetheless, some clinical clues may suggest the presence of neurogenic hypertension. These include paroxysmal or labile hypertension, young age of onset, severe hypertension that is resistant to angiotensin-converting enzyme (ACE) or diuretic therapy and hypertension associated with ingestion of sympathomimetic agent.[9]

SPECIFIC SYNDROMES

Hypertension After Stroke

Epidemiology

BP is commonly elevated in patients with stroke. The reason for this acute hypertensive response after stroke remains a matter of conjecture. In a large retrospective analysis that examined 276,734 patients presenting to the emergency department (ED) with acute ischemic stroke, the incidence of elevated BP was 76.5%.[10] The Chinese Acute Stroke Trial (CAST) and the International Stroke Trial (IST), each enrolling approximately 20,000 patients with ischemic stroke, reported systolic BP (SBP) above 140 mm Hg in 75% and 80% of patients and severely elevated SBP of greater than 180 mm Hg in 25% and 28%, respectively.[11,12]

Hypertension is the most important modifiable risk factor for stroke, and reduction in BP is effective in the primary prevention of both ischemic and hemorrhagic stroke; BP reduction also decreases the risk for a recurrent ischemic or hemorrhagic stroke.[13] Combined data from 40 trials show that a 10% reduction in SBP lowers stroke risk by one-third.[14] A 5-mm reduction in diastolic pressure together with a 9-mm lower SBP confers a 33% lower risk for stroke, and a 10-mm lower diastolic BP (DBP) together with an 18- to 19-mm lower SBP confers more than a 50% reduction in stroke risk.[15] In patients who have had a stroke, the Perindopril Protection Against Recurrent Stroke Study (PROGRESS) showed that BP reduction was associated with reductions of 28% in stroke recurrence and 26% in major coronary and vascular events, even in normotensive subjects. This study also demonstrated a reduction of absolute rates of hemorrhagic stroke from 2% to 1% over a mean of 3.9 years of follow-up.[16]

However, the management of BP in the immediate aftermath of a stroke is controversial.[17] A high proportion of patients have elevated BP immediately after a stroke, but BP spontaneously decreases over 1 to 2 weeks to the prestroke baseline in most patients. Some of the postulated causes of elevated BP are listed in Box 41.1. An increased BP after stroke is associated with a higher mortality. Nonetheless, it is uncertain whether this increase directly contributes to poor outcome and whether immediate lowering of BP will lead to better outcomes. SBP variability may be associated with the risk for cerebrovascular events independent of the mean BP. Home BP monitoring and ambulatory BP monitoring are useful in monitoring BP variability. Normally, BP is highest in the morning and gradually falls to reach its lowest level during sleep. Several alterations in this pattern, including a lack of nighttime decline in BP (nondippers), a rise in nighttime BP (reverse dippers), and a more than 20% fall in nighttime BP (extreme dippers), are associated with increased risk for vascular complications, including stroke. These findings also have a bearing on the choice of the antihypertensive agent for stroke prevention. Calcium channel blockers (CCBs) and nonloop diuretics appear to decrease SBP variability,

BOX 41.1 Postulated Causes of Hypertension After Stroke

- Preexisting hypertension
- "White coat" effect
- Stress of hospitalization
- Cushing reflex[a]
- Catecholamine and cortisol release
- Lesion of brainstem or hypothalamus
- Nonspecific response to brain damage

[a]Hypothalamic response to raised intracranial pressure or ischemia consisting of hypertension with bradycardia.

whereas β-blockers, angiotensin receptor blockers (ARBs), and ACE inhibitors do not appear to decrease BP variability.

Pathophysiology

An understanding of cerebrovascular pathophysiology is essential to understand the pros and cons of treating hypertension in these patients (Table 41.1).

In patients with an ischemic stroke, vascular occlusion leads to a central region of irreversibly ischemic brain surrounded by an ischemic zone where blood flow is reduced but brain tissue is still viable (the so-called penumbra zone). After 2 or 3 days, the ischemic areas either recover or undergo infarction. In the first few days, perfusion of the area surrounding that destined to infarction is marginal and a further decrease in blood flow might lead to infarction there as well. Because cerebral autoregulation is impaired with acute ischemic stroke, a fall in BP could lower blood flow and extend infarction. On the other hand, a very high BP could exacerbate cerebral edema or lead to hemorrhagic transformation, especially if thrombolytic agents have been given.

In patients with intracerebral hemorrhage (ICH), the considerations are different.[18] Hematoma expansion occurs in 73% of patients within 24 hours, and significant expansion (>33% increase in volume) occurs in nearly 40% of patients.[19] Hematoma expansion is frequently associated with decline in neurologic status and is an independent predictor of mortality and poor functional outcome. Therefore, BP is often lowered in these patients in the hope that this might decrease hematoma expansion. However, it is not often clear if the elevation in BP is the cause or the consequence of hematoma expansion. The suggestion that there may be perihematomal ischemia around an ICH has not been supported by recent studies.[20] Furthermore, some patients with ICH might have increased ICP because of the hematoma volume or associated hydrocephalus. In such a situation, lowering of BP is not warranted because it might critically lower CPP. Monitoring of ICP and CPP may be helpful in choosing the appropriate BP target in these circumstances.

In patients with aneurysmal subarachnoid hemorrhage (SAH), there is a significant risk for rebleeding from aneurysmal rerupture, and therefore early BP control is recommended to decrease the rebleeding risk. Some patients with SAH have associated myocardial dysfunction (stunned myocardium), in which case high BP might worsen myocardial function. Like patients with ICH, in patients with hydrocephalus or an associated ICH, ICP and CPP monitoring can help guide BP management. However, many patients develop vasospasm of the intracranial arteries at 4 to 12 days after SAH, and reduction of BP may lead to worsening of cerebral ischemia in this situation. Therefore, once the aneurysmal rupture has been adequately treated with surgical clipping or coiling, BP is usually maintained at a normal or slightly elevated level in these patients.

TABLE 41.1 Acute Treatment of Hypertension in Stroke: Advantages and Disadvantages

Advantages	Disadvantages
Acute Ischemic Stroke	
Might lower mortality	BP decreases on its own
Might decrease stroke progression	No proven benefit
Might decrease hemorrhagic transformation (especially after tPA)	Ongoing ischemia around infarct (ischemic penumbra)
	Altered autoregulation from chronic hypertension, ischemia
Might decrease cerebral edema formation	Large-vessel stenosis might have resulted in reduction of perfusion
Might be helpful for systemic reasons (e.g., associated myocardial ischemia)	Chance of propagating thrombus
	Anecdotal case reports and trial results demonstrating deterioration with BP decrease
Patients likely to be more compliant with antihypertensive use if treatment initiated in hospital	Principle of "do no harm" (primum non nocere)
Acute Intracerebral Hemorrhage	
Might lower mortality	BP decreases on its own
Might decrease hematoma expansion	No proven benefit
	Possible zone of ischemia around intracerebral hematoma
Might decrease cerebral edema formation	Chronically hypertensive patients require higher CPP because of shift in autoregulatory curve
Might be helpful for systemic reasons (e.g., associated myocardial ischemia)	ICP may be elevated, and lowering BP reduces what could be marginal CPP
Patients likely to be more compliant with antihypertensive use if treatment initiated in hospital	Principle of "do no harm" (primum non nocere)
Aneurysmal Subarachnoid Hemorrhage	
Might decrease rebleeding rate	No proven benefit
Might help if there is cardiac ischemia (stunned myocardium)	ICP may be elevated, and lowering BP reduces what could be marginal CPP
	Might lead to cerebral ischemia in presence of vasospasm

BP, Blood pressure; *CPP,* cerebral perfusion pressure; *ICP,* intracranial pressure; *tPA,* tissue plasminogen activator.

Diagnosis and Treatment

Acute management of hypertension in stroke is highly dependent on the type of stroke (ischemic vs. hemorrhagic) and, for ischemic stroke, the use of thrombolysis. The benefits of lowering BP to prevent hematoma expansion in the setting of ICH or hemorrhagic transformations of ischemic stroke should be balanced with the risk for abrupt reduction of CBF in chronically hypertensive patients with shifted cerebrovascular autoregulation, especially if increased ICP and cerebral edema are present.

It is important to distinguish between hypertensive encephalopathy, in which lowering of BP is clearly indicated, and ischemic stroke with hypertension, in which urgent lowering of BP may not be warranted. The level of consciousness, the presence of focal neurologic deficits, and the funduscopic examination can help in making this distinction. Hypertensive encephalopathy is a syndrome of global neurologic dysfunction, usually with papilledema. Focal neurologic deficits are usually less prominent. In acute ischemic stroke, the focal neurologic deficit is prominent, and the symptoms and neurologic signs

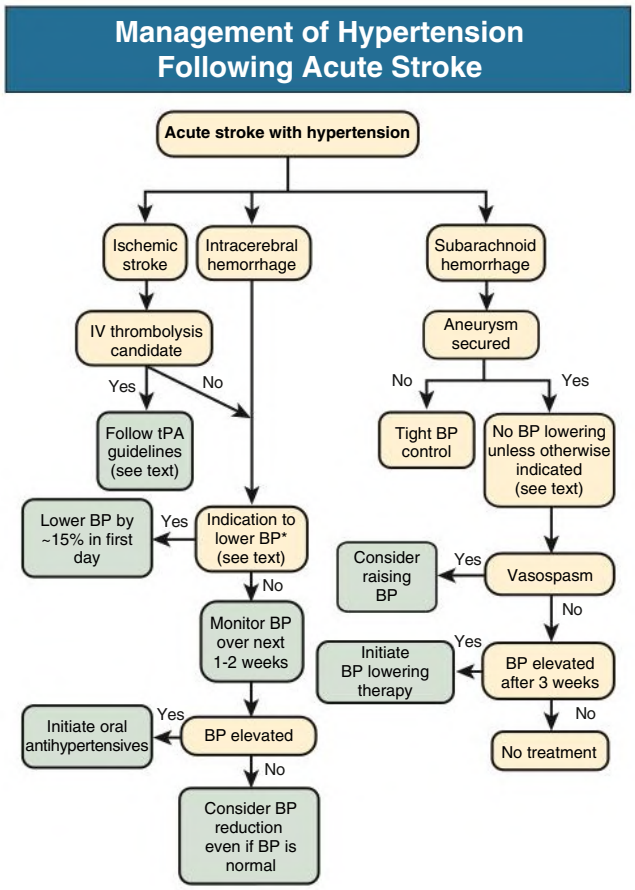

Fig. 41.3 Management of Hypertension After Acute Stroke. *Indication for treatment includes systolic blood pressure (BP) >220 mm Hg or diastolic BP >120 mm Hg for ischemic stroke, the presence of associated conditions such as aortic dissection or myocardial infarction, and, in cases of cerebral hemorrhage, systolic BP >180 mm Hg or mean arterial pressure >130 mm Hg. *IV,* Intravenous; *tPA,* tissue plasminogen activator.

often can be mapped to the vascular territory supplied by a specific cerebral blood vessel. Early alterations of consciousness are less common, except with brainstem strokes or when there is "malignant" brain edema secondary to a massive hemispheric infarction.

Several recent studies assess the benefits and risks of BP lowering after ischemic and hemorrhagic stroke. A Cochrane review on this topic concluded that more research is needed to evaluate and identify the candidates most likely to benefit from management of BP in the acute phase of stroke and the timeframe for such intervention.[21]

An overview of recommendations for treating BP in different clinical situations is outlined in Fig. 41.3.

Acute ischemic stroke. Several large prospective trials of BP lowering in acute ischemic stroke have been completed and are summarized in Table 41.2.[22–32]

The current guidelines of the American Heart Association/American Stroke Association (AHA/ASA) and the European Stroke Organisation (ESO) for BP management in acute ischemic stroke recommend a cautious approach to lowering BP in acute ischemic stroke. Patients receiving thrombolytic therapy should have their BP lowered to less than 185/110 mm Hg before the administration of the thrombolytic agent and maintained at a level of less than 180/105 mm Hg for at least the first 24 hours after thrombolytic treatment. Patients not receiving thrombolytic agents should have antihypertensive medications withheld unless the SBP is greater than 220 mm Hg or the DBP is greater than 120 mm Hg, in which case a 15% reduction in BP in the first 24 hours appears reasonable. Recommendations are summarized in Table 41.3.[33,34]

Thus, available evidence does not support immediate BP reduction after an acute ischemic stroke. Based on the limited data and natural history of BP after ischemic stroke, treatment of newly diagnosed previously untreated hypertension or resumption of long-term antihypertensive medication can be initiated or resumed gradually after the first 24 hours. Reduced dosage and/or number of agents from the prestroke regimen should be used to avoid rapid reduction of BP in the case of prior outpatient noncompliance. It may be advisable to administer BP-lowering agents when the patient's neurologic status is stable.[35]

Intracerebral hemorrhage. Hypertension is the most important modifiable risk factor for ICH. Although long-term benefit in lowering BP in patients with ICH is widely accepted, it remains unclear if elevated BP should be lowered in the acute phase. In recent years, a few randomized trials have attempted to address the issue of acute BP lowering in ICH and are summarized in Table 41.4.[27,36–39]

The currently recommended guidelines of the AHA/ASA and the European Stroke Initiative (ESI) for BP management in acute ICH are summarized in Table 41.5.[40,41] The AHA/ASA guidelines also recommend avoiding peaks and large variability in SBP and initiating BP-lowering treatment within 2 hours of ICH onset and reaching target within 1 hour. If elevated ICP is of concern, such as in patients with large hemorrhages or with hydrocephalus, ICP should be monitored to ensure that the CPP is appropriate before significant BP reduction.

Subarachnoid hemorrhage. Before definitive treatment of the ruptured aneurysm, SBP is usually kept below 160 mm Hg, although there is no conclusive evidence that higher BPs increase rebleeding rates. In patients with suspected elevation of ICP, it is important to monitor ICP and keep the CPP greater than 70 mm Hg. The AHA/ASA guidelines recommend monitoring and control of BP to balance the risk for stroke, hypertension-related bleeding, and maintenance of CPP. An SBP goal of less than 160 mm Hg is considered reasonable.[42] The ESO recommends keeping the SBP at less than 180 mm Hg but keeping the MAP at greater than 90 mm Hg.[43] After the ruptured aneurysm has been secured, aggressive treatment of BP should be avoided, and in the setting of cerebral vasospasm, BP is usually elevated using vasopressors until the neurologic deficits resolve, often as high as an SBP of 200 to 220 mm Hg.

Hypertension After Carotid Endarterectomy and Endovascular Procedures

Definition, Incidence, and Clinical Features

Hemodynamic disturbances such as hypotension, bradycardia, and hypertension are common (10%–40%) after carotid endarterectomy and endovascular procedures such as angioplasty and stenting. A small percentage of these patients develop carotid hyperperfusion (or reperfusion) syndrome. This syndrome occurs in the first week after surgery or angioplasty-stenting and manifests as ipsilateral pulsatile headache, seizures, ICH, transient or permanent contralateral neurologic signs, encephalopathy, or reversible cerebral edema.[44-46] Recently, this syndrome has also been reported after treatment of acute ischemic stroke with intravenous thrombolysis and endovascular treatment. Some subjects with cerebral hyperperfusion after revascularization may not manifest clinical signs acutely but may later develop cortical neuronal loss and cognitive impairment.[47]

TABLE 41.2 Major Trials of Acute Blood Pressure Reduction in Ischemic Stroke

Trial	Study Design	Study Arms	No. of Patients	Results
Acute Candesartan Cilexetil Evaluation in Stroke Survivors (ACCESS)[32]	Prospective, double-blind, placebo-controlled, randomized, multicenter, phase II	Candesartan vs. placebo	342	Lower 12-month mortality and vascular events in the candesartan group, but no significant difference in BP between the two arms.
Scandinavian Candesartan Acute Stroke Trial (SCAST)[31]	Prospective, double-blind, placebo-controlled, randomized, multicenter	Candesartan vs. placebo	2029 (274 had cerebral hemorrhage)	During 6 months of follow-up, the risk of the composite vascular endpoint did not differ between treatment groups. Analysis of functional outcome suggested a higher risk for poor outcome in the candesartan group.
Controlling Hypertension and Hypotension Immediately Post-Stroke (CHHIPS)[29]	Prospective, double-blind, placebo-controlled, randomized, multicenter	Labetalol vs. lisinopril vs. placebo	179 (25 had cerebral hemorrhage)	No difference in death or dependency at 2 weeks, early neurologic deterioration, or serious adverse event.
Continue or Stop Post-stroke Antihypertensive Collaborative Study (COSSACS)[30]	Prospective, open, multicenter, randomized, blinded-endpoint trial	Continue vs. stop preexisting antihypertensive drugs	763 (38 had cerebral hemorrhage)	Continuation of antihypertensive drugs did not reduce 2-week death or dependency, cardiovascular event rate, or mortality at 6 months.
Glycine Antagonist in Neuroprotection (GAIN International)[24]	Prospective, double-blind, placebo-controlled, randomized, multicenter	Gavestinel vs. placebo	1445	A 30% drop in mean arterial pressure from baseline was not associated with poor outcome.
Intravenous Nimodipine West European Stroke Trial (INWEST)[22]	Prospective, double-blind, placebo-controlled, randomized, multicenter	Placebo vs. low-dose vs. high-dose nimodipine	265	Patients with a DBP reduction of ≥20% in the high-dose group had a significantly increased adjusted odds ratio for the compound outcome variable of death or dependency.
Chinese Antihypertensive Trial in Acute Ischemic Stroke (CATIS)[25]	Prospective, single-blind, randomized, blinded endpoint, multicenter	Antihypertensive treatment vs. discontinuing all antihypertensives	4071	BP reduction with antihypertensive medications, compared with the absence of hypertensive medication, did not reduce the likelihood of death and major disability at 14 days or hospital discharge.
Efficacy of Nitric Acid in Stroke (ENOS)[26]	Prospective, multicenter, randomized, placebo-controlled, patient-masked, outcome-assessor-masked, parallel-group trial	Glyceryl trinitrate vs. no treatment; subset taking antihypertensive medications on admission randomized to taking vs. stopping them	4011 (629 had cerebral hemorrhage)	Transdermal glyceryl trinitrate lowered BP and had acceptable safety but did not improve functional outcome. There was no evidence to support continuing prestroke antihypertensive drugs in patients in the first few days after acute stroke.
Valsartan Efficacy on Modest Blood Pressure Reduction in Acute Ischemic Stroke (VENTURE)[28]	Prospective, multicenter, randomized, open-label, blinded-endpoint trial	Valsartan vs. no treatment	393	Early reduction of BP with valsartan did not reduce death or dependency and major vascular events at 90 days but increased the risk for early neurologic deterioration.
Intensive BP reduction with intravenous thrombolysis therapy for acute ischemic stroke (ENCHANTED)[23]	International, partial-factorial, open-label, blinded-endpoint	Intensive (systolic BP 130–140 mm Hg) or guideline (systolic BP < 180 mm Hg) antihypertensive treatment for 72 hours in patients within 6 hours of stroke onset and treated with intravenous alteplase	2227	Fewer patients in the intensive group had intracranial hemorrhage, but there was no difference in clinical outcome between the two groups.
Prehospital transdermal glyceryl trinitrate in patients with ultra-acute presumed stroke (RIGHT-2)[27]	Prospective, multicentric, paramedic-delivered, ambulance-based, randomized, sham-controlled, blinded endpoint	Transdermal nitroglycerin vs. sham dressing	1149 (597 with ischemic stroke, 145 with cerebral hemorrhage, 109 with transient ischemic attack, 297 with a nonstroke mimic)	Nitroglycerin did not lead to an improved outcome at 90 days.

BP, Blood pressure; *DBP,* diastolic blood pressure.

TABLE 41.3 Guidelines for Blood Pressure Management After Acute Ischemic Stroke

AHA/ASA	ESO
Patients Eligible for Thrombolytic Therapy or Mechanical Thrombectomy	• Routine BP lowering is not recommended. • Cautious BP lowering is recommended in patients with extremely high BP (>220/120 mm Hg) on repeated measurements, or with severe cardiac failure, aortic dissection, or hypertensive encephalopathy. • Abrupt BP lowering should be avoided. • BP must be <185/110 mm Hg before, and for the first 24 hours after, thrombolysis.
Before Thrombolytic Therapy • Lower SBP to <185 and DBP to <110 mm Hg.	
During and After Thrombolytic Therapy or Mechanical Thrombectomy • Lower SBP to <180 and DBP to <105 mm Hg.	
Patients Not Eligible for Thrombolytic Therapy • Patients with markedly elevated BP may have their BP lowered. • Lowering BP by ~15% in these patients is reasonable. • Antihypertensive drugs should be withheld unless SBP >220 or DBP >120 mm Hg.	

AHA/ASA, American Heart Association/American Stroke Association; *BP,* blood pressure; *DBP,* diastolic blood pressure; *ESO,* European Stroke Organisation; *SBP,* systolic blood pressure.

After carotid endarterectomy, the incidence of postoperative severe hypertension is reported as 19% and that of carotid hyperperfusion syndrome as 1%. Most cases occurred in the first week and the average time to symptoms was the fifth postoperative day. Seizures (36%), hemiparesis (31%), or both (33%) were common presenting features, and 59% of patients had headache.[48]

Pathophysiology

Preexisting hypertension, baroreceptor impairment after surgical manipulation, and elevated catecholamine levels after cerebral hypoperfusion during intraoperative cross-clamping may contribute to postoperative hypertension that contributes to cerebral hyperperfusion, which may in turn lead to cerebral hemorrhage. The hyperperfusion syndrome may be due, in part, to impaired autoregulation from chronic vasodilation of the distal vascular bed ipsilateral to a hemodynamically significant internal carotid artery stenosis.[49] Other postulated mechanisms include activation of the trigeminovascular axon reflex and derangement of the carotid baroreceptors.[50] Subjects at risk for development of this syndrome are those with extensive microvascular disease, preoperative hypoperfusion and impaired autoregulation, or postoperative hyperperfusion.

Diagnosis and Treatment

Cerebral hyperperfusion represents a postoperative increase in CBF of more than 100% compared with preoperative flow. However, this increase in blood flow may be only approximately 20% compared with the contralateral side.[51] Making a diagnosis based on CBF doubling alone may lead to a significant overestimation of the incidence, and the following four criteria have been suggested: (1) occurrence within 30

TABLE 41.4 Major Trials of Acute Blood Pressure Reduction in Cerebral Hemorrhage

Trial	Study Design	Study Arms	No. of Patients	Results
Koch et al.[38]	Prospective, randomized	Target MBP <110 or 110–130 mm Hg	42	No significant differences in early neurologic deterioration, hematoma and edema growth, and clinical outcome.
INTERACT[36]	Prospective, randomized, blinded endpoint assessment	Target SBP <140 or <180 mm Hg	404	No significant difference in hematoma growth between the two tiers after adjustment for baseline hematoma volume and time to CT scan.
INTERACT 2[63]	Prospective, randomized, blinded endpoint assessment	Target SBP <140 or <180 mm Hg	2839	No significant reduction in the rate of primary outcome of death or severe disability with intensive lowering of BP. Improved functional outcomes with lower BP target on ordinal analysis of modified Rankin Scale score.
ATACH[37]	Prospective, Phase I dose-escalation	Target SBP 110–140 or 140–170 or 170–200 mm Hg	60	Observed proportions of neurologic deterioration and serious adverse events below the prespecified safety thresholds; 3-month mortality rate lower than expected in all tiers.
ATACH 2[39]	Prospective, randomized, multicenter, open-label trial	Target SBP 110–140 or 140–179 mm Hg	1000	BP reduction to a target SBP of 110–139 mm Hg did not result in a lower rate of death or disability than a target of 140–179 mm Hg. The rate of renal adverse events within 7 days after randomization was significantly higher in the group with the lower BP target.
Prehospital transdermal glyceryl trinitrate in patients with ultra-acute presumed stroke (RIGHT-2)[27]	Prospective, multicentric, paramedic-delivered, ambulance-based, randomized, sham-controlled, blinded end-point	Transdermal nitroglycerin versus sham dressing	1149 (597 with ischemic stroke, 145 with cerebral hemorrhage, 109 with transient ischemic attack, 297 with a nonstroke mimic)	Nitroglycerin did not lead to an improved outcome at 90 days.

BP, Blood pressure; *CT,* computed tomography; *MAP,* mean arterial blood pressure; *SBP,* systolic BP.

TABLE 41.5 Guidelines for Blood Pressure Management After Acute Cerebral Hemorrhage

AHA/ASA	ESO
For patients with mild to moderate severity ICH presenting with SBP between 150 and 200 mm Hg, acute lowering of SBP to a goal of 140 mm Hg is safe and may be reasonable for improving functional outcomes (Class 2b; Level of Evidence B-R). In patients with large or severe ICH and in those requiring surgical decompression, the safety and efficacy of intensive BP lowering are not well established (Class 2b, Level of Evidence C-LD). In patients with mild to moderate severity ICH presenting with SBP >150 mm Hg, acute lowering of SBP to <130 mm Hg is probably harmful (Class 3, Level of Evidence B-R).	In acute ICH within 6 hours of onset, intensive BP reduction (SBP target <140 mm Hg in <1 hour) is safe and may be superior to SBP target of <180 mm Hg. No specific agent can be recommended. (quality of evidence: moderate; strength of recommendation: weak).

AHA/ASA, American Heart Association/American Stroke Association; *BP,* blood pressure; *ESO,* European Stroke Organisation; *ICH,* intracerebral hemorrhage; *SBP,* systolic BP.

days post–carotid endarterectomy; (2) evidence of hyperperfusion (on transcranial Doppler, single-photon emission computed tomography, or computed tomography [CT]/magnetic resonance [MR] perfusion imaging) or SBP greater than 180 mm Hg; (3) clinical features such as new headache, seizures, hemiparesis, and Glasgow Coma Scale score less than 15 or radiologic features such as cerebral edema or ICH; and (4) no evidence of new cerebral ischemia, postoperative carotid occlusion, or metabolic or pharmacologic cause to explain the findings.[48]

Because of the risk for development of carotid hyperperfusion syndrome after carotid endarterectomy or stenting, all patients should have continuous intraoperative and postoperative BP monitoring. Most authors advocate strict BP control (SBP <120 mm Hg) from the time of intraoperative internal carotid artery unclamping or angioplasty, particularly in high-risk patients.[52] If high-risk features are absent, aiming for SBP of 140 to 160 mm Hg or preoperative SBP (if lower) in the postoperative period is reasonable. Elevated BP should be treated with intravenous (IV) labetalol or clonidine. Vasodilators such as nitroglycerin, hydralazine, and sodium nitroprusside should be avoided. Because this syndrome may occur after patients have been discharged from the hospital, it is important for physicians to ensure that BP is appropriately controlled even after the immediate postoperative period.

Hypertension After Spinal Cord Injury

Definition and Epidemiology

Hypertension is quite prevalent in patients with spinal cord injury (SCI), with a reported prevalence of 14% to 61%. The prevalence is higher in patients with paraplegia compared with tetraplegia and in those with nontraumatic SCI compared with those with traumatic SCI.[53]

In addition, autonomic dysreflexia occurs in up to 70% of persons after SCI, most often during the first 2 to 4 months after injury. It is defined as an increase in SBP by at least 20%, associated with a change in heart rate, and accompanied by at least one sign (sweating, piloerection, facial flushing) or symptom (headache, blurred vision, stuffy nose).[54] If autonomic dysreflexia is unrecognized, it can result in serious sequelae, such as posterior leukoencephalopathy, ICH, SAH, seizures, arrhythmia, pulmonary edema, retinal hemorrhage, and, rarely, coma or death.[55]

Pathophysiology and Diagnosis of Autonomic Dysreflexia

Autonomic dysreflexia is most commonly seen in patients with complete SCI in which there is loss of all neurologic function below the level of the lesion. The spinal cord lesion is typically at or above the sixth thoracic spinal level. Immediately after the injury, there is initial loss of supraspinal sympathetic control similar to the initial period of muscle flaccidity. This often leads to hypotension and bradycardia (spinal shock). After a few weeks to months, there is extrajunctional sprouting of the α-receptors, denervation hypersensitivity, and impaired presynaptic uptake of norepinephrine. In addition, there may be derangement of spinal glutaminergic interneurons. Noxious stimuli below the neurologic level of the lesion trigger a spinal reflex arc that results in increased sympathetic tone and hypertension.[56] The most common inciting events are an overdistended urinary bladder and fecal impaction. However, it may be secondary to other precipitants, including infections, pressure ulcers, urologic and endoscopic procedures, sympathomimetic medications, and sildenafil citrate used for sperm retrieval.[57]

Clinical symptoms include pulsatile headache, blurred vision, anxiety, nasal congestion, nausea, and sweating above the involved spinal level. The flushed, sweaty skin above the lesion level is because of brainstem parasympathetic activation. At and below the lesion, the skin remains pale, cool, and dry. Heart rate can be quite variable from bradycardia to tachycardia. The hallmark physical finding is elevated BP. However, because BP may normally be quite low after SCI, baseline BP readings may be within the normal range but elevated for a given individual, making clinical suspicion and reliance on other clinical signs and symptoms paramount in the diagnosis if baseline BP is not known.[56]

Treatment

Although it is recognized that BP is often lower in patients with tetraplegia and high paraplegia, current guidelines suggest applying evidence-based guidelines for treating hypertension in the general population to SCI patients as well. However, SCI may affect the choice of the antihypertensive agent. Thiazide diuretics are not preferred in patients who perform intermittent bladder catheterization because they increase urine volume. In addition, SCI patients may experience electrolyte abnormalities or decline in renal function during thiazide use. Some patients with SCI may experience supine hypertension with coexisting orthostatic hypotension, which requires cautious trial and titration of antihypertensive agents.[53]

Vigilant preventive measures for autonomic dysreflexia include proper bowel, bladder, and skin care. However, expeditious treatment of elevated BP is critical to avoid the potentially life-threatening consequences. Placement of the patient upright with the legs lowered to reduce BP and removal of any possible noxious stimuli (such as binding clothing and devices) are the initial treatments. It is also important to look for and appropriately treat other common triggers such as urinary retention or constipation.

Pharmacologic treatment with rapid-acting, short-lived agents may be indicated for SBP elevation of 150 mm Hg or greater that persists after the preceding interventions. Nitroglycerin is often used to treat hypertension associated with autonomic dysreflexia. However, to avoid precipitating hypotension, nitrate-containing agents should not be given for 24 hours before the use of sildenafil or similar agents to facilitate sperm retrieval or treat erectile dysfunction in SCI. CCBs and ACE inhibitors

TABLE 41.6 Preferred Antihypertensive Agents in the Treatment of Stroke-Associated Hypertension

Drug	Mechanism of Action	Intravenous Dose	Advantages	Disadvantages
Labetalol[a]	α_1-, β_1-, and β_2-receptor antagonist	10 mg IV over 1–2 min, may repeat once; IV infusion 2–8 mg/min	Does not lower CBF Does not increase ICP	May exacerbate bradycardia
Nicardipine[a]	L-type CCB	5–15 mg/hr	Does not decrease CBF	May increase ICP Long duration of action
Clevidipine[a]	L-type CCB	Starting dose 1–2 mg/hr; dose can be doubled every 2–5 min up to a maximum dose of 21 mg/hr	Does not decrease CBF	Should be avoided in patients with egg/soy allergy
Esmolol	β_1-receptor antagonist	500-μg/kg bolus, then 50–300 μg/kg/min	Does not lower CBF Does not increase ICP	May exacerbate bradycardia
Sodium nitroprusside	Vasodilator	0.25–10 μg/kg/min	Potent antihypertensive	May increase ICP Can cause cerebral steal Potential for cyanide toxicity
Nitroglycerin	Vasodilator	5–200 μg/min	Can be helpful for concomitant cardiac ischemia	May increase ICP Can cause cerebral steal
Hydralazine	Vasodilator	2.5- to 10-mg bolus	Can be given as IV bolus when labetalol is contraindicated because of bradycardia	May increase ICP Can cause cerebral steal
Enalaprilat	ACE inhibitor	0.625–1.25 mg every 6 hr	Does not decrease CBF	Variable response Long duration of action

[a]Preferred agents listed in 2018 American Heart Association/American Stroke Association guidelines.
ACE, Angiotensin-converting enzyme; *CBF,* cerebral blood flow; *CCB,* calcium channel blocker; *ICP,* intracranial pressure; *IV,* intravenous.

also have been reported to be effective.[58] However, these agents might exacerbate resting hypotension and therefore should be used with caution. Prazosin has been reported to be effective in reducing the severity of autonomic dysreflexia without significantly lowering the resting BP. If the bladder is empty and the BP is less than 150 mm Hg, fecal disimpaction with topical anesthetic should be attempted. If dysreflexia is refractory or associated with severe clinical presentation, other precipitants should be sought, and hospitalization may be indicated.[59]

Up to 90% of pregnant women with upper SCI experience autonomic dysreflexia during labor and delivery. Appropriate epidural or spinal anesthesia techniques can ameliorate the risk.[60]

Cerebrovascular Effects of Antihypertensive Agents

Different classes of antihypertensive agents have different direct effects on the CBF, ICP, and autoregulation. The ideal drug would not increase ICP or decrease blood flow to ischemic regions. In addition, in treatment of hypertension in the acute setting, drugs that can be given by IV, have a short half-life, and do not cause sedation are preferable. In the chronic phase after a stroke, adequate BP lowering is key, and there is no clear evidence favoring one class of antihypertensive agent over another; however, one may consider avoiding the use of nonselective β-blockers that may increase SBP variability.

The advantages and disadvantages of various classes of antihypertensive agents after acute stroke are summarized in Table 41.6.

β-Adrenergic antagonists (e.g., esmolol) and combined α- and β-adrenergic receptor antagonists (e.g., labetalol) do not increase ICP or affect cerebral autoregulation. They are suitable for treatment of hypertension in the setting of acute cerebral ischemia or increased ICP. However, bradycardia secondary to increased ICP is a relative contraindication.

Vasodilators (e.g., sodium nitroprusside, nitroglycerin) cause cerebral arterial dilation and venodilation and can theoretically increase ICP and cause a cerebral steal phenomenon in patients with acute cerebral ischemia. Other disadvantages of sodium nitroprusside are tachyphylaxis, the need to shield the medication from light because of its photosensitivity, and the danger of cyanide and thiocyanate toxicity that may be difficult to detect in patients with brain injury. However, they may be used in patients with small and moderate-sized ICH and in patients with SAH if increased ICP is not a concern.

CCBs have varying effects on cerebral autoregulation. Nifedipine can lead to severe reduction in BP and is not recommended. Nimodipine is used routinely in patients with SAH because it has been shown to improve outcome, possibly because of a neuroprotective effect. Nicardipine has been used in patients with acute ICH without any change in CBF and is often used in patients with SAH. It is becoming quite popular in neurocritical care units because of its efficacy, ease of titration, predictable response, and favorable cerebral hemodynamic effects. Clevidipine has been used to lower BP in patients with ischemic and hemorrhagic stroke with a similar safety and efficacy profile as nicardipine.

ACE inhibitors and the ARB candesartan have been used in patients with acute cerebral ischemia and have no effect on CBF. However, short-acting parenteral forms of these drugs are not available. ACE inhibitors and ARBs shift the lower limit of cerebral autoregulation toward lower BP in rats and humans. However, these agents have a long half-life, which is not desirable in treatment of hypertension in the acute phase.

Similarly, because of its long half-life and sedative effect, the α_2-adrenergic agonist clonidine is not preferred.

The cerebrovascular effects of the newer parenteral antihypertensives such as fenoldopam, a peripheral dopamine-1 receptor agonist, and clevidipine, a CCB, have not been extensively studied. However, in small studies, fenoldopam has been shown to decrease global CBF and increase ICP in patients with impaired intracranial compliance.[61] In a small single-center study, clevedipine was found to be safe and effective in perioperative neurosurgical patients with hypertension.[62]

In practice, we prefer IV boluses of labetalol and hydralazine to treat elevated BP in the setting of an acute stroke. If frequent doses are required, or the BP is extremely elevated, an IV infusion of nicardipine or clevidipine is used.

SUMMARY

This chapter provides a summary of neurologic pathways that may be responsible for mediating systemic BP control and emphasizes management of BP in acute ischemic and hemorrhagic stroke subtypes. For supplemental information on the topical matter emphasized in this chapter and for discussion of first and recurrent stroke prevention and prevention of cognitive impairment and dementia in relation to BP management, readers are referred to a publication by Gorelick et al.[35]

SELF-ASSESSMENT QUESTIONS

1. A 55-year-old man with longstanding hypertension presents with acute right hemiplegia. The onset of symptoms was 45 minutes before presentation. His BP on presentation is 200/110 mm Hg and his noncontrast head CT scan is normal. He is given 10 mg labetalol and his BP is now 175/105 mm Hg. IV tissue plasminogen activator (tPA) is administered for acute ischemic stroke. An hour later, his BP is 170/110 mm Hg. Which of the following statements *best* characterizes BP management in this case?
   - **A.** The patient should not have been given IV tPA because his BP (175/105 mm Hg) was too high.
   - **B.** The patient's current BP of 170/110 mm Hg needs to be lowered with IV labetalol or nicardipine.
   - **C.** Sublingual nifedipine is the drug of choice in the acute management of elevated BP in the setting of an acute stroke.
   - **D.** BP should be increased using vasopressors to augment cerebral perfusion.
   - **E.** None of the above.
2. A 60-year-old man with poorly controlled BP presents to the emergency department with left hemiparesis that was first noticed 2 days ago. He is awake, fully alert, and oriented. His strength on the right side is normal. His head CT scan shows a 2 × 2 cm right putaminal hemorrhage with no hydrocephalus or intraventricular extension. His BP is 150/85 mm Hg. Which of the following statements *best* characterizes BP management in this case?
   - **A.** This patient has a greater than 50% chance of clinically significant expansion of his ICH over the next 48 hours if his BP is not lowered acutely.
   - **B.** BP should be lowered immediately to less than 120/80 mm Hg with intravenous nicardipine to prevent hematoma expansion.
   - **C.** He should have an intracranial pressure monitor inserted to measure intracranial pressure.
   - **D.** There is an area of ischemia surrounding an ICH that may increase in size with additional BP lowering.
   - **E.** None of the above.
3. Which of the following features *best* characterizes carotid hyperperfusion syndrome after a carotid endarterectomy?
   - **A.** Headache
   - **B.** Intracerebral hemorrhage
   - **C.** Increase in cerebral blood flow ipsilateral to the endarterectomy
   - **D.** Seizures
   - **E.** All of the above

Blood Pressure Management in the Dialysis Patient

Panagiotis I. Georgianos, Rajiv Agarwal

Hypertension in dialysis patients is common, remains often uncontrolled, and, when diagnosed objectively with out-of-dialysis blood pressure (BP) monitoring, is directly associated with excess risk for mortality. The pathogenesis of hypertension is multifactorial, but volume overload is the most important cause of hypertension in these patients. Accordingly, the initial management relies on nonpharmacologic strategies, such as dry weight adjustment, sodium restriction, and adequate delivery of dialysis time. When BP remains uncontrolled despite aggressive volume management, non–volume-dependent mechanisms are involved as mediators of sustained hypertension (Box 42.1). In such patients, antihypertensive therapy is the next step to achieve BP control.[1,2] This chapter describes the diagnosis, epidemiology, and management of hypertension among patients on dialysis.

DIAGNOSIS

Peridialytic Blood Pressure Recordings

BP recordings taken shortly before (predialysis) or after dialysis (postdialysis) are the basis for the diagnosis of hypertension among dialysis patients, mainly because these measurements are readily available.[3,4] However, routine pre- or postdialysis BP recordings provide imprecise estimates of interdialytic ambulatory BP.[5] Peridialytic BP remains insufficiently accurate, even when a greater number of recordings are averaged over six dialysis sessions.[6] Thus, BP variability is not the sole factor that accounts for poor diagnostic performance of peridialysis BP recordings.[7] A potential source of bias could be the lack of attention to proper BP measurement technique. However, even when these measurements are obtained under standardized conditions, peridialytic BP is still inadequate for diagnosing hypertension[8,9] (Box 42.2).

Intradialytic (During Dialysis) BP Recordings

The diagnostic accuracy of peridialytic BP is improved when these recordings are considered jointly with BP measurements during the entire dialysis procedure[10]; the average of intradialytic and peridialytic BP over six consecutive dialysis sessions was superior to predialysis or postdialysis BP alone in predicting interdialytic ambulatory BP.[10] Because calculating an average is impractical at the bedside, this study explored the diagnostic performance of median intradialytic BP from a single midweek dialysis session. A midweek median cut-off systolic BP (SBP) of 140 mm Hg provided 80% sensitivity and 80% specificity in diagnosing hypertension.[10] Therefore, median intradialytic BP can be used to quickly screen for hypertension at the bedside, but this is a method of last resort. Interdialytic BP recordings, though less convenient, may be better for the long-term management of hypertension.

Interdialytic (Between Dialysis) Recordings

Home BP monitoring (HBPM) is an established technique[4] recommended by guidelines[11–13] and widely adopted in clinical practice for the assessment and management of hypertension. This technique improves the diagnosis of hypertension among patients on dialysis.[14] A 1-week average home SBP of 150 mm Hg or above provided 80% sensitivity and 84.1% specificity in diagnosing hypertension. In contrast, no cut-point for routine or standardized peridialytic BP provided a satisfactory combination of sensitivity and specificity for diagnosing hypertension.[8] Additional advantages of HBPM also exist. In the Dry Weight Reduction in Hypertensive Hemodialysis Patients (DRIP) trial, home BP could track changes in interdialytic ambulatory BP (see later) provoked by probing of dry weight.[15] Contrary to the poor reproducibility of pre- and postdialysis BP, home BP had even greater test-retest reliability than interdialytic ambulatory BP.[15] HBPM also serves as a useful tool to guide therapeutic decisions and facilitate the achievement of adequate BP control. In a randomized trial enrolling 65 hypertensive dialysis patients,[16] compared with predialysis BP-guided management of hypertension, a home BP-guided strategy provoked a reduction of approximately 9/7 mm Hg in interdialytic ambulatory BP.[16] Furthermore, home BP is superior to peridialytic BP in detecting echocardiographic left ventricular hypertrophy (LVH) and in predicting the risk of mortality.[17-19] For the long-term management of dialysis patients, we recommend twice daily home BP recordings after a midweek dialysis session for 4 days. We tell our patients to keep their home BP monitors in their bedroom and measure BP first thing after they wake up and last thing before going to bed. Monthly monitoring is sufficient for most clinical purposes.

Interdialytic ambulatory BP monitoring (ABPM) is the gold standard technique for diagnosing hypertension.[3,4] ABPM uses an automated device programmed to record BP 2 to 3 times an hour over the entire interdialytic interval. This method is valid,[20] reproducible,[21] and is superior to peridialytic BP recordings in predicting the presence of LVH or long-term outcomes.[17-19] A unique advantage of ABPM is that BP can be recorded during sleep, enabling the diagnosis of nocturnal hypertension and nondipping BP patterns.[22] ABPM also has some weaknesses (i.e., limited availability and costs of equipment, need for training, patient discomfort) that limit the wide adoption of this technique in practice.[3,4,22]

Because the implementation of ABPM in the long-term management of hypertension is often impractical, we recommend the use of HBPM as a simple and reliable approach to diagnose hypertension and guide therapeutic decisions from month to month.[1,2] In patients who are nonadherent to HBPM, we use midweek median intradialytic BP to make therapeutic decisions.[1,2] We do not use peridialytic BP recordings for managing hypertension.

EPIDEMIOLOGY

Prevalence, Treatment, and Control of Hypertension

Epidemiology of hypertension among patients on dialysis differs depending on the method of BP measurement (Table 42.1). Studies

BOX 42.1 Non–Volume-Dependent Causes of Hypertension Among Patients on Dialysis

- Increased arterial stiffness
- Sympathetic overactivity
- Activation of the renin-angiotensin-aldosterone system
- Endothelial dysfunction
- Erythropoietin therapy
- Sleep apnea

that were based on conventional predialysis BP recordings used different definitions and provided variable estimates of the prevalence and control of hypertension.[23-26] A more precise description of the epidemiology was provided by a few studies using ABPM. For example, in a cross-sectional study of 369 patients,[27] the prevalence of hypertension (defined as interdialytic BP ≥135/85 mm Hg or antihypertensive drug use) was 82%. Although 89% of hypertensive dialysis patients were being treated, adequate ambulatory BP control was achieved in only 38%.[27] Subsequent studies using HBPM or ABPM confirmed that the burden of hypertension in the dialysis population is high and its control poor.[28,29]

Among patients on peritoneal dialysis, the absence of acute shifts in pressure and volume parameters is thought to mitigate hypertension. However, the burden of hypertension and prognostic association of BP with mortality follows a pattern similar to that seen among hemodialysis.[30]

Prognosis

In sharp contrast with the direct and linear association between BP and outcome in the general population, large-scale cohort studies conducted in dialysis patients showed a U-shaped or J-shaped association of peridialytic BP with mortality.[31-34] The phenomenon of reverse epidemiology has raised concerns on whether hypertension in dialysis patients is an independent risk factor that should be adequately controlled.[35] However, two separate cohort studies showed that BP measurement technique strongly confounds the relation of BP with mortality.[18,19] In these studies, increasing interdialytic SBP assessed either with HBPM or with ABPM was directly associated with higher mortality risk. In contrast, neither routine nor standardized peridialytic BP recordings were prognostically informative. Home SBP between 120 to 130 mm Hg and 44-hour ambulatory SBP ranging from 110 to 120 mm Hg were associated with the best prognosis.[18]

The reverse epidemiology of hypertension seen in observational studies contrasts with two meta-analyses of randomized trials among dialysis patients showing cardiovascular protection with antihypertensive therapy.[36,37] In the first meta-analysis (eight trials, $N = 1679$), BP-lowering treatment was associated with a 29% reduced risk for cardiovascular events and a 20% reduction in all-cause mortality.[37] In the second meta-analysis (five trials, $N = 1212$), compared with placebo, antihypertensive therapy lowered the risk for cardiovascular events and all-cause mortality by 31%.[36] The cardiovascular benefit of antihypertensive therapy was greater when trials with hypertensive patients were combined separately from trials that included normotensives.[36] Therefore, deliberate BP lowering with antihypertensive therapy has proven cardioprotective benefits for dialysis patients, particularly when they are hypertensive.

THERAPEUTIC TARGETS

The optimal BP threshold for the diagnosis and management of hypertension in the dialysis population is unknown.[12,38] The only trial to compare two different BP targets was the Blood Pressure in Dialysis (BID) trial.[39] In BID, 126 hypertensive dialysis patients were randomized to a tighter (110–140 mm Hg) versus a standard (155–165 mm Hg) control of predialysis SBP over 12 months of follow-up. BID reported a possible safety signal, but on closer examination intensive BP lowering was associated with 1.3-fold higher risk for recurrent intradialytic hypotension, 1.66-fold higher risk for recurrent hospitalization, and 2.8-fold higher risk for recurrent vascular access thrombosis.[39] Regression of LVH, a secondary efficacy endpoint, did not differ between arms.

BID was a feasibility trial aiming to inform the design of a full-scale trial.[39] Although a full-scale trial is warranted to define the optimal BP goals, we do not believe that peridialytic BP recordings are appropriate targets for managing hypertension. Given the evidence supporting the superiority of home over predialysis BP-guided therapy,[14,16] we believe that a future full-scale trial should ideally compare the benefits of tighter versus standard home SBP targets for clinical outcomes. In the meantime, we recommend that controlling home SBP to levels below 140 mm Hg is a reasonable target in dialysis patients.[1,2] If a home BP-guided strategy is not feasible, lowering midweek median intradialytic SBP below 140 mm Hg is an alternative strategy.[1,2] In our practice, we prefer to treat hypertension in dialysis patients than maintain the status quo.

BOX 42.2 Blood Pressure Measurement Techniques in Dialysis Patients

- Predialysis or postdialysis (peridialysis) BP: do not reflect the usual level of BP in the interdialytic period and therefore not useful for management of hypertension.
- Median intradialytic BP: systolic BP ≥140 mm Hg on a midweek dialysis session in a patient being dialyzed 3 times weekly suggests poorly controlled hypertension.
- Home BP monitoring: measurements done twice daily (morning and evening) after 5 min of seated rest in duplicate, after a midweek dialysis session for 4 days on a monthly basis, is the most practical way to manage hypertension in long-term hemodialysis patients.
- Interdialytic ambulatory BP monitoring: measurements after dialysis 2–3 times/hr over the entire 44-hr interdialytic period is the gold standard of diagnosing hypertension in hemodialysis patients.

BP, Blood pressure.

VOLUME MANAGEMENT STRATEGIES

Once an accurate diagnosis is made, the initial management of hypertension is based on nonpharmacologic strategies that target and maintain euvolemia.[1,2] The four basic principles of nonpharmacologic treatment are summarized in Fig. 42.1 and are discussed in detail later.

Probing of Dry Weight

The assessment and management of dry weight is challenging. There is no consensus on the optimal definition of dry weight. In 2009 Sinha and Agarwal stated that dry weight reflects the lowest tolerated postdialysis weight at which the patient experiences minimal signs and symptoms of either hypovolemia or hypervolemia.[40] According to this definition, the management of dry weight is based on an iterative process of gentle and gradual intensification of ultrafiltration guided by the patient's symptoms.[40]

Benefits of Probing Dry Weight

Dry weight was probed without increasing the dialysis duration in the DRIP trial.[41] In DRIP, 150 dialysis patients who had uncontrolled hypertension despite stable background treatment with 2.7 antihypertensive

TABLE 42.1 Prevalence, Treatment and Control of Hypertension Among Patients on Dialysis

Study	Region	*N*	Definition of Hypertension	Prevalence	Hypertensive Patients on Treatment	Control
Studies Using Dialysis Unit BP Recordings						
Salem,[26] 1995	US	649	Predialysis mean BP≥114 mm Hg or antihypertensive drug use	71.9%	81.5%	48.6%
Rahman et al.,[25] 1999	US	489	Predialysis BP≥160/90 mm Hg or antihypertensive drug use	87.7%	92.3%	28.9%
Agarwal et al.,[23] 2003	US	2535	Predialysis BP≥150/85 mm Hg or antihypertensive drug use	85.7%	88.4%	30.3%
Del Vecchio et al.,[24] 2013	Italy	4022	Predialysis BP≥140/90 mm Hg or antihypertensive drug use	70.3%	57.7%	40.0%
Studies Using Home or Ambulatory BP Monitoring						
Agarwal,[27] 2011	US	369	44-hour interdialytic BP≥135/85 mm Hg or antihypertensive drug use	82.0%	89.0%	38.0%
Sarafidis et al.,[28] 2019	Italy, Greece, Slovenia	396	48-hour intra- and interdialytic BP≥130/80 mm Hg or antihypertensive drug use	84.3%	86.8%	28.7%
Tsikliras et al.,[29] 2020	Greece	116	1-week averaged home BP≥135/85 mm Hg or antihypertensive drug use	88.8%	95.0%	32.6%

BP, Blood pressure.

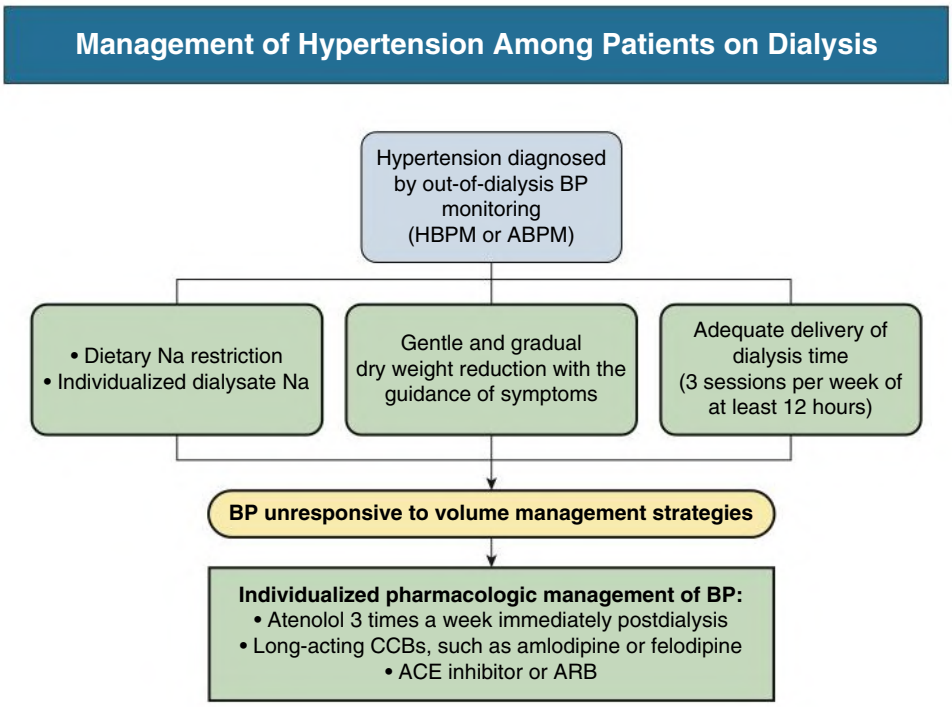

Fig. 42.1 Algorithm for the Management of Hypertension Among Patients on Dialysis. The diagnosis of hypertension among patients on dialysis should be based on blood pressure (BP) recordings taken outside of dialysis. Predialysis and postdialysis BP recordings are not suitable for diagnosing and managing hypertension. Once an accurate diagnosis is made, first-line management of hypertension among patients on dialysis relies on nonpharmacologic strategies that target the achievement and maintenance of euvolemia. The adequate management of volume follows four principles: probing of dry weight, dietary sodium restriction, individualized prescription of the dialysate sodium concentrations, and adequate delivery of dialysis time. If hypertension remains uncontrolled despite adequate volume management, pharmacologic treatment is the next step to achieve an adequate control of BP. The selection of an appropriate antihypertensive regimen should be individualized, taking into consideration the efficacy, safety, and pharmacokinetic properties of the antihypertensive medications in the dialysis population. We use β-blockers, particularly atenolol administered 3 times per week immediately postdialysis, as first-line therapy. We use long-acting calcium channel blockers (CCBs), such as amlodipine or felodipine, as second-line therapy in patients with uncontrolled BP despite the adequate management of dry weight and the administration of atenolol. Angiotensin-converting enzyme (ACE) inhibitors or angiotensin receptor blockers (ARBs) are our third-line option. Because of concerns related to hyperkalemia and in anticipation of stronger safety and efficacy data from ongoing randomized trials, we do not recommend the wide use of mineralocorticoid receptor antagonists for the management of hypertension among patients on dialysis. *ABPM,* Ambulatory blood pressure monitoring; *HBPM,* home blood pressure monitoring; *Na,* sodium.

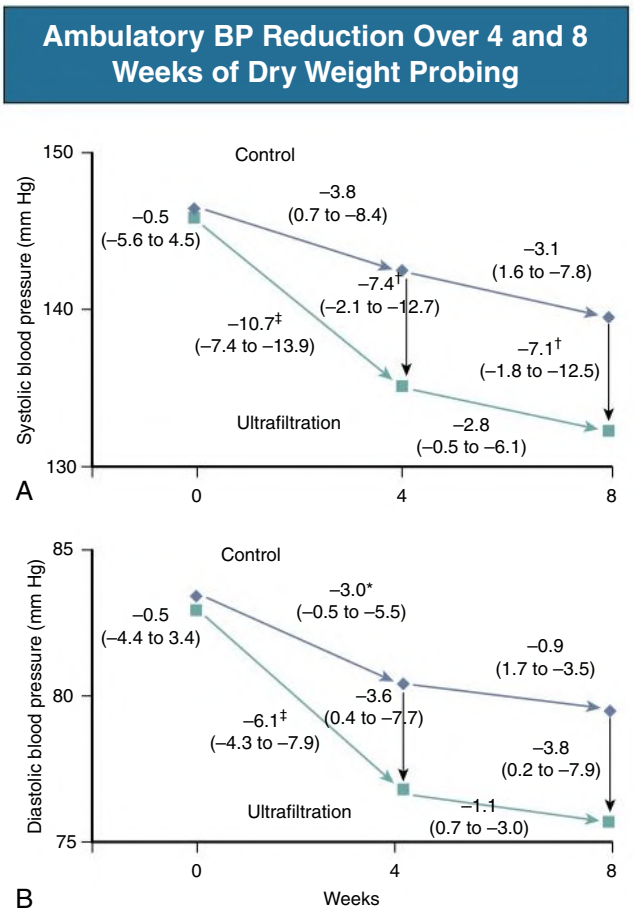

Fig. 42.2 Ambulatory Blood Pressure (BP) Reduction Over 4 and 8 Weeks of Dry Weight Probing in Hypertensive Dialysis Patients. The mean 44-hour ambulatory systolic and diastolic BPs are shown for the control *(blue lines)* and ultrafiltration *(teal lines)* groups. The mean changes in BP are shown for weeks 4 and 8 after randomization *(teal squares and arrows),* as well as the mean differences in BPs *(black arrows)* between the two groups at each 4-week interval. The numbers next to the *blue diamonds and arrows* connecting the data points are the mean changes in BP between groups at 4 and 8 weeks after randomization. The 95% confidence intervals (CIs) are given in parentheses. *$P < .05$, †$P < .01$, and ‡$P < .001$ indicate significant differences between groups or within groups. The placebo-subtracted change in 44-hour systolic BP provoked by probing of dry weight was –6.9 mm Hg (95% CI, –12.4 to –1.3 mm Hg; $P = .016$) at 4 weeks and –6.6 mm Hg (95% CI, –12.2 to –1.0 mm Hg; $P = .021$) at 8 weeks. The placebo-subtracted change in 44-hour diastolic BP was –3.1 mm Hg (95% CI, –6.2 to –0.02 mm Hg; $P = .048$) at 4 weeks and –3.3 mm Hg (95% CI, –6.4 to –0.2 mm Hg; $P = .037$) at 8 weeks.

medications daily were randomized in a 2:1 ratio to ultrafiltration and control groups. In the ultrafiltration group, postdialysis weight was gradually reduced until the development of symptoms indicating dry weight achievement. In the control group, patients received only physician visits.[41] A modest reduction in dry weight by 0.9 kg from baseline to 4 weeks provoked an average placebo-subtracted reduction of –6.9 mm Hg in 44-hour SBP and a placebo-subtracted reduction of –3.1 mm Hg in 44-hour diastolic BP (DBP) (Fig. 42.2).[41] This BP-lowering effect was sustained till study end at 8 weeks. Probing of dry weight also provoked a significant reduction in LV mass index (LVMI) over the first 4 weeks of follow-up.[42]

Assessment and Management of Dry Weight

The results of the DRIP trial[41] have important implications for the assessment and management of dry weight (Box 42.3).

BOX 42.3 Clinical Signs Indicating Volume Excess in a Dialysis Patient

- Overt symptoms of congestive heart failure (e.g., shortness of breath)
- Uncontrolled hypertension confirmed by home or ambulatory BP monitoring
- The use of multiple antihypertensive medications
- Low interdialytic weight gain
- Persistent BP elevation during dialysis (intradialytic hypertension)

BP, Blood pressure.

The DRIP trial explored the hypothesis that hypertension in dialysis is a clinical manifestation of volume excess. Accordingly, patients with clinically overt hypervolemia were a priori excluded from this trial.[40] Despite the fact that DRIP participants were euvolemic based on clinical judgment, probing of dry weight provoked a clinically meaningful reduction of approximately 7/3 mm Hg in 44-hour BP.[41] Thus, among hypertensive dialysis patients, the management of dry weight should not be based on the presence or absence of clinically overt hypervolemia. In such patients, volume excess is more often covert. The discriminatory power of physical examination in ruling in or out volume overload is low.[43,44]

An important sign that should raise the suspicion of volume excess is the use of multiple BP-lowering medications in a dialysis patient. DRIP participants had uncontrolled hypertension despite the administration of 2.7 BP-lowering medications daily.[41] The mediator of sustained hypertension in these patients was subclinical volume excess. In DRIP, the magnitude of ambulatory BP reduction evoked by probing of dry weight was probably much larger than what would be expected by intensifying antihypertensive therapy with one additional drug. This is in line with several cross-sectional studies showing an increasing number of prescribed antihypertensive medications to be paradoxically associated with worse BP control.[23,27,29] These observations suggest that intensification of antihypertensive therapy is likely to fail to control BP if volume excess is not primarily addressed, supporting a "volume-first" approach of hypertension.

A high interdialytic weight gain (IDWG) is often (but erroneously) considered as equivalent with hypervolemia. However, recent studies using more objective methods in the assessment of dry weight inform us that IDWG and volume overload are two discrete components of the dynamic fluid balance.[44] These studies showed that dialysis patients with low IDWG were often volume overloaded.[44] In DRIP,[45] volume status was assessed using the method of relative plasma volume (RPV) monitoring. At baseline, patients with steeper RPV slopes and therefore most euvolemic had the highest IDWG. In contrast, patients with the greatest volume expansion based on RPV monitoring had the lowest IDWG.[45] However, these patients tolerated the greatest dry weight reduction during follow-up (−1.5 kg). Most importantly, these patients experienced the greatest improvement in 44-hour SBP in response to dry weight reduction (−12.6 mm Hg).[45] Therefore, a low IDWG may reflect volume excess, particularly when accompanied by other clinical indications, such as uncontrolled interdialytic hypertension.

Unlike the typical decline in BP with ultrafiltration, BP increases during dialysis in approximately 10% to 15% of patients. This paradoxical hemodynamic response is described as *intradialytic hypertension.*[46] The precise definitions and pathophysiology of intradialytic hypertension is debated; earlier studies suggested that this phenomenon may be mediated through release of vasoconstrictors in response to ultrafiltration.[46] On this basis, the management of intradialytic hypertension often relied on interruption of ultrafiltration and/or immediate administration of potent short-acting antihypertensive agents. However, more recent studies showed a close relation between

TABLE 42.2 Randomized Trials Comparing Management of Dry Weight Guided by Assistive Technologies Versus Usual Care on Clinical Outcomes

Study	Design	Patients	*N*	Intervention	Follow-up	Results
Reddan et al.[58]	Open-label RCT	Patients on dialysis (≥2 mo)	443	RPV monitoring using Crit-Line vs. conventional clinical monitoring	6 mo	Higher risk of hospitalization and all-cause mortality in the RPV monitoring group than in the control group
Onofriescu et al.[57]	Open-label RCT	Patients on dialysis (≥3 mo)	131	BIS every 3 mo to guide dry weight adjustment vs. clinical judgment	30 mo	One death in the BIS group vs. 8 deaths in the control group (HR, 0.112; 95% CI, 0.014–0.918)
Huan-Sheng et al.[55]	Open-label RCT	Patients on dialysis (≥3 mo)	298	BIS every month to guide dry weight adjustment vs. clinical judgment	12 mo	No between-group difference in all-cause hospitalizations (HR, 1.19; 95% CI, 0.79–1.80), cardiovascular events (HR, 0.57; 95% CI, 0.26–1.25), and all-cause mortality (HR, 0.85; 95% CI, 0.29–2.53)
Siriopol et al.[59]	Open-label RCT	Patients on dialysis (≥3 mo) at low cardiovascular risk	250	Lung ultrasound combined with BIS (in case of clinical symptoms of hypovolemia) vs. clinical judgment	Mean 21.3 ± 5.6 mo	No between-group difference in the composite outcome of all-cause death or first nonfatal cardiovascular event (HR, 1.09; 95% CI, 0.64–1.86)
Liu et al.[56]	Open-label RCT	Patients on dialysis (≥3 mo)	445	BIS every 2 months to guide dry weight adjustment vs. clinical judgment	Median 13.7 mo	No between-group difference in the composite outcome of all-cause death or nonfatal cardiovascular event (HR, 0.487; 95% CI, 0.217–1.091)

intradialytic and interdialytic hypertension.[47] In a post hoc analysis of the DRIP trial, probing of dry weight in patients with intradialytic hypertension was effective in normalizing both intradialytic and interdialytic BP profiles.[48] Therefore, persistent BP elevation during dialysis may be another signal of volume excess.

Bioimpedance spectroscopy, RPV monitoring, and lung ultrasound, are under investigation and offer promise for more objective assessment of dry weight.[45,49,50] Observational studies showed that hypervolemia, as assessed with these devices, is prognostically associated with higher mortality risk.[51-54] Randomized trials have so far failed to prove that these technologies are superior to usual care in improving clinical outcomes (Table 42.2),[55-59] although most of these trials had short follow-up and lacked statistical power.[60,61] Therefore, these technologies require further study before being implemented in clinical practice.

Potential Hazards of Probing Dry Weight

Probing of dry weight may be associated with potential hazards, such as higher risk for intradialytic hypotension, vascular access thrombosis, and more rapid loss of residual renal function.[1,2] However, none of these risks has been adequately studied. In DRIP, probing of dry weight provoked temporal intradialytic symptoms of hypotension, but these symptoms did not unduly affect any domain of health-related quality of life.[41] Because DRIP only followed participants for 8 weeks, the benefits and risks of dry weight probing warrant examination in long-term trials.

Dietary Sodium Restriction

Dietary sodium restriction is an established nonpharmacologic approach to limit IDWG and facilitate the achievement of dry weight.[1,2] International guidelines recommend that among patients on dialysis, dietary sodium intake should not exceed 80 to 100 mmol (1.8–2.3 g; equivalent to 4.5–5.8 g sodium chloride) daily.[62] Observational studies support this guidance, showing that compared with pharmacologic management of hypertension, sodium restriction together with adequate adjustment in dry weight was associated with greater regression of LVH and reduced incidence of intradialytic hypotension.[63,64]

Individualized Dialysate Sodium Prescription

Sodium loading in hemodialysis patients occurs when the prescription of dialysate sodium concentration results in a positive sodium gradient during dialysis.[65] This scenario is rather common in daily clinical practice.[66] However, this therapeutic approach perpetuates a vicious cycle. Intradialytic sodium gain is directly associated with increased sense of thirst and greater IDWG, resulting in higher ultrafiltration requirements during the subsequent dialysis sessions. The higher ultrafiltration rates can aggravate the risk of intradialytic hypotension, which might result in the prescription of even higher dialysate sodium concentrations.[1,2]

Lowering the dialysate sodium concentration could possibly interrupt this vicious cycle. The benefit/risk ratio of this intervention was investigated in a meta-analysis of 12 trials involving 266 patients.[67] Compared with neutral (138–140 mEq/L) or high (>140 mEq/L)

dialysate sodium, a low sodium concentration (<138 mEq/L) was associated with reduced IDWG and improvement in BP. However, these benefits were accompanied by higher risk for intradialytic cramps and hypotension.[67] These results should be carefully interpreted because all trials were small. Of the 12 trials included in this meta-analysis, 10 compared a fixed prescription of a lower versus a higher dialysate sodium concentration. Several trials performed large reductions in dialysate sodium concentration over a short-term follow-up.[67] Therefore, an abrupt and fixed intervention may result in a steeply negative sodium gradient, raising the risk for adverse events.

We recommend that lowering of dialysate sodium concentration should be gradual and individualized.[1,2] Observational studies and pilot trials suggest that this approach has the potential for short-term and long-term benefits without excess risk of intradialytic complications.[68-70]

Adequate Delivery of Dialysis Time

The prescription of dialysis duration varies considerably across countries. Approximately one-third of patients in the United States are prescribed hemodialysis with a duration of less than 200 minutes.[71] Among several other risks, nonadherence to the dialysis regimen has been associated with worse BP control.[72] This was also illustrated in a post hoc analysis of DRIP.[73] Median intradialytic SBP followed a rising pattern in the control group. In contrast, probing of dry weight lowered median intradialytic SBP regardless of the duration of dialysis. However, patients with shorter dialysis duration required more dialysis sessions to achieve the BP-lowering benefit of probing dry weight.[73] Therefore, shorter delivered dialysis is a barrier to dry weight achievement, limiting the opportunity for adequate BP control.

Management of Hypertension in Peritoneal Dialysis Patients

As in hemodialysis patients, volume management is of central importance for BP control among peritoneal dialysis (PD) patients.[30] Two unique aspects in PD patients are long-term preservation of both residual diuresis and peritoneal membrane function. To achieve euvolemia, we adapt the PD regimen to the peritoneal transport characteristics. To protect the peritoneal membrane, we limit exposure of peritoneal membrane to bioincompatible solutions and use icodextrin judiciously[30] (prescription of PD is discussed in Chapter 101).

PHARMACOTHERAPY OF HYPERTENSION (BASED ON INTERDIALYTIC MEASUREMENTS)

Despite assiduously adhering to the volume-first management strategies, a large fraction of dialysis patients remain hypertensive, and drug therapy is necessary to achieve an adequate control of BP.

We believe that treatment should be guided by evidence from trials done in the dialysis population and not on extrapolation of evidence from trials conducted in earlier stages of kidney disease or in the general population.[1,2] A summary of key randomized trials is provided in Table 42.3.[74-82]

β-Blockers

The safety and efficacy of β-blocker–based and angiotensin-converting enzyme (ACE) inhibitor–based regimens were compared in the Hypertension in Hemodialysis Patients Treated With Atenolol or Lisinopril (HDPAL) trial.[73] In HDPAL, 200 hypertensive dialysis patients with echocardiographic LVH were randomized to atenolol or lisinopril, each administered 3 times per week immediately postdialysis. Contrary to the original hypothesis that a lisinopril-based regimen would be superior to atenolol in improving LVH, both drugs provoked similar reductions in LVMI over 12 months.[74] In addition, atenolol appeared to be more effective in controlling hypertension, because monthly monitored home BP was consistently lower in the atenolol group despite the need for a greater number of antihypertensive drugs and a greater dry weight reduction in the lisinopril group. Furthermore, compared with lisinopril, atenolol provoked a greater reduction in aortic pulse wave velocity over the first 6 months of follow-up.[83] Because the incidence of serious adverse cardiovascular events was 2.36-fold higher in the lisinopril group than in the atenolol group, HPDAL was terminated early.[74]

Based on the results of the HDPAL trial, we use β-blockers as first-line pharmacotherapy for hypertension among dialysis patients (Fig. 42.1)[1,2] and prefer to use atenolol administered 3 times per week immediately postdialysis based on the results of HDPAL. This dosing regimen overcomes the high dialyzability of atenolol and ensures a potent BP-lowering action of this agent over the entire interdialytic interval (Box 42.4).[84]

BOX 42.4 Dialyzability and Dosing of Antihypertensive Agents[2,73,82,83]

- β-blockers are a heterogeneous drug class with respect to their pharmacokinetic profiles. Recent studies showed substantial dialyzability of atenolol, metoprolol, and bisoprolol; in contrast, carvedilol and propranolol were found to be nondialyzable.
- With the exception of the nondialyzable fosinopril, most other ACE inhibitors are removed during dialysis; in contrast, ARBs are generally nondialyzable.
- Long-acting CCBs, such as amlodipine and felodipine, are also nondialyzable and can be dosed once daily.
- Based on the HDPAL trial, the optimal dosing regimen for long-acting agents with high dialyzability, such as atenolol and lisinopril, is the administration 3 times per week immediately postdialysis.

ACE, Angiotensin-converting enzyme; *ARB,* angiotensin receptor blocker; *CCB,* calcium channel blocker; *HDPAL,* Hypertension in Hemodialysis Patients Treated With Atenolol or Lisinopril.

Calcium Channel Blockers

Long-acting dihydropyridine calcium channel blockers (CCBs) such as amlodipine or felodipine are useful in combination with other agents, such as atenolol, and represent our second-line choice for the pharmacotherapy of hypertension in dialysis patients. The efficacy of this drug class is supported by a double-blind trial in which 251 hypertensive dialysis patients were randomized to amlodipine or placebo.[80] Whereas BP remained constant with placebo, amlodipine provoked a significant reduction of ~10 mm Hg in SBP over 30 months of follow-up. Although amlodipine did not reduce all-cause mortality relative to placebo, there was a significant reduction by 47% in the composite secondary outcome of cardiovascular events and all-cause mortality.[80]

ACE Inhibitors/Angiotensin Receptor Blockers

In the Fosinopril in Dialysis (FOSIDIAL) trial,[81] 397 French dialysis patients who had echocardiographic LVH with or without hypertension were randomized to the ACE inhibitor fosinopril or placebo for 48 months. Compared with placebo, fosinopril had no benefit on cardiovascular outcomes.[81] In contrast, two smaller trials from Japan showed cardioprotective benefit when an angiotensin receptor blocker (ARB)-based regimen was compared either with placebo[79] or with active treatment that was not based on ACE inhibitors or ARBs.[78] However, in a subsequent meta-analysis aiming to elucidate the contradictory results of these three small trials, the use of ACE inhibitors or ARBs was not

TABLE 42.3 Randomized Trials Evaluating the Effect of Antihypertensive Agents on Clinical Outcomes

Study	Design	Patients	*N*	Intervention	Follow-up	Results
Zannad et al.[81]	Double-blind RCT	Dialysis patients (not necessarily hypertensive) with LVH	397	Fosinopril 5–20 mg/day vs. placebo	24 mo	No benefit of fosinopril vs. placebo on the combined outcome of fatal or nonfatal CV events (RR, 0.93; 95% CI, 0.68–1.26)
Takahashi et al.[79]	Open-label RCT	Dialysis patients with clinical evidence of CV disease	80	Candesartan 4–8 mg/day vs. nothing	19 mo	Threefold lower incidence of CV events in the candesartan group than in the control group (45.9% vs. 16.3%, $P < .01$)
Suzuki et al.[78]	Open-label RCT	Hypertensive dialysis patients	366	ARB treatment (losartan, valsartan, candesartan) vs. control therapy not based on ARBs	36 mo	Compared with control therapy, treatment with ARBs improved by 49% the combined outcome of fatal and nonfatal CV events (HR, 0.51; 95% CI, 0.33–0.9)
Iseki et al.[75]	Open-label RCT	Hypertensive dialysis patients	469	Olmesartan 10–40 mg/day vs. control therapy not including ACE inhibitor or ARB	42 mo	No benefit of olmesartan vs. control therapy on the combined outcome of fatal or nonfatal CV events (HR, 1.00; 95% CI, 0.71–1.40)
Cice et al.[82]	Open-label RCT	Dialysis patients with dilated cardiomyopathy	114	Carvedilol (titrated up to 25 mg twice daily) vs. placebo	24 mo	Compared with placebo, carvedilol improved all-cause mortality (HR, 0.51; 95% CI, 0.32–0.82) and CV mortality (HR, 0.32; 95% CI, 0.18–0.57)
Agarwal et al.[74]	Open-label RCT	Hypertensive dialysis patients with LVH	200	Atenolol (25–100 mg) vs. lisinopril (10–40 mg), both administered 3 times a week postdialysis	12 mo	Compared with atenolol, the composite safety outcome of MI, stroke, or CHF occurred more commonly in the lisinopril group (IRR, 2.36; 95% CI, 1.36–4.23)
Tepel et al.[80]	Double-blind RCT	Hypertensive dialysis patients	251	Amlodipine 10 mg/day vs. placebo	30 mo	Amlodipine improved the composite outcome of all-cause death or nonfatal CV event relative to placebo (HR, 0.53; 95% CI, 0.31–0.93)
Matsumoto et al.[77]	Open-label RCT	Oligoanuric dialysis patients	309	Add-on spironolactone 25 mg/day vs. nothing	36 mo	Compared with no add-on therapy, spironolactone reduced the composite outcome of fatal and nonfatal CV events (HR, 0.379; 95% CI, 0.173–0.832)
Lin et al.[76]	Open-label RCT	Patients on dialysis without CHF	253	Add-on spironolactone 25 mg/day vs. placebo	24 mo	Add-on spironolactone improved CV morbidity and mortality relative to placebo (HR, 0.42; 95% CI, 0.26–0.78)

ACE, Angiotensin-converting enzyme; *ARB,* angiotensin receptor blocker; *CHF,* congestive heart failure; *CI,* confidence interval; *CV,* cardiovascular; *HR,* hazard ratio; *IRR,* incident rate ratio; *LVH,* left ventricular hypertrophy; *MI,* myocardial infarction; *RCT,* randomized controlled trial; *RR,* risk ratio.

associated with an overall improvement in cardiovascular morbidity and mortality.[85] In the Olmesartan Clinical Trial in Okinawa Patients under Okinawa Dialysis Study (OCTOPUS) trial[75]—the largest trial conducted so far, enrolling 469 hypertensive dialysis patients—the ARB olmesartan was not superior to control for improving the primary composite cardiovascular outcome or all-cause mortality over a mean follow-up of 3.5 years.[75]

Taken together, unlike the established cardioprotective benefit of these two antihypertensive drug classes in the general population, the evidence to support the use of ACE inhibitors or ARBs for cardioprotection in patients on dialysis is thin. Therefore, we use ACE inhibitors and ARBs as a third-line option in dialysis patients with inadequately controlled BP despite combination treatment with atenolol and a long-acting CCB.

Mineralocorticoid Receptor Agonists

Among patients not on dialysis with heart failure and reduced ejection fraction, add-on therapy with spironolactone or eplerenone confers a substantial cardioprotective benefit.[86,87] However, the safety and efficacy of mineralocorticoid receptor antagonists (MRAs) among patients on dialysis has not been adequately studied.[76-88] In a 2016 meta-analysis of nine trials (including 829 patients), MRA use was associated with improvement in cardiovascular and all-cause mortality, but this benefit was accompanied by a threefold higher risk of hyperkalemia.[89] These results should be interpreted with caution because most of the included trials had short follow-up and small sample sizes, indicating lack of high-quality evidence.[89] The benefit/risk ratio of MRAs in patients on dialysis is currently under investigation in two large ongoing phase III trials. Because of concerns related to hyperkalemia and in anticipation of more reliable evidence, we do not routinely prescribe MRAs to our dialysis patients.

Vasodilators

Many patients on dialysis are prescribed vasodilators such as hydralazine or minoxidil. Hydralazine is short acting, which is why it needs to be administered 3 times daily. In reviewing ABPM data on patients on this drug, we often note large drops in SBP with rapid increases to baseline; we therefore discourage its use. Minoxidil prescription is associated with hirsutism that is troublesome for women and sometimes can cause pericardial effusions. Patients who require a vasodilator to achieve blood pressure control typically will benefit from nonpharmacologic strategies for the control of hypertension.

Role of Bilateral Nephrectomy

We have rarely seen patients with bilateral nephrectomies as a strategy to treat hypertension in dialysis. In one such patient, BP was still elevated several months after surgery and the patient was being administered an intravenous agent to control hypertension in the intensive care unit. Two days of continuous venovenous hemofiltration normalized the BP and required removal of several antihypertensive drugs including the intravenous agent, attesting to the fact that the optimal control of volume and an adequate delivery of dialysis are central to the management of hypertension in most hemodialysis patients. Instead of an as-needed prescription of an antihypertensive drug for the patient with asymptomatic elevation of BP to 200 mm Hg systolic, we prefer to address volume and dialysis delivery for the holistic care of the patient.

SELF-ASSESSMENT QUESTIONS

1. Which of the following methods is useful to screen for hypertension in a dialysis patient at bedside?
   - **A.** Predialysis BP recordings averaged over six consecutive dialysis treatments.
   - **B.** Postdialysis BP recordings averaged over six consecutive dialysis treatments.
   - **C.** Median intradialytic BP from a single midweek dialysis treatment.
   - **D.** None of the above methods provides a satisfactory combination of high sensitivity and high specificity for diagnosing hypertension.
2. A 60-year-old patient on chronic dialysis with a known history of hypertension receives stable treatment with nebivolol 5 mg/day, amlodipine 10 mg/day, and olmesartan 20 mg/day, but the average of home BP recordings taken with a validated automatic device twice daily for 4 days after the midweek dialysis session is 149/78 mm Hg. The patient is asymptomatic, and the physical examination reveals no clinical signs of volume excess. Which of the following would be the optimal approach to achieve an adequate control of home BP in this patient?
   - **A.** Increase the dose of olmesartan
   - **B.** Add spironolactone
   - **C.** Add clonidine
   - **D.** Probe dry weight
3. In a dialysis patient who gains 1 kg during the interdialytic interval, the predialysis BP is of 154/82 mm Hg. During dialysis, BP increases to 180/89 mm Hg, and the nurse calls you with this high BP. Which of the following interventions would be the *best* next step to treat the patient?
   - **A.** Stop ultrafiltration immediately and administer 10 mg sublingual nifedipine
   - **B.** Stop ultrafiltration
   - **C.** Administer clonidine 0.3 mg orally
   - **D.** Probe dry weight

Renovascular Hypertension, Atherosclerotic Renal Vascular Disease, and Thromboembolic Kidney Disease

Barbara A. Greco, Kostas E. Papamarkakis

NORMAL RENOVASCULAR ANATOMY

The clinical presentations of renovascular disease are influenced by the acuity, nature, and site of renal vascular compromise. In most individuals, the kidney has a single renal artery (RA) with a lumen diameter of 3 to 7 mm. The main RA branches in a double or triple fork pattern or ladder pattern.[1] The incidence of multiple RAs is about 31%, with bilateral supernumerary arteries in 11%.[2] The collaterals to the kidney, depicted in Fig. 43.1, can maintain renal parenchymal viability in the face of main RA occlusion.

Renal veins (RVs) begin in the subcapsular region of the kidney, communicate with perirenal and cortical venous channels, and empty into interlobular and then arcuate veins. The venae rectae drain the pyramids and join the arcuate veins, which leave the renal parenchyma through interlobar vessels, converging into four to six trunks near the hilum of the kidney. Approximately 20% of people have two or more RVs. The main RVs empty into the inferior vena cava. The left RV is three times longer than the right (7.5 cm vs. 2.5 cm) and traverses behind the splenic vein and body of the pancreas before it crosses in front of the aorta near its termination at the inferior vena cava. About 25% of people have retroaortic or circumaortic RVs. RV anatomy is shown in Fig. 43.2.

CLINICAL SYNDROMES ASSOCIATED WITH RENAL VASCULAR DISEASE

Impairment of blood flow is associated with one or more distinct clinical syndromes. These are summarized in Box 43.1. Discussion of these syndromes as distinct entities is meant to help with recognition and understanding that often, in clinical practice, there is significant overlap. The first section will focus on the three most common clinical presentations of RA stenosis: renovascular hypertension (RVH), atherosclerotic renovascular disease (ARVD; formerly called ischemic renal disease [IRD]), and unstable cardiac syndromes including flash pulmonary edema. The second section will address the distinct clinical presentations of transplant renovascular disease, renal infarction, atheroembolic disease, and RV thrombosis.

RENOVASCULAR HYPERTENSION

A reduction in renal perfusion pressure activates a series of hormonal and neuronal responses that raise systemic arterial pressure to restore RA perfusion pressures.[3] Renovascular hypertension (RVH) is defined as a syndrome of elevated blood pressure (BP) produced by any condition that leads to reduced perfusion of the kidneys.

Central to the pathogenesis of RVH is activation of the renin-angiotensin-aldosterone system (RAAS) with release of renin from the juxtaglomerular apparatus. This is mediated in part by stimulation of neuronal nitric oxide synthase and cyclooxygenase-2 in the macula densa. Blockade of RAAS during creation of an experimental RA stenosis prevents development of hypertension.[4] Studies in transgenic mice without receptors for angiotensin II (Ang II) confirm that development of RVH requires an intact RAAS.[5] In the absence of RAAS blockade, systemic arterial pressures increase until renal perfusion is restored. Studies in experimental models and humans indicate that additional mechanisms contribute to long-term BP elevation in the presence of RA stenosis, including activation of the sympathetic nervous system, impairment of nitric oxide generation, release of endothelin, and hypertensive microvascular injury to the kidney.[6]

Mechanisms responsible for sustained RVH differ depending on whether one or both kidneys are affected; these mechanisms have been studied in animal models in which RA perfusion is reduced by clipping the vessel proximally. The nomenclature distinguishes between a situation in which one clip is present with a normal contralateral unclipped kidney ("1-clip–2-kidney hypertension") and a situation in which the entire renal mass is affected ("1-clip–1-kidney hypertension"). Both these situations begin with impaired renal perfusion and initial activation of RAAS with sodium retention. However, in the 1-clip–2-kidney hypertension model, the elevated pressure generated by RAAS activation mediates a pressure natriuresis in the nonstenotic kidney. This restores plasma volume and results in sustained hypoperfusion and RAAS activation in the poststenotic kidney. This sequence of events produces Ang II–dependent hypertension (Fig. 43.3A).

By contrast, 1-clip–1-kidney hypertension represents a model in which the entire kidney mass is exposed to reduced perfusion pressure. As a result, sodium retention leads to expanded blood volume and sustained elevation in pressure, which then restores renal perfusion pressure beyond the stenosis and inhibits RAAS activation (see Fig. 43.3B). Hypertension in this model is typically more volume dependent than Ang II dependent. It may be less responsive to RAAS blockade than 1-clip–2-kidney hypertension. Box 43.2 lists causes of RVH based on these mechanisms.

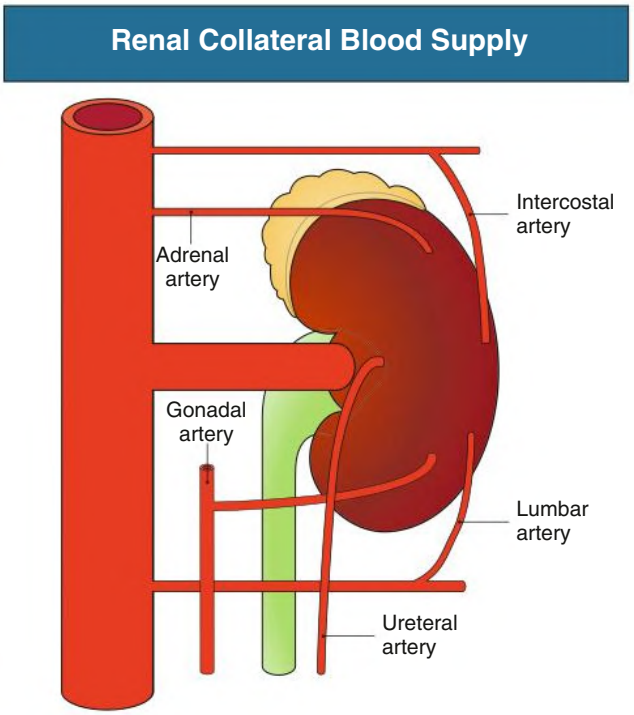

Fig. 43.1 The potential collateral renal arterial vessels to the kidney.

In RA stenosis, RAAS activation occurs when luminal stenosis is relatively severe, usually in the range of at least 60% to 80% cross-sectional diameter narrowing (Fig. 43.4). In experimental models, the relative importance of pressor mechanisms, including measurable activation of the RAAS, changes with time. Levels of circulating plasma renin activity tend to decrease. Several mechanisms have been proposed to explain such changes, including a slowly developing pressor action of Ang II, transition to alternative pressor mechanisms, and hypertensive injury to the nonstenotic kidney. In experimental models, this translates into a time limit for reversibility of RVH by removal of the clip. Clinically, this makes it difficult to determine when patients are most likely to benefit from RA revascularization for cure of hypertension.

Widespread use of RAAS blockers to manage hypertension, congestive heart failure (CHF), and diabetic and other proteinuric nephropathies has increased the exposure of individuals with undetected RVH to these agents. Therefore, many cases of RVH go undiagnosed unless hypertension becomes more difficult to control or kidney dysfunction develops. Patients who typically undergo diagnostic evaluation for RA stenosis are a subset of patients with more severe or resistant hypertension or those presenting with renal impairment or cardiac syndromes.

Clinical differentiation of RVH and primary hypertension is difficult, and they may be superimposed. If secondary to unilateral RA stenosis, for example, RVH often can be easily controlled with the use of RAAS blockers. Certainly, some cases of RVH present with accelerated, resistant, or hypertension emergency. Clinical studies suggest that for any level of BP, patients with RVH have higher nocturnal pressures ("nondippers") and have more severe target organ manifestations, such as left ventricular hypertrophy (LVH) and albuminuria, than patients with primary hypertension.[7] Patients with RVH may present with hypokalemia and metabolic alkalosis, which are clues to secondary aldosteronism. Clinical suspicion for RVH arises when hypertension develops either very early (<30 years) or later in life (>70 years) or when well-controlled hypertension becomes more resistant. Renovascular hypertension may rarely be associated with renin-mediated and hemodynamically induced nephrotic range proteinuria

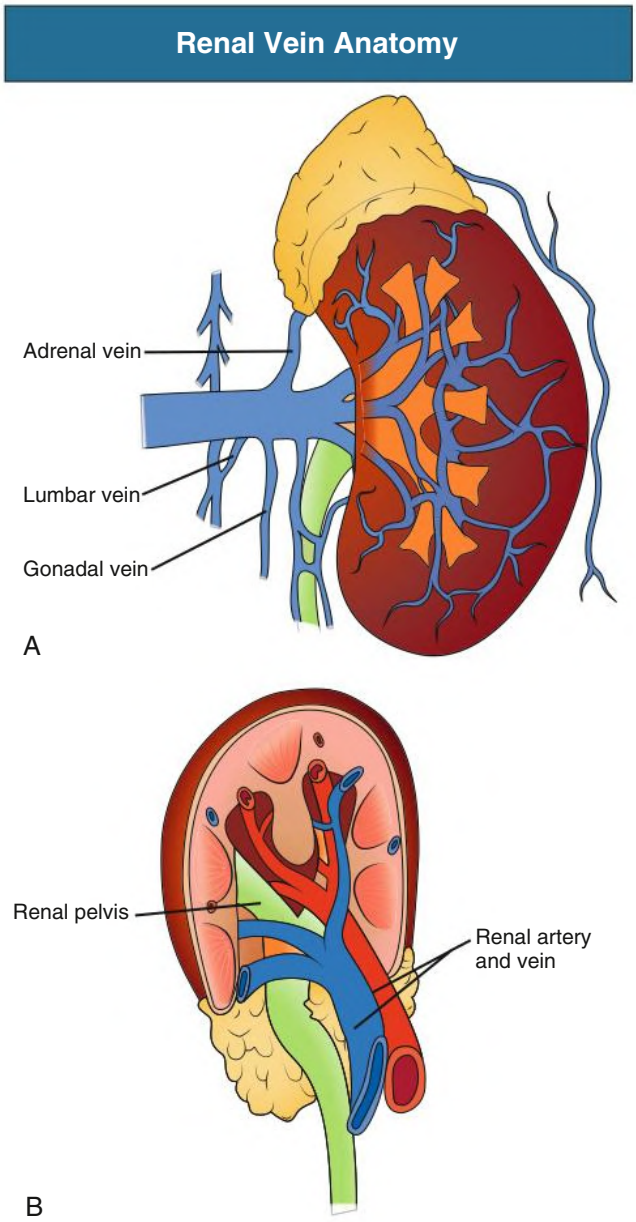

Fig. 43.2 **Renal Vein Anatomy.** (A) There is extensive communication between the renal venous plexus and lumbar, gonadal, and adrenal veins, which provide alternative outflow in the setting of renal vein thrombosis, particularly on the left. (B) Transverse section of the kidney showing relative position of vascular structures in the renal pelvis. (From Graham SD, Keane TE, Glenn JF, eds. *Glenn's Urologic Surgery*. 7th ed. Wolters Kluwer/Lippincott Williams & Wilkins Health; 2010.)

BOX 43.1 Clinical Presentations of Renovascular Disease

- Renovascular hypertension
- Ischemic renal disease
- Unstable cardiac syndromes
- Renal infarction
- Atheroembolic renal disease
- Renal vein thrombosis
- Transplant renovascular disease

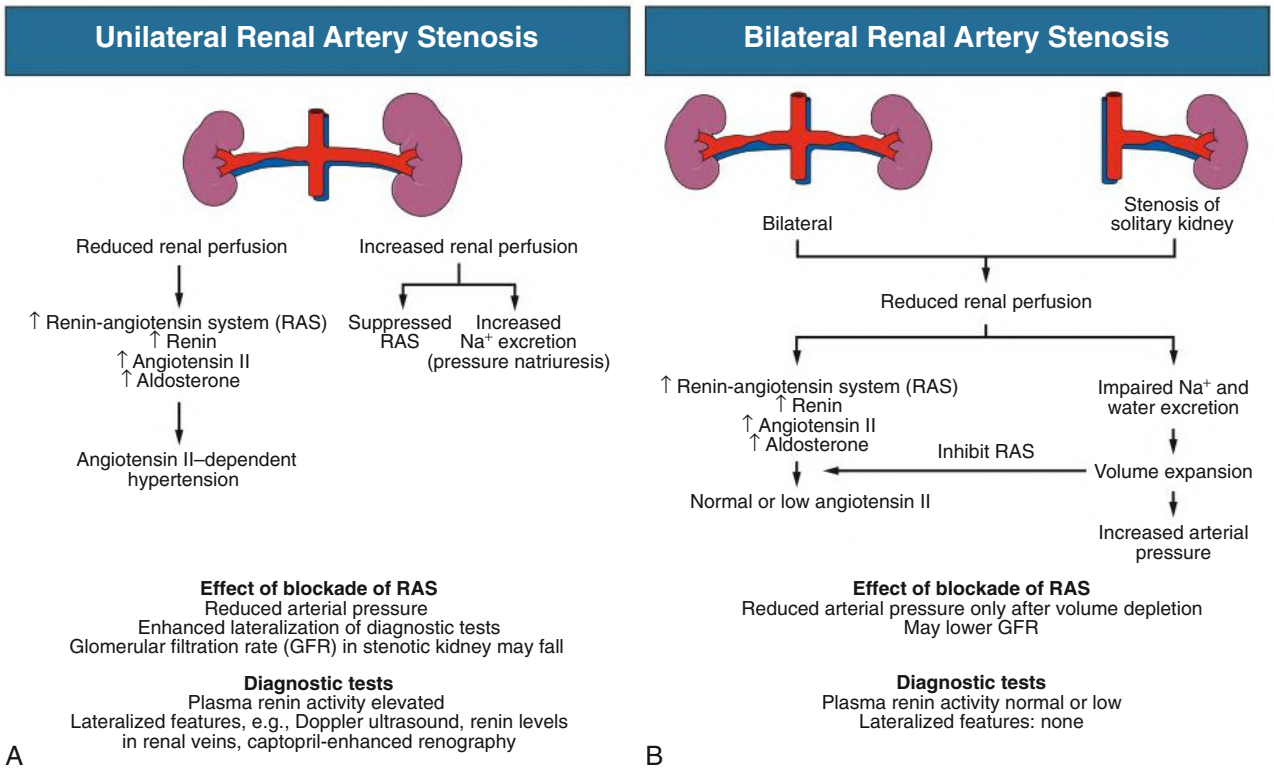

Fig. 43.3 Pathogenesis of Renovascular Hypertension in One-Kidney Versus Two-Kidney Model. (A) In unilateral stenosis with two kidneys, opposing forces between the stenotic kidney, which has reduced perfusion pressures, and the nonstenotic contralateral kidney, which has increased perfusion pressures, result in laboratory and clinical features of angiotensin-dependent hypertension. (B) In unilateral stenosis with a solitary functioning kidney or in a patient with bilateral critical renal artery stenosis, reduced perfusion pressure to the stenotic kidney in the absence of a normal kidney excreting sodium leads to sodium and volume retention, ultimately associated with hypertension without persistent activation of the renin-angiotensin system (RAS). *GFR,* Glomerular filtration rate.

that resolves with treatment. A syndrome of polydipsia associated with hyponatremia attributed to the dipsogenic action of Ang II has also been observed in patients with RVH. Clinical features of RVH are summarized in Box 43.3.

Renal Artery Stenosis

The most common cause of RVH is RA stenosis. Fibromuscular dysplasia (FMD) and atherosclerotic disease are the two most common causes of RVH. The unique clinical presentations of congenital and inflammatory arteritis as exemplified by aortic coarctation and Takayasu arteritis will also be discussed.

Fibromuscular Dysplasia

Fibromuscular dysplasia is the most common cause of RVH in children and young adults and is defined as an idiopathic, segmental, noninflammatory, nonatherosclerotic disease of the muscular arterial wall. Fibromuscular dysplasia is defined by pathognomonic arteriographic abnormalities, most commonly either a focal stenosis involving any portion of the vessel or multifocal stenoses in a string of beads appearance (Fig. 43.5) in mid to distal portions of small and medium-sized arteries. Nonstenotic angiographic findings associated with FMD include aneurysms, dissection, or vessel tortuosity, the latter often seen in the carotid circulation as an S-curve or in the coronary circulation. The presence of focal or multifocal stenosis in at least one vascular bed is necessary for the diagnosis of FMD, with the recognition that tortuosity, aneurysm, or dissection in another vascular bed may be associated but not sufficient for the diagnosis.[8]

The vascular distribution of FMD involves primarily the renal and extracranial cerebral and vertebral arteries but may involve any artery. In the FMD registries, RAs are involved with FMD in 66% to 92% of cases.[8] Bilateral RA involvement is seen in 25% to 35% of adult cases. Cerebrovascular involvement was identified in 80% and 59% of patients in the US and European registries, respectively.[8,9] Evaluation of 489 patients for RA and cerebral vascular involvement found that 48% had two territories involved, and 66.1% had dysplastic stenosis, aneurysms, or dissections at another site.[10] Of those with imaging of other vascular beds reported in the US registry, 48% had coronary involvement and 45% had lower extremity vascular involvement. Less common extrarenal sites of involvement with FMD include mesenteric, celiac, splenic, and aortic arteries.

Given the potentially systemic nature of FMD, we recommend thorough imaging assessment with computed tomographic angiography (CTA) or magnetic resonance angiography (MRA) of the entire vasculature at least once in patients with FMD to look for involvement at other sites, including occult aneurysms.[8]

The prevalence of renovascular FMD is estimated at 4 in 1000.[11] Angiography data from potential kidney donors suggest that the prevalence may be higher, with FMD observed in 3.8% to 6.6% of individuals.[12] Approximately 80% to 90% of cases of FMD occur in women, with most of these having multifocal FMD. Men with FMD tend to have a more aggressive phenotype, with a greater prevalence of focal FMD and aneurysms.[13]

Of those enrolled in the US FMD registry, 91% are White, and the mean age of onset of hypertension is 44.8 years. The mean age at

diagnosis was 53.3 years. As this presentation overlaps with the age of onset of primary hypertension, FMD may be missed in many adults. This racial predilection could represent recruitment or geographic bias.

BOX 43.2 Causes of Renovascular Hypertension

Two-Kidney Hypertension[a]

- Unilateral fibromuscular dysplasia
- Unilateral atherosclerotic renovascular disease
- RA aneurysm
- RA embolism and infarction
- Traumatic arterial occlusion
- Arteriovenous fistula
- RA dissection or thrombosis
- Aortic dissections with compromise to renal ostium
- Page kidney
- Takayasu arteritis
- Metastatic tumor compressing renal parenchyma
- Pheochromocytoma compressing RA
- Phakomatosis pigmentovascularis type IIb
- Neurofibromatosis
- Behçet disease
- Covering of origin of RA by aortic stent graft
- RA spasm

One-Kidney Hypertension[b]

- Stenosis to solitary kidney
- Bilateral arterial stenosis or dissection
- Coarctation of the aorta
- Vasculitis involving RAs
- Congenital vascular anomalies
- Atheroembolic renal disease

[a]Two-kidney hypertension implies that a contralateral, nonaffected kidney is present.
[b]One-kidney hypertension implies that the entire renal mass is beyond the vascular lesion, either bilateral disease or a solitary functioning kidney.
RA, Renal artery.

Histologically, FMD is associated with distortion of the architecture of the arterial wall involving one or more layers. The former distinction between adventitial, medial, intimal, and perimedial variants is no longer considered clinically relevant. Both genetic and environmental factors have been implicated in the etiology of FMD. In current registries, less than 7.5% of cases have family history of FMD. Data are biased by the significant percentage of asymptomatic cases and underdiagnosis. Genome-wide association studies have identified a single nucleotide polymorphism in the PHACTR1 locus on chromosome 6 as a risk allele. This genetic location is associated with regulation of expression of endothelin 1, which has effects on vascular tone and remodeling.[14] The current consensus is that there is no genetic test specific for FMD, and relatives of patients with FMD should be screened clinically and with imaging if signs, including hypertension, or symptoms develop. Environmental factors implicated in the etiology of FMD include cigarette smoking, hormonal influences, and vascular trauma or stretching of the RA during development or associated with nephropthosis.[13] US registry data observed a higher incidence of aneurysms and major vascular events among smokers with FMD.[15] Ongoing research is exploring potential roles of circulating transforming growth factor-β (TGF-β) and proinflammatory lipid mediators in the vascular wall in the pathogenesis of FMD.[16]

BOX 43.3 Clinical Features of Renovascular Hypertension

- Activation of renin-angiotensin system (early)
- Early-onset (<30 years) or late-onset (>60 years) hypertension
- Activation of sympathetic nervous system
- Abnormal circadian rhythm: loss of nocturnal fall
- Secondary aldosteronism: hypokalemia
- Accelerated target organ damage
- Microvascular disease
- Left ventricular hypertrophy
- Reduced glomerular filtration rate
- Hyponatremic hypertensive syndrome
- Unstable cardiac syndromes
- Rarely, nephrotic range proteinuria

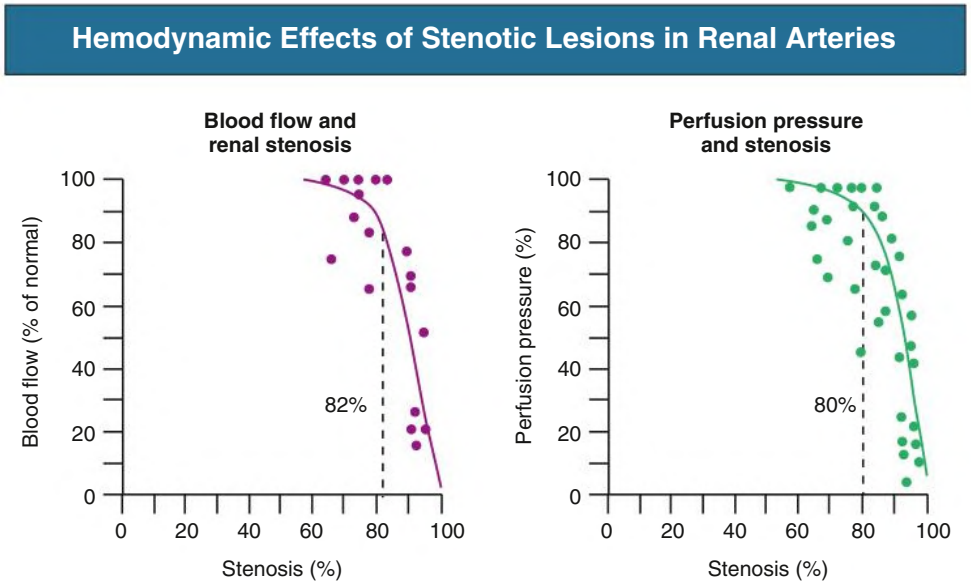

Fig. 43.4 Hemodynamic Effects of Stenotic Lesions in Renal Arteries. Changes in blood flow and arterial pressure across a carefully quantitated arterial lesion are barely detectable until cross-sectional area diminishes by 75% to 80%.

The most common adult clinical presentation is early-onset RVH in young to middle-aged women. Cerebrovascular lesions may manifest with headaches, pulsatile tinnitus, and bruits over the carotid arteries. Fibromuscular dysplasia should be considered in younger patients presenting with hypertension and stroke, transient ischemic attacks, subarachnoid hemorrhage, or amaurosis fugax. Clinical presentations of FMD and associated disorders are shown in Box 43.4.

The natural history of FMD has not been adequately studied. Progression of disease may manifest as new lesions within the same arterial bed, worsening arterial luminal narrowing within a specific lesion, involvement of a new vascular territory, or development or enlargement of arteriovenous fistulas or aneurysms. Up to 37% of patients may demonstrate angiographic progression of FMD, with few patients developing new or progressive lesions after the age of 40 years.[17] Progression may be associated with kidney cortical thinning but rarely causes advanced kidney failure.

Atherosclerotic Renal Artery Stenosis

Atherosclerotic RA stenosis is the most common cause of RVH in patients over 50 years old. Estimates of the prevalence of atherosclerotic RA stenosis depend on the population screened. One population-based study of 870 patients over 65 years old and screened with RA duplex ultrasound found a 6.8% prevalence of atherosclerotic RA stenosis, defined as greater than 60% stenosis.[18] Autopsy series report an overall prevalence of 4% to 20%, with progressively higher prevalence for those older than 60 years (25%–30%) and older than 75 years (40%–60%). Atherosclerotic RA stenosis occurs in patients with more generalized atherosclerosis involving the aorta, peripheral vasculature, and coronary arteries. Approximately 14% of patients with hypertension and 20% of patients with hypertension and diabetes mellitus (DM) have evidence of atherosclerotic RA stenosis. Coexistent RA stenosis is found in 11% to 30% of patients undergoing coronary angiography and in up to 45% of patients undergoing peripheral angiograms.[19] Among patients with chronic CHF, RA stenosis has been reported in 50% to 68%.[20] The American College of Cardiology and American Heart Association recommend screening for atherosclerotic RA stenosis in patients presenting with resistant or accelerated hypertension and those presenting with heart failure.

Predictors of RA stenosis include a history of hypertension, presence of chronic kidney disease (CKD), coexisting peripheral vascular or coronary artery disease, the presence of abdominal bruits, and a history of smoking. Atherosclerotic RA stenosis is bilateral in 20% to 40% of patients. In many of these cases, the degree of stenosis is below the threshold to cause activation of RAAS or have other clinical implications. However, the presence of atherosclerotic RA stenosis is a marker for increased cardiovascular and mortality risk.[21] Accordingly, its presence should prompt clinical attention to cardiovascular risk factors, including the use of high-dose statin therapy, efforts to promote smoking cessation, and optimal control of BP and metabolic syndrome.

Some patients with atherosclerotic RA stenosis will experience progressive RA luminal narrowing and develop RVH or other clinical syndromes described later. Prospective studies between 1990 and 1997 using duplex ultrasound in patients with atherosclerotic RA stenosis indicated progression in 30% over 3 years, varying by degree of initial stenosis, with progression more common in those with more than 60% luminal diameter stenosis. Total occlusion is rare but devastating, often leading to loss of kidney function. There are few prospective data assessing progression in patients treated with optimal medical therapy targeting atherosclerotic risk factors in the modern era.

Clinical presentations and treatment of atherosclerotic RA stenosis are discussed later in this chapter.

Takayasu Arteritis

Initially described in 1761, Takayasu arteritis, often termed *pulseless disease,* is one of several inflammatory disorders involving the renal

BOX 43.4 Clinical Manifestations and Disorders Associated With Fibromuscular Dysplasia

Clinical Manifestations

- Incidental finding (e.g., living kidney donors)
- Renovascular hypertension
- Renal infarction
- Loin or flank pain
- Hematuria
- Retroperitoneal hemorrhage
- Cerebrovascular accident (stroke)
- Transient ischemic attack
- Headaches
- Pulsatile tinnitus
- Horner syndrome
- Neck pain
- Dizziness
- Imaging finding of aneurysm dissection
- Amaurosis fugax
- Myocardial infarction
- Ischemic chest pain/dyspnea
- Postprandial abdominal pain
- Weight loss
- Hemobilia
- Claudication

Associated Disorders

- Tuberous sclerosis
- Marfan syndrome
- Ehlers-Danlos syndrome
- Cystic medial necrosis
- Coarctation of the aorta
- Alport syndrome
- Renal agenesis or dysgenesis
- α_1-Antitrypsin deficiency
- Medullary sponge kidney
- Cigarette smoking
- Collagen III glomerulopathy
- Atherosclerotic renovascular disease
- Alagille syndrome
- Ask-Upmark kidney
- Celiac disease
- Cocaine exposure (intrauterine)
- Crohn disease
- Homocystinuria
- Macrophagic myofasciitis
- Neurofibromatosis
- Williams syndrome
- Pheochromocytoma
- Infantile myofibromatosis
- Ergotamine preparation, methysergide

vasculature causing RVH. Although rare in the United States, its prevalence varies geographically, with reports as high as 1 in 3000 in Japan.[22] Takayasu arteritis usually presents between the ages of 25 and 41 years. The diagnosis should be considered in any child or young adult with hypertension and/or asymmetric peripheral pulses. In half of cases, identification of arterial stenosis is preceded by a prodromal illness characterized by fever, night sweats, malaise, and weight loss. Inflammatory markers are often elevated during this phase. Later, vascular stenoses can lead to RVH, kidney dysfunction, stroke, cerebral hemorrhage, myocardial infarction, or CHF, depending on sites of involvement.[22]

The diagnosis of Takayasu arteritis requires arteriographic narrowing or occlusion of a vascular territory of the aorta, its branches, or large arteries not attributable to atherosclerosis, middle aortic syndrome, or FMD.[23] One distinguishing feature of Takayasu arteritis is the presence of inflammatory thickening of the vascular wall seen on imaging.[23]

Theories about the pathophysiology of Takayasu arteritis include autoimmunity and hypersensitivity response to proposed antigens, including heat shock protein and *Mycobacterium tuberculosis.* Histologically, granulomatous inflammation involves all layers of the vessel wall during the active phase of disease, followed by fibrotic stenosis.

Treatment generally starts with corticosteroids or other immunomodulatory therapy during the inflammatory phase of disease, followed by medical or interventional treatment to reduce organ injury.[24]

Coarctation and Middle Aortic Syndrome

Coarctation occurs in about 1 in 1550 births and accounts for about one-third of all causes of RVH in infants. Interestingly, only 35% of isolated coarctation cases are diagnosed in the first year of life. Cases missed in childhood present as early onset hypertension in adults. Those cases treated in childhood can develop restenosis of the coarct segment later in life. It is estimated that 1 in 150 adults have congenital heart disease, with aortic coarctation accounting for 5% to 10%.

Adult presentations of RVH associated with coarctation include signs and symptoms of collateral development. Bruits may be heard over the carotids, and intercostal pulses may be palpable. A radial-femoral pulse delay is a sensitive physical examination finding. Present in only about 50% of cases, a harsh, systolic blowing murmur is heard best over the posterior thorax. Either MRA or CTA is necessary to confirm coarctation in adults. Indications for the treatment of coarctation in adults include upper limb hypertension and greater than 20 mm Hg systolic BP gradient across the stenosis with evidence of significant collateral flow. These patients have a fivefold excess risk of cerebral aneurysms, and screening cerebrovascular imaging is recommended. Current guidelines recommend multispecialty consultation among cardiologists, interventionalists, and surgeons to determine the optimal approach (endovascular vs. surgical) to repair. Success rates for cure of hypertension range from 69% to 80%, with highest chance for cure and best survival data when treated in children younger than 10 years. Adults with prior coarctation have a higher risk of developing hypertension than the general population. This risk is attributed to vascular noncompliance, reduced aortic arch baroreceptor sensitivity, early kidney injury with sustained RAAS activation, and, in some cases, restenosis of the repaired coarct segment.

A rare entity, middle aortic syndrome is a congenital segmental or diffuse narrowing of the abdominal or distal descending aorta, causing RVH usually noted in infancy. Concomitant proximal RA stenosis occurs in up to 80% of cases, with variants including RA atresia, hypoplasia, or dysplasia.[25] Associations between middle aortic syndrome and FMD, neurofibromatosis, Williams syndrome, and Takayasu arteritis have been reported, and these cases can present later in life. Middle aortic syndrome can cause claudication of the lower extremities and mesenteric ischemia. Angioplasty and stenting of stenotic segments, surgical bypass grafting, and autotransplantation of ischemic organs are treatment options.[25]

Renal Artery Aneurysms

Renal artery aneurysms are a rare cause of RVH and can be associated with atherosclerosis, FMD, and vasculitis. Thrombosis within an aneurysm can lead to distal emboli and renal infarcts (Fig. 43.6). Aneurysms

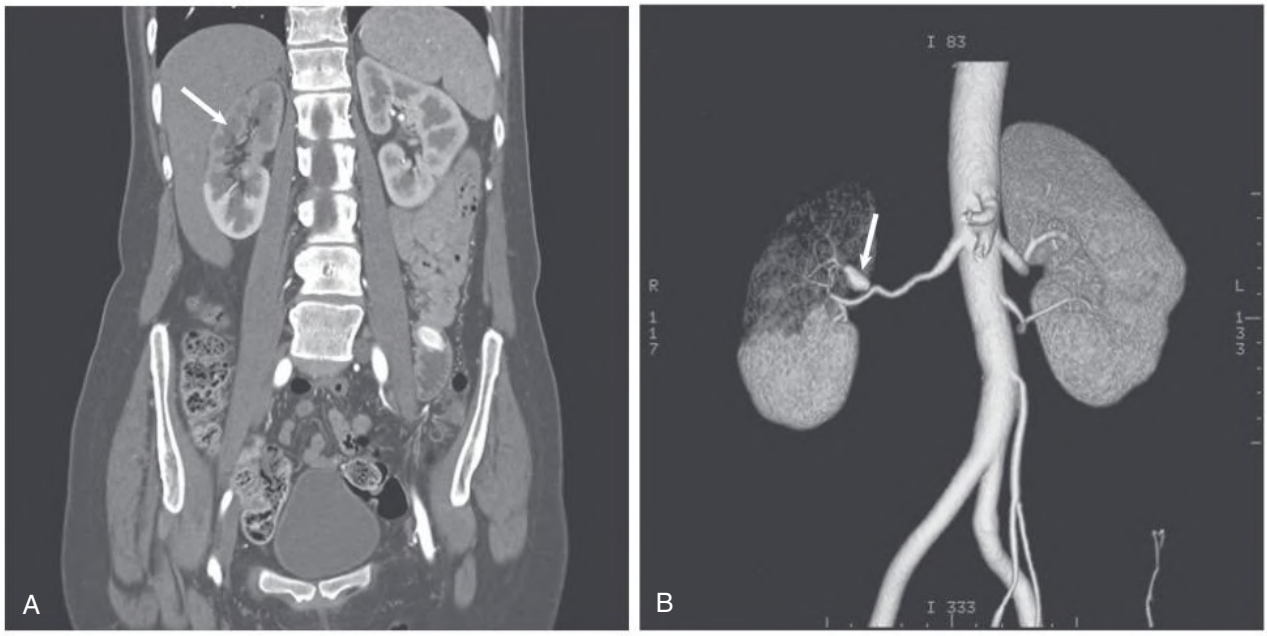

Fig. 43.6 Computed Tomography Angiogram of Renal Artery Aneurysm With Area of Infarction in Right Kidney. (A) Coronal image demonstrates area of intact tissue with no blood perfusion within the kidney parenchyma *(arrow).* (B) Reconstructed view with vascular aneurysm *(arrow)* and minimal flow in the distribution beyond this segment consistent with near-total occlusion. This patient presented with accelerated renovascular hypertension treated primarily with renin-angiotensin system blockade.

with diameters of greater than 1.5 cm have a significant risk of rupture. Other complications of RA aneurysms include vessel dissection and arteriovenous fistula formation.

ATHEROSCLEROTIC RENOVASCULAR DISEASE OR ISCHEMIC RENAL DISEASE

A second clinical presentation of renovascular disease is kidney dysfunction. Recent investigations have broadened our understanding of the processes leading to kidney injury, atrophy, and reduced glomerular filtration rate (GFR) in the setting of ARVD. Formerly called ischemic renal disease (IRD), it is now recognized that other factors in addition to ischemia are important in the pathogenesis. Severe RA stenosis or occlusion can decrease GFR by reducing glomerular capillary pressure below the threshold for renal autoregulatory compensation. This hemodynamic effect on kidney function occurs when renal blood flow is severely compromised. The histologic correlates of this reduced renal perfusion pressure include glomerular involution with basement membrane wrinkling and tubular cell atrophy and simplification and loss of brush border. The reduced energy-dependent tubular function and energy expenditure matches the reduction in oxygen delivery. Revascularization to improve renal blood flow can restore GFR and reverse these adaptive changes. In this scenario, the kidney is not chronically ischemic. Studies using blood oxygen level–dependent magnetic resonance imaging (BOLD MRI) indicate that, despite reductions in blood flow and GFR, many patients with RA stenosis maintain normal renal cortical and medullary tissue oxygenation.[26,27] Thus, many poststenotic kidneys have no more ischemia than normal kidneys.

However, it is clear from randomized controlled trials evaluating the effects of revascularization on retrieval of kidney function, studies in experimental RA stenosis, and renal biopsies of poststenotic kidneys that factors other than hemodynamics play a significant role in the pathogenesis of ARVD (Fig. 43.7). Severe RA stenosis may cause intermittent ischemic insults associated with acute or chronic regional or global hypoxia, which trigger maladaptive processes and ongoing kidney injury even when perfusion is restored.[28] These insults might be caused by fluctuations in BP and renal perfusion, embolic events, or progression of stenosis. Biopsies from poststenotic kidneys demonstrate influx of inflammatory cells and macrophages and increased expression of inflammatory cytokines including monocyte chemoattractant protein-1, tumor necrosis factor-α, interferon-γ, and interleukin-6. Biomarkers of tubular injury, including neutrophil gelatinase–associated lipocalin, are increased in poststenotic kidney RVs. Profibrotic factors including TGF-β and mitogen-activated protein kinase p38 are upregulated and associate with interstitial fibrosis and tubular atrophy. Ischemia leads to production of reactive oxygen species, which cause increased renal microcirculatory vascular tone and endothelial cell dysfunction.[29] This results in remodeling and rarefaction of the renal microvasculature at the level of the interlobar, arcuate, interlobular arteries and small arterioles.[30] This is associated with a decrease in expression of angiogenic factors including vascular endothelial growth factor (VEGF). Kidney hypoperfusion and ischemic-reperfusion insults also result in renal mitochondrial dysfunction.[31]

Through these processes, unilateral atherosclerotic RA stenosis leads to atrophy and dysfunction of the poststenotic kidney. The contralateral kidney often hypertrophies and compensates with hyperfiltration but develops progressive parenchymal injury mediated by the combined effects of high pressure and Ang II. In some cases, the kidney with the patent RA has worse function than the poststenotic kidney. In addition, studies in animal models of RA stenosis support the concept that the contralateral kidney participates in activation of proinflammatory and profibrotic pathways, which negatively affect the response of the poststenotic kidney to revascularization. In rats, nephrectomy of the contralateral kidney promotes recovery of the poststenotic kidney after reperfusion.[32]

In summary, reduced renal perfusion and ischemia ultimately activate numerous mechanisms of tissue injury. This results in macrophage

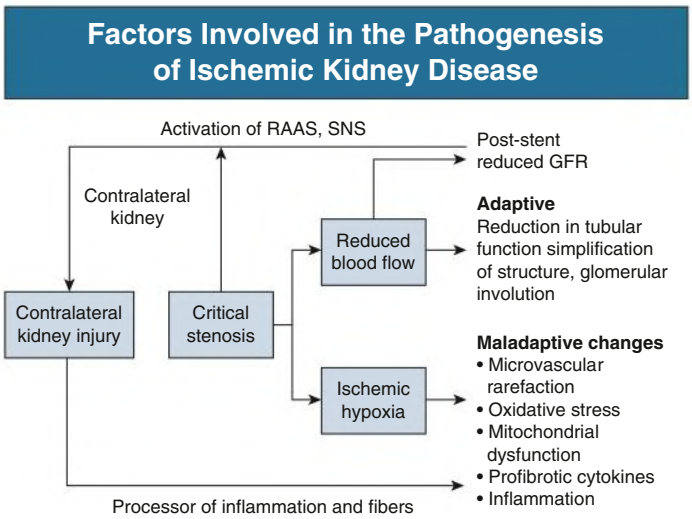

Fig. 43.7 The factors involved in the pathogenesis of ischemic renal disease (kidney dysfunction associated with atherosclerotic renal vascular disease). *GFR,* Glomerular filtration rate; *RAAS,* renin-angiotensin-aldosterone system; *SNS,* sympathetic nervous system.

accumulation with progressive tubular cell loss and interstitial fibrosis. Glomeruli are usually preserved but often appear involuted. The ischemic kidney develops microvascular rarefaction, contributing to ongoing irreversible structural and functional changes. Atherosclerotic renovascular disease or IRD comprises both the potentially reversible hemodynamic component and these adaptive and structural changes, some of which are not reversed by revascularizing the kidney.

Clinical presentations of ARVD or IRD are outlined in Box 43.5. The most common is unexplained CKD in patients with generalized atherosclerosis. Often, BP is well controlled, particularly when RAAS blockade is used, though it may present with resistant hypertension. Risk factors for atherosclerosis are often present: long-standing hypertension, cigarette smoking, and hyperlipidemia. When investigated, these patients are found to have unilateral or bilateral RA stenosis and often have small or asymmetric kidneys. As an etiology of CKD, ARVD is usually associated with minimal proteinuria. Proteinuria develops in response to kidney injury over time and is a predictor of poorer response to revascularization. Urinary sediment is bland.

Atherosclerotic renovascular disease can also present as acute kidney injury (AKI) in patients with RA stenosis treated medically or in those with recurrent stenosis within a stented RA. New or episodic AKI, or AKI on CKD with recent rapid decline in eGFR in patients with known RA stenosis or those with diffuse atherosclerosis, should prompt evaluation for ARVD. In patients with high-grade RA stenosis, AKI can follow normalization of systemic BP with any agent. The sudden reduction in systemic BP can reduce RA pressure below levels needed to sustain GFR. With RAAS inhibitors, these alterations in glomerular hemodynamics may be more common or pronounced.[33] Normally, activation of Ang II causes efferent arteriolar vasoconstriction, which preserves transcapillary filtration pressures at the glomerulus when preglomerular pressures are reduced, thereby maintaining GFR. The loss of this compensatory mechanism induced by RAAS blockade can result in functional AKI. This typically occurs within a few days from the start of therapy and is usually reversible. An acceptable rise in serum creatinine above baseline is less than 0.5 mg/dL or a less than 30% change in estimated GFR (eGFR). If the change exceeds this, ARVD should be considered. An excessive drop in eGFR after initiation of RAAS inhibitors is not specific for the presence of RA stenosis and is seen frequently in patients with cardiac or hepatic dysfunction or patients with intravascular volume depletion because, in these settings, maintenance of GFR is also Ang II dependent.

Oligoanuria in the setting of AKI in patients with atherosclerosis or risk factors should prompt testing for critical renovascular disease. Often, concomitant RVH is present.

BOX 43.5 Clinical Presentations of Ischemic Renal Disease Associated With Atherosclerotic Renal Artery Stenosis

- AKI with control of BP: ACE inhibitors or ARBs
- AKI with aggressive diuresis in patients with congestive heart failure
- CKD otherwise unexplained in atherosclerotic age range
- CKD with asymmetric renal size
- Acute or chronic kidney disease and renovascular hypertension
- Acute on chronic kidney injury with episodes of "flash" pulmonary edema
- Unexplained rapid decline in GFR in CKD
- Oligoanuric kidney failure not otherwise explained in a patient with atherosclerosis and hypertension
- Renal atrophy

ACE, Angiotensin-converting enzyme; *AKI,* acute kidney injury; *ARB,* angiotensin receptor blocker; *BP,* blood pressure; *CKD,* chronic kidney disease; *GFR,* glomerular filtration rate.

RENOVASCULAR DISEASE AND HEART FAILURE AND UNSTABLE CARDIAC CONDITIONS

Some patients with RA stenosis present with recurrent episodes of "flash" pulmonary edema, called Pickering syndrome.[34] These presentations are usually characterized by hypertensive urgency or emergency, hypervolemia, and echocardiographic evidence of diastolic dysfunction.[35] Such patients have increased mortality and hospitalization rates compared with those who have CHF without renovascular disease.[36] Case series and retrospective reviews suggest that renal revascularization can facilitate volume management, reduce hospitalizations, and improve GFR and cardiac function in this high-risk subgroup of patients with atherosclerotic RA stenosis.[37,38] This cohort of patients has been underrepresented in randomized controlled trials evaluating the relative efficacy of revascularization and medical therapy. Some

believe that chronic stimulation of the RAAS secondary to RA stenosis contributes to the abnormal left ventricular remodeling in patients with chronic systolic heart failure, as well as to the frequency of CHF decompensation.[39]

Patients with CHF have a high prevalence of concomitant RA stenosis. About half of patients with a diagnosis of systolic heart failure have concomitant RA stenosis and nearly 70% of those with both CHF and CKD.[40] The presentation of decompensated CHF, worsening kidney function, and hypertension should raise suspicion for this diagnosis along with other forms of cardiorenal syndrome. In cases with severely depressed left ventricular function, hypertension may be absent. Clinicians should consider the presence of critical RA stenosis if GFR continues to deteriorate during treatment of decompensated CHF.

Finally, some patients with RA stenosis and LVH can present with chest pain syndromes with no significant lesions in the coronary arteries.

IMAGING RENOVASCULAR HYPERTENSION AND RENAL ARTERY STENOSIS

Conventional direct angiography remains the reference standard to define the RA anatomy. Noninvasive options include RA duplex ultrasound, CTA, and MRA, each with their limitations and strengths.

Renal artery duplex scanning is often used to identify and follow hemodynamic effects of RA stenoses. It is most effective in detecting lesions of the main RA near the ostium and thus is a good screening test for atherosclerotic RA stenosis. The reliability of duplex ultrasound depends on the skill and experience of the operator and the body habitus of the patient. Duplex ultrasound provides little functional information beyond the vascular lesion, although structural features such as kidney size and echogenicity can be determined. The duplex diagnostic criteria for hemodynamically significant RA stenosis consider the comparative rates of blood flow in the stenotic area to that in the remaining segments of the RA and the aorta. Parameters measured include peak systolic velocity (PSV) at various sites along the RA and in the suprarenal aorta; the renal aortic ratio (RAR), which compares the PSVs at these segments; acceleration time and index, which help evaluate the RA waveform; and the intrarenal resistive index. The resistive index has been associated with intrinsic small vessel renal disease, and a value greater than 0.80 has a strong negative predictive value for a good BP response to intervention.[41] Normal PSV in the RA will depend on the lumen diameter of the vessel and ranges from about 120 to 160 cm/sec. Peak systolic velocity greater than 200 to 220 cm/sec and RAR greater than 3.0 to 3.5 usually indicate RA stenosis of greater than 60% narrowing.[42] Most laboratories provide interpretation as to whether parameters support at least 60% luminal diameter narrowing, but clinicians should be familiar with aortic and RA velocities and waveforms to evaluate the validity of these interpretations. Generally, the higher the PSV, the more severe is the stenosis. However, a very blunted (tardus-parvus) RA waveform can represent critical RA stenosis in the absence of an elevated PSV. Renal artery duplex allows for serial testing, hence monitoring for progression and changes in kidney size. It is the preferred test for evaluating for restenosis of a stented RA segment. Duplex screening can miss accessory renal vessels.

Three-dimensional MRA with gadolinium enhancement provides excellent visualization of the arteries and functional information about the kidneys (Fig. 43.8). Limitations include interobserver variability, a tendency to overestimate degree of stenosis, interference by motion and breathing artifact, and limited sensitivity for middle and distal vascular lesions and small accessory vessels. Magnetic resonance angiography has the advantage of avoiding radiation exposure. The use of group II gadolinium-based contrast media is now considered safe for use in imaging in patients with AKI and advanced CKD or kidney failure with an extremely low incidence, if any, of nephrotoxicity or nephrogenic sclerosing dermopathy.[43]

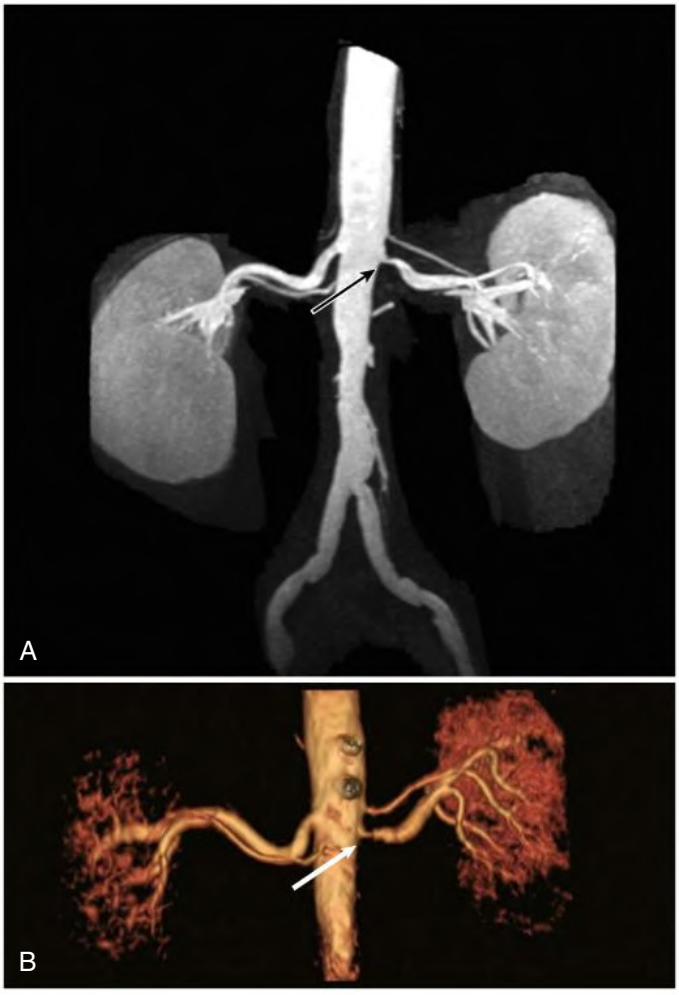

Fig. 43.8 Magnetic Resonance Angiogram With and Without Gadolinium Contrast Enhancement. (A) High-grade stenosis affecting the left inferior renal artery is evident, with functioning kidney tissue as reflected by gadolinium nephrogram *(black arrow)*. Concerns about the role of gadolinium in the development of nephrogenic systemic fibrosis have greatly reduced the use of this contrast agent. (B) As a result, methods to image the vasculature without contrast material are being developed that produce excellent reconstructed images *(white arrow)*.

In CTA with vascular reconstruction, imaging definition is nearly equal to that of conventional angiography but requires significantly more contrast, usually 100 to 125 mL. Focal vascular calcification often obscures accurate assessment of stenoses. Computed tomographic angiography is highly sensitive for identifying lesions in the mid and branch vessels often associated with FMD and is the recommended screening test for these patients based on recent consensus recommendatons.[8]

Angiography remains the gold standard for defining the degree of stenosis and is the most reliable modality for identifying distal and branch or small vessel disease, which may be missed by other screening modalities. Aortography provides the opportunity to perform intravascular ultrasound to assess lesions and for the measurement pressure gradients across a stenosis, an aid in determining the hemodynamic significance of a lesion. When there is complete proximal arterial

occlusion, direct aortography can identify distal reconstitution by collaterals and a renal "blush" confirming parenchymal viability. Limited selective renal angiography can be performed with as little as 10 mL of contrast. In cases at highest risk for contrast-induced AKI, carbon dioxide can be used instead of nonionic iodinated contrast.

In cases of unilateral RA disease, captopril renography provides functional information regarding the size and excretory capacity of the kidney and demonstrates the rate of isotope appearance as an index of renal blood flow and filtration. It detects the presence of a differential role of Ang II on GFR between the kidneys. This test has a high negative predictive value for the presence of RVH when completely normal.[44] It is less specific in the setting of intrinsic kidney dysfunction.

Renal vein renin measurements may help predict the BP response to renal revascularization. Previous studies indicated that lateralization of RV levels (>1.5:1 stenotic-to-nonstenotic kidney ratio) predicts a favorable BP response for more than 90% of patients. Because failure to lateralize also carries a favorable response in almost half of patients, the negative predictive value is limited. Some clinicians use these measurements to verify lower renin levels in the pressor (i.e., nonstenotic) kidney before undertaking nephrectomy.

TREATMENT OF FIBROMUSCULAR DYSPLASIA AND ATHEROSCLEROTIC RENOVASCULAR DISEASE

Medical and Endovascular Treatments

Fibromuscular dysplasia of hemodynamic significance should be treated with revascularization. Current consensus defines significance as having a translesional pressure gradient of 10% of the mean aortic pressure. The treatment of choice for FMD is percutaneous renal artery angioplasty (PTRA). Stenting is not recommended and is reserved as a rescue procedure for complications of PTRA such as dissection. Successful PTRA results in disruption of the abnormal collagen bands in the lumen of the artery and the vascular wall leading to larger lumen diameter and less turbulent RA blood flow. Complete cure, defined as normalization of BP without the need for medications, occurs in 35% to 45% of cases. In more than 85% of cases treated with PTRA, BP is improved with reduction in the number of antihypertensive medications.[45] Predictors of response to intervention include lower preintervention systolic BP, younger age at treatment, shorter duration of hypertension, and a positive pretreatment captopril renogram.[46] Primary technical success rates exceed 90%. Inadequate initial treatment or restenosis has been reported in up to 34% of treated cases and is most common with multifocal variant. Subsequent procedures to address all areas of stenosis may be required. Use of intravascular ultrasound to guide endovascular treatment of these lesions can improve treatment success. When FMD is associated with aneurysmal dilations greater than 1.5 cm in diameter, surgical revascularization or endovascular exclusion using a covered stent may be required. Women of childbearing age with RA aneurysms should be treated before pursuing pregnancy because of the risk for rupture during pregnancy or delivery. Other recommended treatments for patients with FMD are antiplatelet agents and smoking cessation.

The optimal treatment of atherosclerotic RA stenosis presenting with RVH or other clinical syndromes is controversial. Primary percutaneous renal artery stenting (PTRS) became standard treatment in many centers during the mid to late 1990s. Target vessel patency rates using PTRS regularly exceed 95%. Between 1996 and 2005, enthusiastic application of PTRS in the treatment of atherosclerotic RA stenosis led to a marked rise in stent placement in these patients. Most case series and observational studies reported stabilization of BP and renal function in half of patients undergoing PTRS, improvement in up to 25%, and a decline in kidney function after PTRS in 25%.

The relative effectiveness of endovascular treatment of atherosclerotic RA stenosis compared with medical therapy has now been studied in several randomized controlled trials. These are summarized in Table 43.1. The two largest trials, the Angioplasty and Stent for Renal Artery Lesions (ASTRAL) and Cardiovascular Outcomes in Renal Atherosclerotic Lesions (CORAL), comparing medical therapy and stenting to medical therapy alone, demonstrated no differences in the primary endpoints between groups.[47,48] In the ASTRAL trial, 806 subjects with hypertension, many with CKD, were randomized to PTRS versus medical therapy and followed for a mean of 33.6 months. Of the enrolled patients, 53% had bilateral RA stenosis; the mean degree of luminal narrowing was 75.5%. The ASTRAL trial reported no difference in the primary endpoint of change in kidney function as measured by reciprocal creatinine. Investigators in the CORAL trial enrolled 947 patients, all treated with well-defined medical therapy addressing all cardiovascular risk factors, used RAAS blockade as the cornerstone of antihypertensive therapy, and randomized half the group to medical therapy plus stent. The CORAL trial had an imaging oversight laboratory and allowed enrollment based on angiographic as well as CTA, MRA, and duplex ultrasound definition of RA stenosis greater than 60%. At a median of 43 months of follow-up, there were no differences in the composite endpoint of mortality, cardiovascular and renal events, or any of the individual components between the treatment groups.

Current consensus is that the initial treatment of patients with RVH and stable CKD associated with atherosclerotic RA stenosis should be a focused medical management approach to addressing all cardiovascular and renal risk factors in addition to hypertension. In CORAL, there was no difference in number of medications required to control BP between groups. For those patients with diabetes and CKD, attention to achieving hemoglobin A_{1C}, as well as CKD mineral bone disease and anemia targets, are important therapeutic goals. Statins are recommended in these patients both for cardiovascular risk reduction and with the goal of slowing progression of the RA lesion; there are also experimental data suggesting that statins attenuate kidney parenchymal injury associated with atherosclerotic renovascular disease.[49,50]

Whether all patients with RA stenosis should be treated with RAAS blockade remains controversial. There is a risk for RAAS blockers to induce AKI, and this risk is higher in patients with bilateral RA stenosis or stenosis to a single functioning kidney. Although the unique properties of RAAS blockers allow more effective BP control in patients with RVH, there is the potential for early loss of filtration pressure in patients with critical RA stenosis.

Clinical experience with RAAS blockers in the treatment of RVH is reassuring. Registry data and prospective follow-up studies in patients with atherosclerotic RA stenosis indicate that blockade of the RAAS is usually well tolerated.[51,52] In the CORAL trial, in which 20% of patients had bilateral RA stenosis, most patients received an angiotensin receptor blocker or angiotensin-converting enzyme (ACE) inhibitor. The lack of differences in kidney endpoints suggests that this was generally well tolerated. However, it is strongly advised that patients with atherosclerotic RA stenosis who are prescribed these agents have electrolytes and creatinine measured within 2 to 4 weeks after starting these agents and regularly over the course of follow-up.

Indications to Consider Kidney Revascularization in Atherosclerotic Renal Artery Stenosis

Despite the lack of randomized controlled data and the risks, some high-risk patients may benefit from RA revascularization when medical therapy falls short.[53] Indications to consider revascularization are listed in Box 43.6. First, uncontrolled hypertension, despite all efforts

TABLE 43.1 Randomized Controlled Trials Comparing Medical Therapy to Medical Therapy With Renal Artery Stenting for Renal Artery Stenosis

Study	ASTRAL (2009)	STAR (2009)	CORAL (2014)
Cohort	Hypertension	Hypertension and CKD	Hypertension and/or CKD
Entry BP	No BP threshold required	BP <140/90 mm Hg and stable for 1 month and eGFR <80 mL/min	SBP >155 mm Hg on two or more medications or eGFR <60 mL/min
Stenosis	>50% by MRA, CTA, angiography	>50% by MRA, CTA, or angiography	>60% by MRA, CTA, angiography, DUS
Excluded	Clinician certain patient would benefit from stent or require stent within 6 months	Malignant hypertension Pulmonary edema with bilateral RA stenting Intolerance to ACEI/ARBs as evidenced by >20% drop in CrCl	Entry creatinine >4 mg/dL Kidney length <7 cm
% Stenosis	75.5 mean %	NA	67.3%/66.2%
CKD	Mean creatinine 2.0 mg/dL	Mean creatinine 1.7 mg/dL	Mean eGFR 58 mL/min/1.73 m^2
% Bilateral	53.5%	47.9%	22%
Subjects per arm (N/N)	403/403	76/64	459/472
Follow-up	33.6 months	24 months	43 months
Treatment	Stent	Stent	Stent
Medical treatment	At discretion of sites BP control with or without ACEI or ARB No specified target BP	BP target <140/90 mm Hg ACEI/ARB last resort ASA Statin Smoking cessation counseling	BP target <140/90 mm Hg 130/80 mm Hg for DM and CKD ACE/ARB first-line ASA Statin goal LDL <70 mg/dL Hb A_{1c} <7.0% for DM Smoking cessation counseling
Endpoint	Rate of progression of CKD based on reciprocal creatinine over time	≥20% decrease in CrCl	Composite cardiovascular and renal events
Outcome	No significant difference	No significant difference	No significant difference

BOX 43.6 Clinical Indications to Consider Renal Artery Revascularization

- Worsening kidney function due to IRD
- Uncontrolled hypertension failing medical therapy
- Intolerance to medical therapy
- Recurrent hospitalizations for pulmonary edema without other obvious cause while on optimal medical therapy
- Other unstable cardiac or renal trajectories
- Progressive renal atrophy (controversial)
- Potentially reversible dialysis dependence due to IRD

IRD, Ischemic renal disease.

to optimize pharmacologic and dietary interventions and to enhance adherence, should prompt evaluation for all potential causes of resistance. Blockade of the RAAS should be included in the antihypertensive regimen in these resistant cases. Some patients will be intolerant of the very medications they need to control BP. Others may present with hypertensive urgency or emergency despite therapy. Some of these patients may respond to PTRS. Second, when RA stenosis critically reduces glomerular capillary pressure such that there is a rapid decline in GFR, renal revascularization may improve kidney function and avoid the need for dialysis. In these cases, there are often multiple other potential contributors to declining GFR that must be considered. Given the need to balance the potential risks and benefits of intervention, input from a multidisciplinary team including nephrologists, vascular surgeons, and interventionalists is often helpful. In one series, PTRS in dialysis-dependent patients with ARVD led to enough improvement in kidney function to allow for discontinuation of dialysis.[54] Finally, some patients with recurrent hospitalizations for decompensated heart failure or flash pulmonary edema that is attributed to medically resistant RA stenosis may benefit from RA revascularization.[53]

Fig. 43.9 outlines a proposed clinical algorithm for managing patients with atherosclerotic RA stenosis.

For patients who undertake PTRS, surveillance for in-stent RA stenosis should be undertaken based on changes in either control of BP or kidney

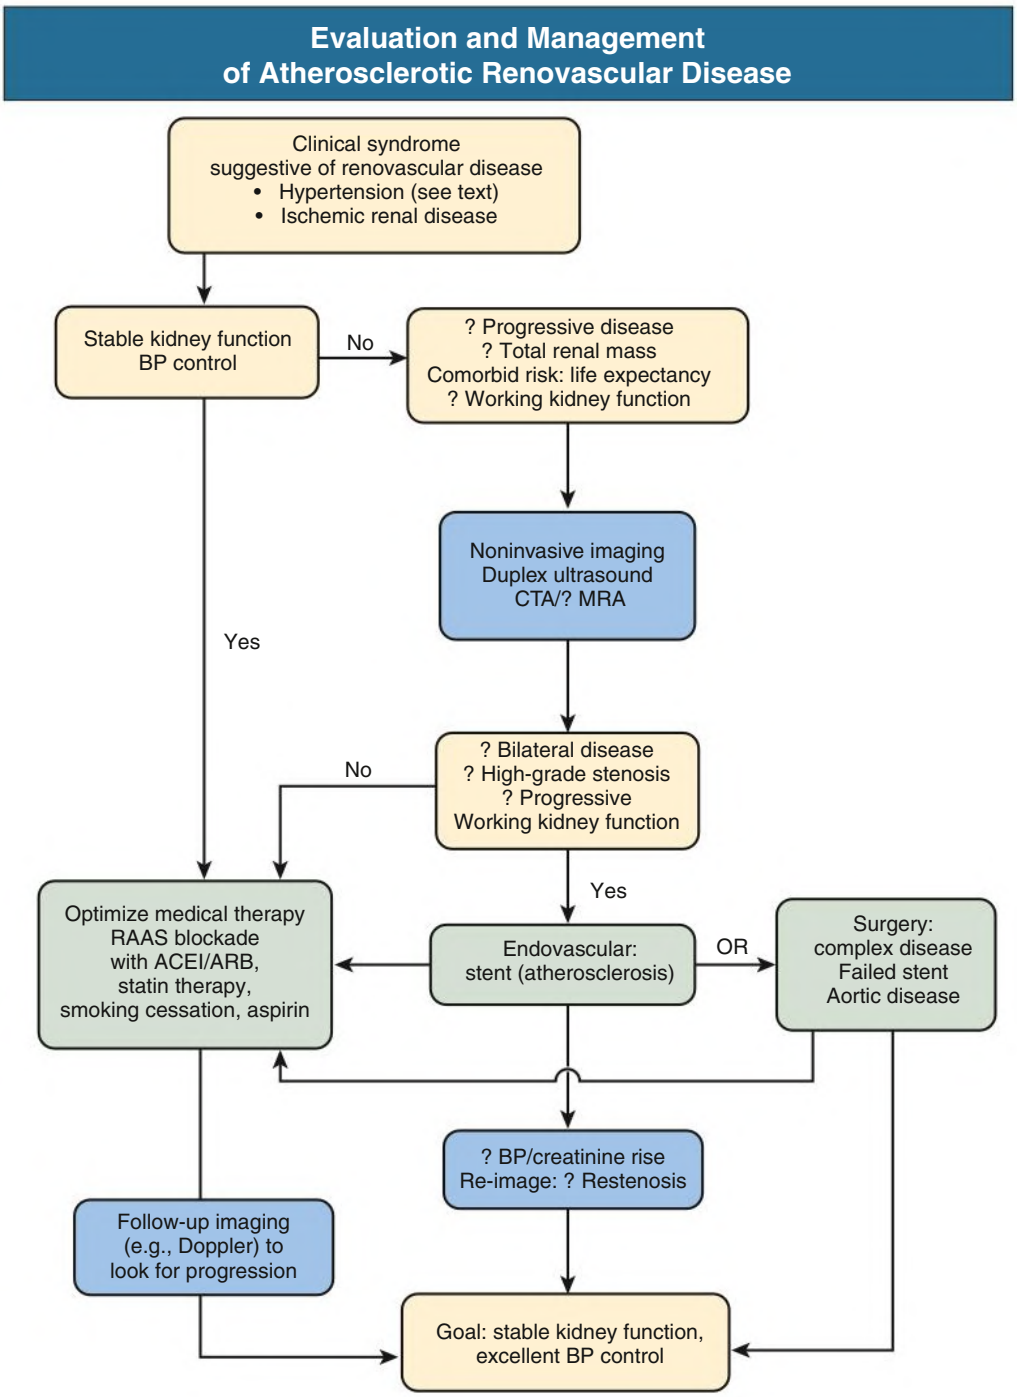

Fig. 43.9 Algorithm for the Management of Renal Artery Stenosis. The intensity of imaging and revascularization depends on both the level of kidney function and the blood pressure (BP), in addition to the comorbid disease risks for the individual patient. The overall goal should focus on stable kidney function and BP levels. As with any other vascular disease, monitoring for disease progression and recurrence is an important element of long-term management. *ACEI,* Angiotensin-converting enzyme inhibitor; *ARB,* angiotensin receptor blocker; *CTA,* computed tomographic angiography; *MRA,* magnetic resonance angiography; *RAAS,* renin-angiotensin-aldosterone system.

function. In-stent stenosis remains a significant complication occurring in up to 33% of cases and can occur at any time after stent placement, with the highest risk within the first year after primary PTRS.[55] Patients with RA stents should be followed closely at regular intervals for this complication, which can be treated to prevent occlusion. An example of stent fracture as a cause of RA thrombosis and infarction is demonstrated in Fig. 43.10. Clinicians should inform patients with atherosclerotic RA stenosis about the risk and uncertain benefits of PTRS.

Surgical Renal Revascularization

Before the introduction of endovascular techniques, surgical revascularization was the standard treatment for patients with ARVD and

Fig. 43.10 Thrombosis of Renal Artery Complicating Renal Artery Stenting. Right and left renal artery stents. The left renal stent *(arrow)* is triangular, indicating crimping of the proximal portion, which in this patient was associated with thrombosis of the renal artery, seen here as no contrast entering the vessel. The right renal stent is patent.

RVH. Such procedures carry considerable risk, cost, and morbidity. As a result, surgical intervention for renovascular disease is generally reserved for patients who do not respond to best medical and endovascular therapy or who have associated aortic disease that is not amenable to endovascular therapy. Despite these caveats, successful surgical revascularization in well-selected cases provides durable restoration of kidney blood supply with good long-term patient survival.[56] Overall, the effects of surgical revascularization on BP and renal function response in patients with atherosclerotic RA stenosis mirror those for PTRS. Surgical revascularization in the modern era may provide more durable patency than PTRS with lower complication rates and risk for restenosis.

Surgical revascularization should be considered in patients with total occlusion of the RA and abrupt loss of GFR for retrieval of kidney function. Some dialysis-dependent patients and some with advanced CKD with ARVD experience recovery of kidney function after revascularization.[57] Treatment involves assessment of the risks versus potential benefits of heroic revascularization procedures. The status of the contralateral kidney and overall residual kidney function should be weighed against the potential retrievable function from the underperfused kidney, as well as the perioperative risk associated with surgery. Predictors of GFR recovery with revascularization in the setting of critical RA occlusion include preserved kidney size, evidence of a renal blush or nephrogram by imaging, recent decline in GFR, and recent baseline creatinine concentration less than 3 mg/dL.[58]

When a poorly functioning atrophic kidney causes RVH refractory to optimal medical therapy including RAAS blockade, nephrectomy of this pressor kidney may improve BP control with minimal impact on total GFR.

Atherosclerotic Renal Vascular Disease: Beyond the Stenosis

The recognition that ARVD or IRD is more than a hemodynamic disorder has led to early investigation into targeting the inflammatory ischemic-reperfusion and vascular rarefaction aspects of this form of kidney disease. Early studies suggest that intraarterial infusion of autologous mesenchymal stem cells increase tissue oxygenation, blood flow, and GFR in poststenotic kidneys, with associated reduction in inflammatory biomarkers. Other studies looking at administering VEGF and strategies to mitigate mitochondrial dysfunction in models of ARVD have also shown promising results.[59]

Renovascular Disease in the Renal Transplant

Recognition of vascular complications of renal transplantation can prolong allograft survival. Early posttransplant, RA, and vein stenosis or thrombosis are rare but treatable complications.

Renal artery thrombosis occurs in about 0.4% of transplants within minutes to hours after transplantation. Causes include hyperacute rejection, kinking of the RA, anastomotic arterial occlusion, or intimal flap. It has also been reported associated with decubitus positioning.

Transplant RV thrombosis is more common, occurring in 5% of adult transplants and 8.2% of pediatric cases, usually within the first 5 days after transplantation, and is more common with right kidney donation. It usually leads to graft infarction, but rupture of the allograft can occur. Risk factors include donor age over 60 years, donor artery atherosclerosis, and longer allograft cold ischemia time. Recipient risk factors include age younger than 6 years or older than 50 years, hypovolemia in the perioperative period, multiple RVs, DM, technical or surgical complications, and prior peritoneal dialysis. When thrombotic vascular complications occur without obvious cause, an evaluation for hypercoagulable state is recommended. There are some data supporting the protective effects of low-dose aspirin in this population. Renal salvage is possible with early diagnosis, surgical exploration, and thrombectomy.

The most common posttransplant vascular complication is transplant RA stenosis, which occurs between 3 months and 2 years posttransplantation and accounts for about 5% of all posttransplant hypertension. The incidence ranges from 1.3% to 23%, depending on the screening tests used.[60] In many cases, anastomotic stenoses are not hemodynamically significant. Renal artery stenosis is more common in deceased donor transplants than in living donor transplants and in allografts with multiple renal vessels. The use of pediatric kidneys in adult recipients is associated with a higher rate of stenosis because of greater turbulent flow from mismatch between donor and recipient vessel size.

The cause for transplant RA stenosis is usually intimal scarring and hyperplasia in response to trauma to the vessel during harvesting or anastomotic stenosis, which is most commonly associated with end-to-end anastomoses and may be related to suture technique. In end-to-side anastomoses, stenosis is typically postanastomotic, suggesting that turbulence or other hemodynamic factors play a role. Immunologic causes of transplant RA stenosis have been proposed on the basis of histologic similarities with chronic vascular rejection and association with prior acute rejection. In addition, de novo class II donor-specific antibodies have been associated with postanastomotic stenosis.[61] Other possible pathogenic mechanisms include atherosclerosis of the donor artery, calcineurin inhibitor toxicity, and cytomegalovirus infection. External compression on the transplant artery by large native polycystic kidneys or pseudoaneurysms have also been reported causes. Renal artery stenosis occurring many years after transplantation most often represents atherosclerotic disease. As the transplant population ages, there has been increasing recognition of another subset of patients with pseudo-transplant RA stenosis, in which atherosclerotic vascular disease proximal to the allograft artery, particularly involving the iliac vessel, results in reduced kidney perfusion.

Patients typically present with new-onset or worsening hypertension with or without kidney dysfunction. An example of the 1-clip–1-kidney Goldblatt model, transplant RA stenosis often presents with fluid retention and even flash pulmonary edema. Often, a two-component RA bruit can be heard over the allograft.

Pseudo-transplant RA stenosis, which is suprarenal iliac artery stenosis, often presents with ipsilateral lower extremity claudication along with hypertension and worsening allograft function. Risk factors for the development of transplant RA stenosis include older donor age and extended criteria donor and recipient male sex, DM, hyperlipidemia, smoking, ischemic heart disease, and elevated serum creatinine at discharge from transplantation.[62]

Renal duplex ultrasound is the initial screening test for transplant RA vascular complications, with the sensitivity and specificity ranging from 90% to 100% and 67% to 100%, respectively, depending on parameters and cut-off values. Compared with native renal arteries, data show that PSVs are often higher at the anastomosis even without stenosis due to the angle at the anastomosis, with 26% of normal transplant RAs having a PSV greater than 250 cm/sec at 9 months posttransplant.[63] Using a combination of a PSV greater than 300 cm/sec, acceleration time of more than 0.1 second, and the presence of poststenotic spectral broadening (indicative of turbulent flow), the probability of stenosis approaches 99%.[64] Magnetic resonance angiography provides excellent anatomic definition of the transplant RA. It may be associated with clip artifact at the anastomosis. Non–contrast-enhanced MRA has emerged as a good option for visualizing the iliac artery and the transplant arteries.[65] Computed tomographic angiography is comparable to renal arteriography but requires more contrast. Carbon dioxide angiography can allow for visualization and successful treatment using as little as 9 mL of iodinated contrast.[66]

Percutaneous renal artery angioplasty with or without stenting is often the initial approach to transplant RA stenosis, with success rates of 90% for technical outcomes and 66% to 94% for clinical outcomes (BP and kidney function improvement) and a complication rate of 9.9% including vessel dissection, thrombosis, and site hematoma.[67] Restenosis rates are higher after primary PTRA (18.9%) versus stenting (9.1%). Long-term outcomes for transplant patients treated for transplant RA stenosis are reported to be equal to those without this complication.[68] Surgical renal revascularization of allografts is difficult and associated with high complication rates. Extensive fibrosis develops around the allograft and often involves the renal vessels, making surgical access to the renal vessels risky. Historically, complications include graft loss (in 15%–30% of cases), ureteral injury (14%), and death (5%). A recent small study of 10 cases requiring surgery for transplant RA stenosis or occlusion reported better patient and long-term graft outcomes.[69]

KIDNEY INFARCTION

Kidney infarction represents a distinct clinical syndrome associated with abrupt loss of blood flow to kidney parenchyma. Small areas of the cortex or medulla or the entire kidney may be affected. Autopsy series suggest the incidence is between 0.5% and 1.5%, with incidences reported from emergency department series at 0.004% to 0.007%, indicating that this diagnosis is often missed.[70] Bilateral renal infarction is reported in up to 20% of cases. The clinical presentation of kidney infarction mimics that of more common disorders, such as kidney stones, pyelonephritis, and muscle strains. A high clinical suspicion is needed to pursue the diagnosis.

Risk factors associated with kidney infarction include preexisting hypertension, cigarette smoking, arrhythmias (especially atrial fibrillation), hyperlipidemia, structural heart disease, prior embolic events, and diabetes.

The most common symptom is loin, flank, or abdominal pain, occurring in over 95% of cases. Transient RVH occurs in about 50% of cases. Nausea and/or vomiting are present in up to 45% of cases. However, nearly 25% of cases are asymptomatic, identified only by enhancement or functional defects on kidney imaging. Laboratory abnormalities include elevated lactate dehydrogenase levels in over 90% of cases, with leukocytosis and elevated inflammatory markers such as C-reactive protein in up to 78% of cases, and may last up to 30 days from presentation. Microhematuria and proteinuria are present in 20% to 60% of cases.[71]

Acute kidney injury frequently accompanies kidney infarction, reported in between 11.1% and 64.7% of cases. When bilateral occlusion of the RAs or infarction of a single functioning kidney occurs, the patient may present with oliguric or anuric AKI. The development of CKD after kidney infarction has been reported in between 6% and 44% of cases.[72]

Computed tomography with intravenous contrast is the imaging modality of choice for the diagnosis of renal infarction. Findings include focal wedge-shaped areas of decreased attenuation or global infarction with or without a rim sign indicating intact collateral circulation. Perinephric stranding is common. Simultaneous infarcts in the liver and spleen occur in 10% to 15% of cases. Other potential imaging techniques include MRA with gadolinium or nuclear scintigraphy with dimercaptosuccinic acid.

Causes of kidney infarction are listed in Box 43.7. Common causes include RA embolism from a cardiac source, arterial injury from dissection, trauma, or complications of endovascular procedures, and hypercoagulable or prothrombotic factors. In approximately 18.4% of cases, no cause is found.[73] In a review of over 186 patients with renal infarction, a RA lesion (atherosclerotic, dissection, hematoma, or FMD) was the cause in over 81.2% of cases, with emboli accounting

BOX 43.7 Causes of Renal Infarction

Renal Artery Thrombosis

Spontaneous

- Renal artery atherosclerosis or fibromuscular dysplasia
- Renal artery or aortic dissection
- Renal or aortic aneurysms

Traumatic

- Postprocedure
- Endovascular stents
- Renal transplantation
- Hypercoagulable disorders
- Malignancy
- Antiphospholipid syndrome
- Renal artery vasculitis
- Vascular rejection
- Thrombotic microangiopathies
- Genetic
- Ehlers-Danlos vascular variant

Renal Embolism

- Atrial fibrillation
- Cardiac mural thrombi
- Valvular heart disease
- Paradoxical embolism
- Tumor or fat embolism
- Atheroemboli

Renal Vein Thrombosis

- Nephrotic syndrome
- Post–kidney transplantation
- Traumatic

for only 9.1%.[74] Spontaneous RA thrombosis or dissection can lead to RA occlusion. Spontaneous RA dissection has a male predominance, with a 4:1 male-to-female ratio and average age of onset in the mid 40s.

Renal infarction secondary to traumatic RA injury occurs in 1% to 4% of all nonpenetrating abdominal trauma associated with deceleration injury and direct blunt trauma to the loin or flank regions. Evidence of lumbar vertebral injury should raise suspicion in the emergency department for renovascular trauma. Traumatic renal vascular occlusion often leads to kidney infarction within 3 to 6 hours. The success rate for revascularization of traumatic RA thrombosis remains low, even when diagnosed early.[75]

Emboli to the right and left RA occur with equal frequency, with 12% of cases being bilateral. Atrial fibrillation, cardiac thrombus after myocardial infarction, atrial myxoma or other cardiac tumors, endocarditis, paradoxical emboli, and aortic thrombus are the most common conditions associated with embolic kidney infarction. Atrial fibrillation is the most common cardiac cause with the highest risk during the first year after the onset and when anticoagulation is subtherapeutic.[76] When echocardiography is performed, cardiac thrombus is rarely detected. There is a 30-day mortality rate of 10% to 13% after renal infarction, due to atrial fibrillation. Other sources of emboli to the kidneys include fiber related to cardiac bypass, gel foam due to embolization procedures, calcium from valve annuli, and even "bullet emboli" in the setting of trauma. Paradoxical RA embolism may occur in patients with right-to-left cardiac shunts, most commonly due to atrial septal defects present in 9% to 35% of the general population. The diagnosis requires clinical, angiographic, or pathologic evidence of systemic embolization and an abnormal communication between the right and left circulations with a favorable pressure gradient (typically diagnosed by "bubble" echocardiography) for the passage of a clot from the right to the left side of the heart. The presence of source of venous thrombus should be sought.

Less common causes of infarction include hypercoagulable states, inflammatory diseases of the retroperitoneum, thrombotic microangiopathies, and RA vasculitis or vasospasm. Antiphospholipid antibody syndrome is associated with both arterial and venous thrombotic events and is the most common cause of spontaneous arterial thrombosis.[77] Rare causes of kidney infarction include autoimmune diseases and drug abuse, such as intravenous injection or nasal insufflation of cocaine or even marijuana smoking. During the COVID-19 pandemic, several reports of kidney infarction due to COVID-19-associated hypercoagulability emerged.[78]

Aortic dissection can compromise renal blood flow and cause kidney infarction. Aortic dissection occurs most commonly in association with atheromatous vascular disease of the thoracic aorta, but it can occur in collagen disorders, such as Ehlers-Danlos type IV or Marfan syndrome, and with arteritis, such as Takayasu arteritis.

Kidney infarction can be a complication of endovascular procedures. Endovascular aortic stents commonly used to treat abdominal aortic aneurysms can compromise flow to main or accessory RA orifices.[79,80] Increasingly, fenestrated or branched covered stent grafts have been designed to allow for preservation of branch visceral vessels. Accessory RAs supplying less than half of the kidney may be intentionally sacrificed during these procedures in up to 25% of cases. When this occurs, up to 75% of patients will experience renal infarction postprocedure. In some reports, this is associated with significant decline in eGFR at 3 years.[81] Furthermore, RA stents are usually placed through fenestrations with a goal of preserving RA flow. Renal artery occlusion can complicate these procedures with development of occlusion or stenosis in up to 30% of cases by 4 years postprocedure. The aortic graft and branch stents alter the natural RA motion during the cardiac cycle, and kinetic forces over time can result in RA stent fracture or kinking, leading to vessel occlusion. Aortic stent graft migration and endoleaks can also impair RA inflow.[82]

Treatment of kidney infarction is usually conservative and includes pain control and treatment of associated RVH. If RA occlusion is caused by thrombosis associated with a hypercoagulable state or an embolism from a central source, systemic anticoagulation is indicated, and consideration should be given to thrombolytic therapy. Anticoagulation for idiopathic renal infarction is controversial. Echocardiography is indicated to seek intracardiac or aortic arch thrombi and valvular abnormalities. Emergent endovascular recanalization of thrombosed stents associated with fenestrated aortic grafts can sometimes be successful in averting global kidney infarction.

ATHEROEMBOLIC KIDNEY DISEASE

Atheroembolic kidney disease describes a subacute kidney injury due to occlusion of small arteries and arterioles by cholesterol emboli. It is estimated to account for up to 10% of unexplained kidney failure in the elderly, with 7% of renal biopsies in a large study of patients with AKI over 60 years of age showing histologic findings of atheroembolism.[83] Atheroembolism may occur in up to 30% of patients with extensive aortic atherosclerosis after endovascular interventions. The incidence of atheroembolism after cardiac catheterization is estimated near 1.4%.[84] Furthermore, studies using filters to capture embolic material confirm that PTRA and PTRS release thousands of atheromatous particles of various sizes in 70% to 100% of cases.[85] Preprocedural treatment with antiplatelet agents and intraprocedural use of embolic protection devices may reduce the burden of embolic atheromata.[86] However, use of distal protection devices can be particularly challenging in the RAs due to shorter length and bifurcations.

Risk factors for atheroembolic disease include older age, male sex, cigarette smoking, diabetes, hypertension, and hyperlipidemia. Atheroembolic disease is iatrogenic in 70% of cases, that is, associated with arterial intervention such as angiography, cardiovascular surgery, thrombolytic therapy, or anticoagulation. Spontaneous aeroembolism may occur in patients with extensive atherosclerosis and unstable plaque.

Acute or subacute reduction in eGFR caused by kidney microinfarctions developing as long as 6 months after the atheroembolic insult is the most common presentation leading to the diagnosis. It is important to differentiate atheroembolic from thromboembolic disease. Atheroembolic particles originate from upstream unstable atherosclerotic plaque and cause downstream partial occlusion of small vessels. The cholesterol cleft induces a foreign body reaction leading to an interstitial inflammatory response and subacute kidney injury.

The clinical picture is multisystemic and involves the kidneys in about 75% of patients. If a large atheroembolic shower induces significant renal tubular damage, the resulting AKI may manifest with an oliguric phase characterized by a high fractional excretion of sodium. More often, the kidney failure is nonoliguric, slowly progressive, often with a stair-stepping subacute course. Some patients will have only moderate impairment in GFR, whereas others progress to kidney failure.[87] Urinalysis findings are nonspecific but may include mild proteinuria, microhematuria, pyuria, and eosinophiluria. Renin release by ischemic zones in areas of embolization can lead to labile hypertension early in the course, sometimes associated with transient marked proteinuria. Fever, often low grade, is characteristic.

Although the kidneys are the organs most commonly involved, extrarenal cholesterol embolization may provide clues to aid in the diagnosis. Eosinophilia and hypocomplementemia commonly occur in the acute phase, reflecting immunologic activation.[88] Cutaneous findings are seen in up to 60% of patients during initial presentation.

Fig. 43.11 Livedo Reticularis. The mottled skin changes associated with peripheral cholesterol embolization may be seen over the legs, buttocks, back, or flank and may be transient.

These findings include blue or purple toes, mottled serpiginous rash (livedo reticularis; Fig. 43.11), petechiae, and purpura or necrotic ulceration in areas of skin embolization, such as the lower back, buttocks, lower abdomen, legs, feet, or digits.

Other organs often involved include the spleen (55% of cases), pancreas (52%), gastrointestinal tract (31%), liver (17%), and brain (14%). Symptoms associated with extrarenal atheroembolic disease include abdominal or muscle pain, nausea, vomiting, ileus, gastrointestinal bleeding, ischemic bowel, hepatitis, angina, Hollenhorst plaques, and visual and neurologic deficits.

Atheroembolic kidney disease should be suspected when subacute kidney failure develops after a vascular intervention in the presence of livedo reticularis. Many laboratory abnormalities indicative of tissue injury are often present, including elevated erythrocyte sedimentation rate (97% of cases), elevated serum amylase (60%), leukocytosis (57%), anemia (46%), hypocomplementemia (especially low C3) (25%–70%), and elevated lactate dehydrogenase and creatine kinase (38%–60%). Peripheral eosinophilia, which may be transient, is seen in up to 57% of patients. The presence of eosinophilia should raise suspicion for atheroembolic renal disease in the appropriate clinical setting. Definitive diagnosis is made by biopsy of an involved organ. A skin or muscle biopsy in an involved area may preclude the need for kidney biopsy. However, tissue biopsy is usually unnecessary when the classical clinical triad is present: precipitating event, subacute kidney injury, and typical skin findings.

If clinical or other pathologic evidence has not secured the diagnosis, kidney biopsy may be helpful. Diagnosis is based on the presence of birefringent, biconvex, elongated cholesterol crystals or biconcave clefts within the lumina of small vessels left behind in formalin-fixed tissue (Fig. 43.12). Due to the patchy nature of this disorder, open-wedge kidney biopsy has a higher likelihood of successful diagnosis relative to a percutaneous approach because it allows visualization and

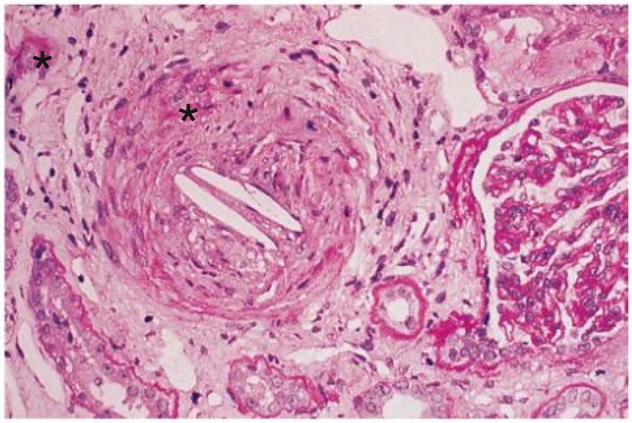

Fig. 43.12 Cholesterol Emboli in Kidney Biopsy Specimen. Biconvex cholesterol clefts with giant cell reaction *(asterisks)* and recanalization of the lumen of a medium-sized renal vessel. (Periodic acid–Schiff stain.) (Courtesy Dr. R. Horn, Vanderbilt University, Nashville, TN.)

direct sampling of areas of mottled cortex. In frozen sections of tissue, the cholesterol material can be identified with polarized light microscopy. The pathologic findings also may include intimal thickening and concentric fibrosis of vessels, giant cell reaction to the cholesterol particles, vascular recanalization, endothelial proliferation, tubulointerstitial fibrosis with both eosinophil and mononuclear cell infiltrates, glomerular ischemia, and even focal segmental glomerulosclerosis. In the kidney, the most commonly affected vessels are the arcuate and interlobular arterioles, leading to patchy ischemic changes distal to these vessels.

Atheroembolic kidney disease mimics other systemic disorders including vasculitis, infection, or thrombotic microangiopathy. Often these patients have undertaken procedures in which the differential diagnosis would include contrast nephropathy, acute tubular necrosis, renal infarction, or renal infarction. Peripheral eosinophilia and, in some cases, eosinophiluria, rash, fever, and reduced eGFR can be seen associated with acute interstitial nephritis. Chronic Cholesterol embolization syndrome may appear similar to hypertensive nephrosclerosis or IRD. In the kidney transplant recipient, kidney atheroembolism may mimic acute rejection or chronic allograft nephropathy.

The natural history is determined by the extent of organ involvement and the degree of the embolization. In one series of cases, eGFR declined rapidly in 29%, with a slower progressive course seen in 61%.[87] Among the latter group, the decline in eGFR was thought to result from a combination of cholesterol embolization and ARVD. Patients also may manifest acute or subacute reductions in eGFR followed by partial recovery. Conversely, the outcome can be dismal, particularly when cerebral embolization occurs or when there is a large unstable atheromatous burden. Some patients with cholesterol embolization may develop kidney failure.[89]

There is no specific therapy for atheroembolic disease; treatment is supportive and focused on secondary prevention. As such, statins, aspirin, BP control, smoking cessation, and glycemic control are helpful measures in the prevention of atherosclerosis.

Prevention remains the most effective management strategy. Patients with extensive aortic atherosclerosis should be considered for alternative approaches to cardiac catheterization, for example, such as through the brachial artery. Once the diagnosis of cholesterol embolization has been established, further endovascular interventions should be avoided. When clinical factors dictate the need for aortic, renal, or peripheral arterial surgery, optimal timing and surgical approach are critical. Conversely, there is a growing surgical experience with segmental aortic replacement to remove the source of emboli, particularly

when atheroembolic disease occurs spontaneously. Transesophageal echocardiography is often used to identify mobile ulcerative plaque in the aorta to guide intervention.

Angiotensin-converting enzyme inhibitors are effective in managing the labile hypertension seen early in the course. Corticosteroids have been used with some success in patients with atheroembolic disease and associated inflammatory symptoms.[90] Several reports note stabilization of skin signs of cholesterol embolization after administration of statins.[91] Because anticoagulation has been associated with atheroembolic disease, it is recommended to avoid anticoagulation in the acute phase. Although direct causality between anticoagulants and cholesterol embolization has not been established, the proposed mechanism is that anticoagulants prevent thrombus organization over the ulcerative plaques.

RENAL VEIN THROMBOSIS

Renal vein thrombosis is rare in adults most often associated with nephrotic syndrome, kidney tumors, hypercoagulable states, and after surgery or trauma to the renal vessels. When it occurs, the diagnosis is often never considered.

Thrombosis of the longer left RV also may involve the ureteral, gonadal, adrenal, and phrenic branches that drain into the left vein, whereas on the right side, the adrenal and gonadal veins drain directly into the inferior vena cava. Because of the larger network of venous complexes, occlusion of the left RV results in enlargement of the systemic collateral vessels, which provides some protection against infarction, which is a rare complication of RV thrombosis on either side.

Experimentally, acute RV thrombosis is associated with immediate enlargement of the kidney, with a marked increase in RV pressure, leading to a significant decrease in renal arterial flow. Complications include hemorrhagic infarction, kidney rupture, and retroperitoneal hemorrhage.

Acute RV thrombosis is usually symptomatic with loin, testicular, or flank pain and even the development of scrotal swelling or hydrocele. The patient may present with fever, leukocytosis, and, in the setting of a single kidney or renal transplant, oliguric AKI. Acute RV thrombosis is associated with renal edema and swelling. Nausea and vomiting often accompany it, and symptoms might be confused with those of acute pyelonephritis. Hematuria is nearly universal and most often is microscopic. The high venous pressures result in a marked increase in proteinuria. Urinalysis sometimes reveals evidence of proximal tubule dysfunction, such as glycosuria. In some patients, RV thrombosis is diagnosed only after the patient has developed an acute pulmonary embolus and the source of the embolus is investigated or with worsening of eGFR in the setting of proteinuric CKD.

Chronic RV thrombosis may be asymptomatic. Extensive venous collaterals may allow for minimal impairment of kidney function and structure. Often, however, microhematuria, proteinuria, and evidence of reduced GFR or tubular dysfunction are present, particularly when indices of differential kidney function are sought, such as with nuclear studies. When RV thrombosis causes renal infarction, the distribution of the hypoperfused region tends to be medullary or subcortical. The hypoperfused areas also tend to be patchy and subtotal. These patients can develop severe hypertension acutely.[92]

The causes of RV thrombosis are listed in Box 43.8.

The prevalence of renal vein thrombosis in nephrotic syndrome is unclear because it is largely undiagnosed; studies report frequencies from 5% to 62%.[93] Numerous abnormalities promoting a prothrombotic state occur secondary to heavy proteinuria. It is interesting to note that RV thrombosis appears to be more common in membranous nephropathy and lupus nephritis but can complicate any cause of proteinuric kidney disease. In this setting, RV thrombosis can lead to an increase in baseline proteinuria and present with AKI superimposed on CKD.

Pregnancy and the postpartum state are hypercoagulable states. There have been reports of spontaneous RV thrombosis in the postpartum period associated with kidney infarction. Renal vein thrombosis

BOX 43.8 Causes of Renal Vein (RV) Thrombosis

- Malignant neoplasia
  - Direct invasion of tumor into the RV
  - Retroperitoneal adenopathy, fibrosis, or tumor compressing the RV
  - Extension of IVC obstruction by tumor invasion
  - Hypercoagulable state associated with malignant disease
- Complication of IVC filters
- Complication of PICC lines
- Nephrotic syndrome
  - Membranous nephropathy
  - Lupus nephritis
- Acute pyelonephritis
- Complicating inflammatory bowel disease
- Acute pancreatitis
- Inflammatory aortic aneurysm
- Neonatal
  - Congenital
  - Dehydration
  - Thrombophilia
  - Complication of umbilical vein catheterization
  - Transmission of maternal procoagulant factors
- Hypercoagulable states
  - Antiphospholipid antibody syndrome
  - Factor V Leiden mutation
  - Antithrombin III deficiency
  - Protein S and C abnormalities
  - Hyperhomocysteinemia
  - Elevated levels of clotting factors VIII, IX, and XI
  - Heparin-induced thrombocytopenia
  - Birth control pill
- Thrombophilia
- Chuvash polycythemia
- Post–renal transplantation
  - Acute rejection, OKT3
  - Vascular rejection
  - Compression or kinking of RV
  - Hypercoagulable disorders
  - Sticky platelet syndrome
  - Calcineurin inhibitors
  - Viral infection of the allograft
- Complication of surgical compression
  - After aortic aneurysm surgery
  - After pyeloplasty
  - After partial nephrectomy
- Traumatic RV thrombosis
- Pregnancy
  - Compression
  - Preeclampsia, eclampsia
- Complication of embolization of gastric varices
- Budd-Chiari syndrome
- Behçet disease

IVC, Inferior vena cava; *PICC,* peripherally inserted central catheter.

complicating pregnancy should be suspected when clinical clues such as flank pain, proteinuria, and hematuria are present.

Malignancy accounts for the greatest number of cases of RV thrombosis.[94] It can result from invasion of a kidney tumor into the RV. About half of renal cell carcinomas are associated with RV thrombosis at autopsy. In addition, neoplasia originating in the RV or inferior vena cava (IVC), such as leiomyosarcoma or cavernous hemangioma, can cause RV thrombosis. Extrinsic compression of the RV by a tumor or retroperitoneal fibrosis also may cause this syndrome.

Diagnosis of RV thrombosis requires imaging. Conventional ultrasound may demonstrate alterations in size and echogenicity. Sonographic findings include kidney enlargement, loss of corticomedullary differentiation, and linear echogenicity radiating from the renal hilum as a result of interlobular and interlobar venous clot. Later scans may show linear, punctuate, or lace-like calcifications in these regions, representing calcified thrombi. Renal duplex ultrasound may show increases in resistive indices and can directly visualize the filling defect. In patients with renal transplant vein thrombosis, the duplex waveform pattern demonstrates reversal of diastolic flow.[95] Imaging of the RV by magnetic resonance or computed tomographic (CT) venography is needed to confirm thrombosis. In adults, these modalities have much greater sensitivity than RV duplex studies for the diagnosis. Fig. 43.13 is a CT venogram demonstrating unilateral RV thrombosis.

Treatment is controversial and depends on the setting, acuteness, and clinical consequences. If there is no contraindication, most patients are treated acutely with systemic anticoagulation. In adults with acute RV thrombosis that is compromising renal function, catheter-directed thrombolytic therapy with urokinase or tissue plasminogen activator with or without percutaneous mechanical thrombectomy can restore vessel patency.[96] The long-term benefit of this approach is unclear, and it is less successful when the thrombotic process begins in the small intrarenal venules rather than in the major veins, as is often the case when primary kidney disease or a hypercoagulable state initiates the process.

Surgical interventions include nephrectomy, thrombectomy, and retroperitoneal surgery for non–renal-associated abnormalities, such as tumor, retroperitoneal fibrosis, aortic aneurysm, and acute pancreatitis. Surgery tends to be reserved for situations in which the RV thrombosis results in hemorrhage from renal capsular rupture or for long-term consequences, such as hypertension or infection of a nonfunctioning kidney.

Fig. 43.13 Computed tomography venogram demonstrating left renal vein thrombosis *(arrow).* (Courtesy Dr. S. Rankin, Guy's Hospital, London.)

A conservative approach may be favored when left RV thrombosis occurs because of the extensive collateral venous supply on that side, ultimately allowing venous drainage and delayed improvement in renal function. Systemic anticoagulation is indicated acutely to prevent extension of thrombus into the IVC and pulmonary emboli. Anticoagulation should be continued indefinitely in patients with a persistent hypercoagulable state.

Long-term kidney-related outcomes following RV thrombosis vary with the cause of thrombosis. When associated with membranous nephropathy, it has a more favorable outcome than with other causes. Normal kidney function prior to RV thrombosis is the most important prognostic factor.[97]

SELF-ASSESSMENT QUESTIONS

1. A 33-year-old White woman presents with hypertension that was noted during a regular gynecologic check-up. During examination, you note she has equal BP in both arms, no radial-femoral delay, and a soft abdominal bruit. Which is the most appropriate screening test for the cause of her hypertension?
   A. RA duplex ultrasound
   B. CTA of renal arteries
   C. MRA of renal arteries
2. A 76-year-old woman presents to you because her primary care doctor has had difficulty getting her BP controlled. She states she never had hypertension until about 4 years ago. She has a history of smoking one pack per day of cigarettes for 40 years. She had a femoral-popliteal bypass 2 years ago for claudication. Examination is notable for systolic BP of 180 mm Hg. She has a left carotid bruit audible. Her creatinine is 1.3 mg/dL and potassium is 3.4 mg/dL. A renal duplex ultrasound shows normal velocities in the left RA but a peak systolic velocity of 350 cm/sec in the proximal portion of the right RA. She is on the following antihypertensive medications: metoprolol 50 mg twice daily, amlodipine 5 mg/day, hydrochlorothiazide 25 mg/day, and atorvastatin 80 mg/day, and she is taking aspirin. What is the most appropriate next action?
   A. Refer for RA stent
   B. Start ACE inhibitor and follow BP response and potassium and creatinine closely
   C. Refer to vascular surgery for RA bypass
3. A 32-year-old woman with lupus nephritis class V is currently being treated with induction therapy with mycophenolate mofetil 1500 mg twice daily and oral steroids. She continues to have proteinuria, and her last 24-hour quantitative protein concentration was 6 g. Fortunately, her creatinine has remained normal at 0.8 mg/dL. She presents to the emergency department with pleuritic chest pain. A ventilation/perfusion scan shows high probability for pulmonary embolism. On examination, you note that her creatinine is 1.4 and urine protein/creatinine is 30 g/g. She is started on anticoagulation therapy and admitted. Which of the following tests would you recommend the team order?
   A. Antiphospholipid antibody
   B. Renal vein Doppler study and renal ultrasound
   C. CTA of pulmonary arteries
   D. Both A and B
4. An 83-year-old woman presents with congestive heart failure and hypertension. She has a history of peripheral vascular disease and chronic kidney disease with a baseline creatinine of 1.5 mg/dL and

a single kidney because she donated one to her son with diabetic nephropathy 30 years earlier. She is admitted and treated with diuretics and achieves a net negative fluid balance of 6 L over 3 days. Her BP, which was 180/90 mm Hg on admission, is now 120/80 mm Hg. An echocardiogram shows left ventricular hypertrophy with diastolic dysfunction, preserved ejection fraction, and no valvular abnormalities. Over the past 24 hours, her creatinine has risen to 3.8, and she has produced almost no urine. She has no flank pain. Despite stopping her diuretics, her creatinine does not improve over the next 72 hours, and she is oliguric. She appears euvolemic and does not respond to empiric intravenous fluids for 24 hours. Her medications are reviewed, and she is receiving no nephrotoxic agents and all diuretics and antihypertensives are on hold. An ultrasound and Doppler examination show a blunted waveform concerning for possible critical RA stenosis. What test would be best to rule out critical RA stenosis?

A. MRA of RAs
B. CTA of RAs
C. Captopril renography
D. Peripheral renin level

5. A 62-year-old man with a history of hypertension presents with acute left-sided abdominal pain with no dysuria. Urinalysis shows hematuria without pyuria. He has a temperature of 99.8°F and a white blood cell count of 12,000. He is in new-onset atrial fibrillation. His creatinine is noted to be 1.3, which is above his recent normal level of 0.9 mg/dL 1 month previously. The kidneys appear normal on abdominal ultrasound. Which of the following tests is most likely to provide a diagnosis?

A. Echocardiogram
B. RA duplex ultrasound
C. CT with and without contrast

6. A 60-year-old White man with a history of hypertension and diabetes undergoes cardiac angiography with stent placement after presenting to the emergency department with symptoms consistent with unstable angina. Two weeks later, he is noted to have a rise in serum creatinine from a baseline of 0.8 to 1.3. Along with this rise, he is noted to have a slight increase in eosinophils on his complete blood count. On examination the patient is noted to have a serpiginous rash on the bilateral lower extremities to the level of the ankles. Which of the following is the likely cause for the acute kidney injury?

A. Cholesterol emboli
B. Contrast-induced nephropathy
C. Acute interstitial nephritis

Kidney Physiology and Complications in Normal Pregnancy

Kate Wiles, Mark A. Brown

KIDNEY PHYSIOLOGY IN NORMAL PREGNANCY

Kidney physiology changes significantly in pregnancy. Marked volume expansion and vasodilation result in alterations in systemic and renal hemodynamics and kidney volume, with physiologic urinary tract dilation being common (Fig. 44.1A). Renal plasma flow (RPF) increases by up to 80% and glomerular filtration rate (GFR) by 50%.[1] Kidney tubular function responds to these changes with alterations in water and electrolyte handling, leading to clinical changes including lower serum osmolality, gestational hyponatremia, and increased urinary glucose and protein excretion (Table 44.1).

ANATOMY

In pregnancy, there is progressive dilation of the renal pelvis, calyces, and ureters. These changes are thought to be due to a reduction in smooth muscle tone and peristalsis mediated by progesterone, in conjunction with mechanical compression of the ureters by the gravid uterus. Dilation of the ureters is estimated to occur in up to 80% of pregnancies and is more prominent on the right side due to dextrorotation of the uterus by the sigmoid colon and kinking of the ureter as it crosses the right iliac artery.[2] Ureteric dilation of up to 20 mm on the right and 8 mm on the left is consistent with the altered physiology and anatomy of pregnancy[3] (see Fig. 44.1). Distinction between gestational dilation and pathologic hydronephrosis can be challenging. A dilated ureter distal to the pelvic brim, abnormal resistive indices in the kidney, and an absence of ureteric jets in the supine position are suggestive of obstructive pathology.[4] The dilated collecting system can hold 200 to 300 mL of urine, promoting urinary stasis and increasing the risk for clinical infection in women with asymptomatic bacteriuria (ASB).

HEMODYNAMIC CHANGES

Systemic

Plasma volume increases until 32 to 34 weeks' gestation by as much as 1.25 L (Fig. 44.2). Despite an increase in red blood cells (RBCs), there is a disproportional increase in plasma, causing a physiologic anemia of normal pregnancy.[5] Cardiac output increases by 40% to 50% secondary to increased heart rate, stroke volume, and venous return.[6] Despite this, systemic blood pressure (BP) decreases as a result of reduced systemic vascular resistance (SVR) thought to be mediated by vasodilatory factors, including progesterone, relaxin, and nitric oxide (NO).

Kidney

Systemic vasodilation, increased arterial compliance and decreased vascular resistance, and increased cardiac output result in increased kidney perfusion and glomerular filtration measurable at as early as 4 weeks' gestation, peaking at 40% to 50% above prepregnancy values by the second trimester.[7] These changes result in decreased serum creatinine concentrations in pregnancy (Table 44.2). Systematic review data show that serum creatinine in pregnancy falls to 86% or less of the nonpregnant upper reference limit. This means that where the nonpregnant reference interval is 0.51 to 1.02 mg/dL (45–90 μmol/L), a serum creatinine of more than 0.87 mg/dL (>77 μmol/L) should be considered outside the normal range for pregnancy and prompt investigation for either acute kidney injury (AKI) or chronic kidney disease (CKD).[8,8a]

Mechanisms of Increased Glomerular Filtration Rate

The exact mechanisms behind increased GFR in pregnancy are incompletely understood. GFR is calculated as:

$$GFR = (\Delta P - \pi_{GC}) \times Kf$$

where ΔP is the net hydraulic pressure in the glomerulus, π_{GC} is the oncotic pressure in the glomerulus, and *Kf* is the glomerular ultrafiltration coefficient. As a result of plasma volume expansion, π_{GC} is decreased in pregnancy, contributing to the rise in GFR. Changes in hydraulic permeability and the surface area for filtration may cause minor changes in *Kf*. Despite increased RPF, there is no overall change in glomerular pressure because dilation of the pre- and postglomerular resistance vessels are equal.

Measuring Glomerular Filtration Rate

True GFR measurement in pregnancy has historically been achieved using inulin or creatinine clearance methods. Estimation of GFR in pregnancy is challenging because the Modification of Diet in Renal Disease (MDRD) and Chronic Kidney Disease Epidemiology Collaboration (CKD-EPI) formulas significantly underestimate true GFR in pregnancy. Similarly, cystatin C concentrations do not correlate with other measures of GFR in pregnancy.[9] The absence of large-scale

Fig. 44.1 Hydronephrosis in Pregnancy. Intravenous urogram (IVU) at 36 weeks' gestation. Note bilateral hydronephrosis, more marked on the right side. In contemporary clinical practice, ultrasound is the first-line imaging modality in pregnancy, with a possible role for magnetic resonance imaging or limited IVU.

TABLE 44.1 Changes in the Mean Value of Some Common Indices During Pregnancy

	Nonpregnant	Pregnant
Hemoglobin (g/L)	135	>105
Hematocrit (%)	40	34
Serum sodium (mmol/L)	140	135
Serum creatinine, mg/dL (mmol/L)	0.76 (67)	0.59–0.63 (52–56)[a]
Serum osmolality (mOsm/kg)	285	270
Blood urea nitrogen (mg/dL)	12.7	9.0
Serum urea (mmol/L)	4.5	3.2
Serum uric acid, mg/dL (μmol/L)	4.0 (240)	3.2–4.3 (190–260)
Serum albumin (g/L)	40	30
pH	7.40	7.44
Arterial P_{O_2}, mm Hg (kPa)	100 (13.3)	112 (15.0)
Arterial P_{CO_2}, mm Hg (kPa)	40 (5.3)	26 (3.5)
Serum bicarbonate (mmol/L)	25	20
Systolic BP (mm Hg)	115	113–121[b]
Diastolic BP (mm Hg)	70	69–78[b]

[a]Data from Ogueh O, Brookes C, Johnson MR. A longitudinal study of the maternal cardiovascular adaptation to spontaneous and assisted conception pregnancies. *Hypertens Pregnancy*. 2009;28(3):273–289.

BP, Blood pressure.

normative data for eGFR in pregnancy by any formulas means that it cannot be used as a measure of kidney function in pregnancy, despite ubiquitous use outside of pregnancy.[10] Serum creatinine concentrations therefore remain the only current method for the clinical assessment of kidney function during pregnancy.

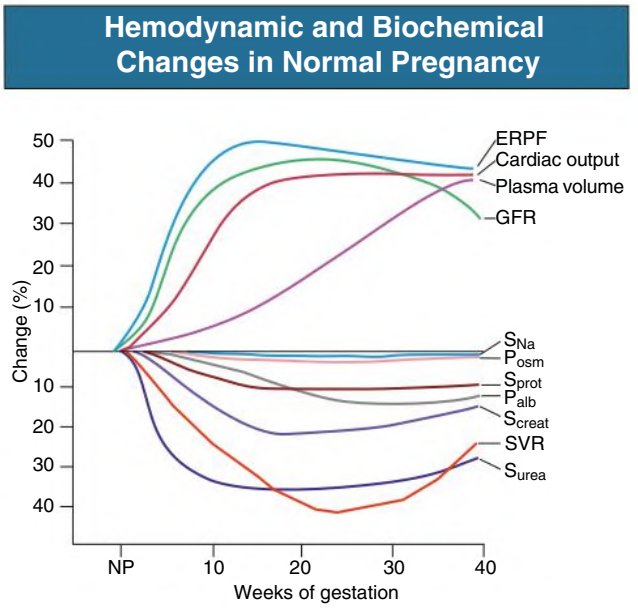

Fig. 44.2 Hemodynamic Alterations Induced by Normal Pregnancy. Increments and decrements in hemodynamic and biochemical parameters shown as percentage of change from nonpregnant baseline. *ERPF,* Effective renal plasma flow; *GFR,* glomerular filtration rate; *NP,* nonpregnant state; *Palb,* plasma albumin concentration; *Posm,* plasma osmolality; *S,* serum; *SVR,* systemic vascular resistance.

Renin-Angiotensin-Aldosterone System

In early gestation, vasodilation and decreased systemic vascular resistance activate the renin-angiotensin-aldosterone system to increase circulating concentrations of renin and angiotensin II. This mediates an aldosterone-dependent increase in plasma volume, thought to be essential for adequate uteroplacental blood flow. Maternal BP, however, does not increase, perhaps due to reduced responsiveness to the pressor effect of angiotensin II through altered sensitivity of arterial smooth muscle and downregulation of angiotensin receptors. Angiotensin,[1–7] which counterregulates angiotensin II and has vasodilatory and antihypertensive properties, is elevated in pregnancy and may contribute to vasodilation. Relaxin is a key mediator for enhanced nitric oxide signaling in pregnancy[11] and probably contributes to the vasodilated state of normal pregnancy. Relaxin is produced in the corpus luteum and the placenta in early gestation, leading to a peak in concentration at 6 weeks' gestation, returning to nonpregnant levels at 6 weeks postpartum. However, other mechanisms, possibly progesterone and nitric oxide, also have a role. This is evidenced by physiologic adaptation to early pregnancy after assisted conception, in which the corpus luteum is absent and relaxin is not detected.[12]

Sodium Handling and Osmoregulation

In early gestation, serum osmolality decreases by approximately 10 mOsm/kg to a new set point of about 270 mOsm/kg, with a reduction in serum sodium (see Table 44.1).[1] In pregnancy the physiologic vasopressin (AVP) release mechanisms of thirst are reset to recognize this new set point in osmolality, with β-human chorionic gonadotrophin (β-hCG) and relaxin hypothesized to play a role in this resetting. The gestational decrease in serum sodium concentration is thought to be secondary to systemic vasodilation, arterial underfilling, and subsequent release of AVP.[13] Although the natriuretic effects of increased GFR and elevated progesterone promote sodium excretion, this is balanced by increased aldosterone and angiotensin II directly increasing sodium reabsorption, increased deoxycorticosterone promoting

TABLE 44.2 Expected Normal Serum Creatinine Values According–Gestational Week: Derived From 244,866 in Pregnant Women With Uncomplicated Pregnancies

	SERUM CREATININE MG/DL (μMOL/L)		
Gestational Week	50th Percentile	75th Percentile	95th Percentile

TABLE 44.3 Antinatriuretic and Natriuretic Factors Influencing Sodium Excretion During Pregnancy

Antinatriuretic	Natriuretic
Aldosterone	Increased glomerular filtration rate
Angiotensin II	Progesterone
Estrogen	Atrial natriuretic peptide
Deoxycorticosterone	Nitric oxide
Epithelial sodium channel	Prostaglandins
Supine posture	
Upright posture	
Decreased blood pressure	
Increased urethral pressure	
Placental shunting	

sodium retention, and upregulation of the epithelial sodium channel (ENaC).[14] Although there is a gradual gain in total body sodium during pregnancy of about 900 to 1000 mmol, there is greater water gain (Table 44.3).

Potassium

Despite increased aldosterone and mild alkalosis in pregnancy, hypokalemia does not occur, and typical serum potassium concentrations in pregnancy are at the lower limit of the nonpregnant reference range. This may be partly due to the antimineralocorticoid effect of progesterone, as well as the capacity of progesterone to inhibit potassium excretion independent of antimineralocorticoid effects.

Uric Acid

Serum uric acid concentrations fall early in pregnancy before a return toward nonpregnant concentrations during late gestation (see Table 44.1). By 37 weeks' gestation, serum uric acid can reach nonpregnant levels. Gestational changes in the handling of uric acid by the kidney include increased clearance secondary to gestational hyperfiltration in conjunction with reduced fractional reabsorption. Other factors include dietary intake of purines and maternal and fetoplacental metabolism of purines; gastrointestinal excretion may also contribute.

Acid-Base

In pregnancy there is typically a chronic mild respiratory alkalosis secondary to an increase in tidal volume that lowers arterial carbon dioxide tension. Increased minute ventilation probably results from direct stimulation of the respiratory centers by progesterone and occurs without a change in respiratory rate.[15]

Urine Protein

There is a rise in urine protein excretion in normal pregnancy. The mechanisms and clinical implications of proteinuria in pregnancy are discussed later.

Glucose

Glycosuria in pregnancy occurs secondary to increased glucose filtration coupled with decreased tubular reabsorption. Once the filtered load of glucose has reached the maximum resorptive capacity of the proximal tubule, there is physiologic glycosuria, which can occur with normal plasma glucose concentrations.

Calcium

There is increased urinary excretion of calcium but also of magnesium, citrate, acidic glycoproteins, and nephrocalcin, which help prevent calcium stone formation associated with supersaturation.

KIDNEY DISEASE IN PREGNANCY

Urinary tract infection (UTI) is common in pregnancy. The most common causes of kidney injury in late pregnancy are preeclampsia and postpartum hemorrhage.

URINALYSIS AND MICROSCOPY

Many young women have urinalysis and urine microscopy performed for the first time during pregnancy, leading to the detection of hematuria, proteinuria, and pyuria either related to or coincidental to pregnancy.

Hematuria

Definition and Epidemiology

Nonvisible dipstick hematuria (microhematuria) is detected during pregnancy in about 20% of women[16] and in isolation, rarely signifies a disorder likely to influence pregnancy outcome. Clinically significant nonvisible hematuria is defined as three or more RBCs per high-power field on microscopic evaluation of two of three properly collected (clean catch, midstream) urine specimens,[17] or more than 2500 RBCs/mL. Nonvisible hematuria disappears in the majority of women after delivery, but if it is secondary to glomerular disease, it will persist, warranting further investigation.

Etiology and Outcome

Assessment of urinary RBC morphology differentiates dysmorphic red cells from isomorphic red cells. Outside of pregnancy, this may be used to help distinguish glomerular from nonglomerular sources of blood. However, dysmorphic red cells have been detected in women with severe preeclampsia in the absence of underlying glomerulonephritis.[18] In pregnancy, isomorphic hematuria is most likely to be caused by urinary tract infection. Isolated nonvisible hematuria (i.e., without proteinuria and with normal kidney function) has no adverse effect on pregnancy outcome with no measurable difference in gestational age at delivery, birth weight, gestational hypertension, or preeclampsia compared to pregnancies without nonvisible hematuria.[19]

Visible hematuria (macrohematuria) in pregnancy is most often the result of vaginal bleeding or hemorrhagic cystitis. Less common

causes include renal calculi, renal arteriovenous malformations, renal vein thrombosis, polycystic kidneys, and rarely bladder or kidney neoplasms.

Differential Diagnosis

When nonvisible hematuria is found, a urine culture is required to exclude infection. If there is no proteinuria, and BP and serum creatinine values are normal, further investigations can be delayed until 3 months postpartum, when serologic tests and kidney ultrasound can be performed if hematuria persists. When there are significant numbers of dysmorphic urinary RBCs in pregnancy that persist postpartum, the most likely glomerular pathologies are thin basement membrane nephropathy, immunoglobulin A nephropathy, or lupus nephritis.

Treatment

There is no specific treatment for glomerular disease during pregnancy if kidney function and BP are normal, proteinuria is not clinically significant (see "Proteinuria" below), and lupus is excluded. Renin-angiotensin blockade is contraindicated in pregnancy due to fetal toxicity in the second and third trimesters. The treatment of UTI and calculi are discussed later.

Proteinuria

There is a physiologic increase in proteinuria in pregnancy due to increased permeability of the glomerular barrier in conjunction with impaired protein resorption in the proximal tubule. The established upper limit for normal protein excretion in pregnancy is based on data from small cohorts and expert opinion rather than an association with adverse pregnancy outcomes. The largest study of protein excretion measured by 24-hour urine collection included 270 women with mean protein excretion of 117 mg/day and an upper confidence interval limit of 259 mg/24 h.[20] This was extrapolated to produce the now established reference limit for pregnancy of 300 mg/24 h, compared with 150 mg/24 h outside of pregnancy. The increase is greater in twin pregnancy. The gestational increase in proteinuria can continue into the postpartum period and may take many months to resolve.[21]

Assessment

Proteinuria is most frequently detected in pregnancy by dipstick urinalysis, but this method is notoriously unreliable, with a significant proportion of false-positive and false-negative results.[22] Inaccuracy generally occurs due to the variable osmolality of a random urine specimen. Coexisting hematuria, alkaline urine (pH >7.0), and additives in the urine collection container also contribute to false positive tests. False-negative results may occur with acidic urine, low specific gravity (<1.001), and high salt concentration. In clinical practice, a dipstick result is sufficiently sensitive for the absence of significant proteinuria when testing is negative and for the detection of pathologic proteinuria when dipstick readings are 3+ (>3 g/L) or more. At intermediate levels, false-positive rates are as high as 71%. Detection is improved using an automated urinalysis device, thereby reducing observer error.[23]

Timed urine collections over 24 hours are limited by underestimation,[24] variability,[25] and the potential for treatment delay. Consequently, they have been superseded in clinical practice by spot quantification using a ratio of urinary protein or albumin to creatinine (uPCR or uACR, respectively).

Differential Diagnosis

Proteinuria quantified as uPCR greater than 30 mg/mmol (0.30 mg/mg, 300 mg/g) and uACR greater than 8 mg/mmol have high sensitivity and specificity for the detection of clinically significant proteinuria in pregnancy.[26] If detected before 20 weeks' gestation, preexisting kidney disease should be considered. Glomerular disease may present for the first time in pregnancy, or pregnancy may unmask kidney disease secondary to systemic disorders such as diabetes mellitus, systemic lupus, or chronic hypertension. The course of pregnancy in women with prepregnancy proteinuria is discussed in Chapter 45.

Gestational proteinuria is isolated, de novo proteinuria in pregnancy, without features of preeclampsia. Thus, the diagnosis can only be made in retrospect after completion of pregnancy. The significance of this is not known. In the absence of CKD, it is not thought to be associated with adverse effects for fetus or mother,[27] though surveillance is warranted for the development of preeclampsia.

Though proteinuria is no longer mandatory for the diagnosis of preeclampsia where other clinical features exist, when preeclampsia does cause proteinuria, it arises after 20 weeks' gestation and requires simultaneous de novo BP higher than 140/90 mm Hg.[28] Once above the diagnostic threshold for preeclampsia, the level of proteinuria has not been consistently associated with adverse pregnancy outcomes and repeat quantification is not recommended,[28,29] as it does not guide management.

We limit investigation of isolated, normotensive, nonnephrotic-range proteinuria during pregnancy to measurement of serum creatinine, electrolyte, and albumin concentrations; antinuclear antibody (ANA) titers; and an ultrasound to confirm normal renal tract morphology. A kidney biopsy is not indicated unless it will change management. In many cases appropriate investigations can be delayed until the postpartum period. However, kidney biopsy may be indicated in the first and early second trimester, when the bleeding risks of biopsy are lower[30] and where a histologic diagnosis will determine appropriate treatment during pregnancy, for example, the immunosuppressive management of nephrotic syndromes and lupus nephritis.

Treatment

Nephrotic syndrome due to primary kidney disease (and not preeclampsia) is associated with adverse maternal and fetal outcomes including preeclampsia, AKI, infection, preterm delivery, intrauterine growth restriction, and fetal loss.[31,32] Angiotensin-converting enzyme (ACE) inhibitors and angiotensin receptor blockers are contraindicated in the second and third trimesters of pregnancy due to toxic effects on the fetal kidney leading to anuria, oligohydramnios, fetal limb contractures, craniofacial deformities, and pulmonary hypoplasia. Diuretics are prescribed and sodium restriction is implemented for severe, intractable maternal edema including pulmonary complications, as in these settings the clinical benefit outweighs the theoretical concern of reduced plasma volume and uteroplacental perfusion. There is no established role for the use of intravenous (IV) albumin in managing nephrotic syndrome during pregnancy.

Nephrotic syndrome is a significant risk factor for venous thromboembolism. However, there is no consensus on the definition of nephrotic syndrome in pregnancy, which is complicated by gestational changes in protein excretion and serum albumin concentrations, and physiologic peripheral edema. There is expert consensus that nephrotic range proteinuria (uPCR >300 mg/mmol or uACR >250 mg/mmol) accompanied by low serum albumin warrants thromboprophylaxis with low-molecular-weight heparin (in the absence of contraindications or anticipated delivery within 12 hours) in pregnancy and the immediate postpartum period, with risk reassessed at 6 weeks postpartum. There is also consensus, but insufficient evidence, that subnephrotic levels of proteinuria confer an increased risk of thrombosis. Nonnephrotic range proteinuria (uPCR >100 mg/mmol or uACR >30 mg/mmol) is therefore considered a risk factor for thrombosis, and prophylactic use of low-molecular-weight heparin should be considered when there are additional risk factors for thromboembolism.[33]

URINARY TRACT INFECTION

Definitions

Bacteriuria is the detection of a clinically significant quantitative count of bacteria in the urine, defined as more than 10^5 organisms per milliliter. If this phenomenon exists without symptoms, it is defined as asymptomatic bacteriuria (ASB). Cystitis defines infection in the presence of lower urinary tract symptoms such as frequency, dysuria, and strangury. Although more than 10^5 organisms/mL defines ASB, as few as 10^2 organisms/mL may be sufficient to diagnose cystitis if accompanied by pyuria and characteristic symptoms. In *acute pyelonephritis* there are generally more than 10^5 organisms/mL in the urine, in association with parenchymal bacterial infiltration causing upper urinary tract symptoms. Pyelonephritis is usually diagnosed clinically by fever and loin pain and may progress to systemic sepsis.

Epidemiology

ASB is estimated to affect 2% to 9% of all pregnant women. The prevalence is higher in women from lower socioeconomic groups and increases with age, parity, and coexistent genital tract infection. ASB is also more common in women with urinary tract abnormalities including reflux nephropathy and neurogenic bladder, in diabetic patients, and in women with previous UTIs. Between 1% and 2% of pregnancies are complicated by acute bacterial cystitis. The overall incidence of acute pyelonephritis in pregnancy is approximately 1%. Pyelonephritis is more common in pregnant women with urologic abnormalities or diabetes and more often affects the right kidney, probably because physiologic dilation of the ureter is greater on the right. It is thought that about 70% of women who develop acute pyelonephritis have preceding covert bacteriuria, but this is difficult to prove. Pyelonephritis is estimated to occur in up to 30% of women with ASB. When ASB is treated, the incidence of pyelonephritis in pregnancy is estimated to be reduced by more than 80%.

Pathogenesis

Certain host characteristics may increase the risk for UTI or pyelonephritis (see Chapter 53). Women, such as those who do not express the antibody to the O antigen of *Escherichia coli,* may be chronically colonized and have ASB that predates pregnancy. Pregnancy is a state of relative urinary tract stasis; the calyces, pelvices, and ureters dilate, particularly on the right, and this contributes to the risk of ASB developing into ascending acute pyelonephritis. The most common mechanism of infection is through the urethra from perineal bacteria. Box 44.1 lists common organisms causing UTI in pregnancy. Some strains of *E. coli* are particularly virulent and are associated with both ASB and pyelonephritis. They possess fimbriae, which enable the bacteria to attach themselves to the uroepithelial cells with pili, allowing them to ascend the urinary tract from the perineum. Infection with multiresistant organisms is increasingly common.

BOX 44.1 Organisms Typically Causing Urinary Tract Infection in Pregnancy

- *Escherichia coli* (>70% of infections)
- *Klebsiella* spp.
- *Proteus* spp. (particularly in diabetic women or urinary tract obstruction)
- Enterococci
- Staphylococci, especially *Staphylococcus saprophyticus*
- *Pseudomonas*

Clinical Manifestations

Most maternity units operate a policy of screening all pregnant women at least once for ASB, either by dipstick urinalysis or by urine culture. Because isolated pyuria on dipstick testing is very common in normal pregnancy due to contamination from vaginal secretions, primary urine culture is recommended over dipstick testing.

Pyelonephritis most commonly presents between 20 and 28 weeks' gestation. Not all women will describe preceding lower urinary tract symptoms. Pyelonephritis can present in pregnancy as acute abdominal pain and may be associated with preterm labor, which is hypothesized to be triggered by proinflammatory cytokines secreted in response to bacterial endotoxins. The diagnosis of pyelonephritis is usually made on clinical grounds. Definitive diagnosis requires positive urine culture, but treatment should not be delayed while this is awaited. *E. coli* is the most common infecting organism (>85% of cultures). Bacteremia is a common and usually transient complication of pyelonephritis, although sepsis can develop with sequelae including AKI, disseminated intravascular coagulation, and respiratory distress. Pyonephrosis and perinephric abscess are rare complications but should be suspected in women who do not show a clinical response to treatment. In the pre-antibiotic era, maternal mortality was 3% to 4%; death from pyelonephritis is now rare in high-income countries.

Treatment

Asymptomatic Bacteriuria

A Cochrane systematic review has indicated that treatment of ASB during pregnancy may reduce the incidence of pyelonephritis, low birth weight (<2500 g), and preterm delivery,[34] though confidence in the effect is limited given the low certainty of the evidence. Most available studies are historical with low methodological quality and do not necessarily reflect contemporary advances in diagnosis and treatment and accessibility to medical services. A more recent study randomized 85 women with ASB (out of 4283 screened) to treatment with either nitrofurantoin 100 mg twice daily for 5 days or placebo. This trial showed no association between ASB and preterm birth. Although there was an increased rate of pyelonephritis with untreated ASB compared with antibiotic use, the absolute risk of pyelonephritis in untreated ASB was low (2.4%). Although such findings question a universal screen-treat policy for ASB in pregnancy, there is consensus in high-income countries that more data are required before this routine and long-standing strategy is reconsidered.

There is no clear evidence that any particular antibiotic or dosage regimen is superior for treatment of ASB in pregnancy. In choosing treatment, the clinician must consider urine culture and susceptibility results, previous antibiotic use, and safety data for pregnancy. In most women, amoxicillin or cephalexin is first-line therapy. Nitrofurantoin is not teratogenic, though it is used with caution close to term or anticipated delivery because of a rare risk of neonatal hemolysis. Trimethoprim can be used in pregnancy but should be avoided in established folate deficiency, low dietary folate intake, and in women taking other folate antagonists. Many clinicians avoid trimethoprim in the first trimester because of its antifolate effects. There is insufficient evidence to compare the effectiveness of a single dose compared with longer treatment duration, or a 3-day with a 7-day course of treatment, and a 7-day treatment regimen is therefore usually recommended. A urine culture should be performed after completion of antibiotic treatment to check for eradication.

Without treatment, ASB will persist in 80% of women, and even with treatment, 20% will have persistent bacteriuria. Those with persistent colonization are difficult to treat, with eradication achieved in only 40% after a second course of antibiotics. Where eradication is not achieved, prophylactic antibiotics may be considered throughout

pregnancy to prevent pyelonephritis and its consequences; however, no studies specifically address this situation.

Cystitis

Cystitis is managed in the same way as ASB with a follow-up urine culture to confirm eradication of infection.

Pyelonephritis

It is usual practice to admit pregnant women with pyelonephritis to hospital, although successful outpatient management for milder cases has been reported.[35] Initial treatment with a broad-spectrum antibiotic is recommended with review according to clinical response and culture results. Prophylactic antibiotics are then recommended until delivery to prevent recurrence and the risk of preterm labor. Periodic urine culture can be considered to monitor for antibiotic resistance. Kidney ultrasound may be performed to ensure normal renal tract anatomy and is indicated in those not responding to antibiotic treatment. If pyelonephritis persists despite adequate antibiotic therapy and pathologic urinary tract dilation is confirmed, percutaneous nephrostomy under ultrasound guidance may be indicated to definitively manage an infected, obstructed renal tract.

KIDNEY STONES

Epidemiology

Despite normal pregnancy being an ideal environment for kidney stone formation, the incidence of kidney calculi remains similar in pregnant and nonpregnant women, in the range of 1 in 188 to 1 in 4600 in cohort studies, with lower incidences in unreferred pregnant populations.[36]

Pathogenesis

Most stones in pregnancy are calcium stones. However, in pregnancy, calcium phosphate stones are most common, in contrast to calcium oxalate in the nonpregnant population. Struvite stones are the next most common, usually when the urinary tract is infected with organisms such as *Proteus* spp. Small proportions of kidney stones are formed from uric acid or cystine. Although pregnancy is a physiologic state of relative urinary stasis and increased calcium and uric acid excretion, this is balanced by enhanced excretion of inhibitors of stone formation, such as magnesium, citrate, and the glycoprotein nephrocalcin.

Clinical Manifestations

Although symptomatic stones during pregnancy are rare, they are a relatively common cause of nonobstetric abdominal pain in pregnancy. Kidney and bladder stones usually present in the second or third trimester with acute flank pain radiating to the groin or lower abdomen, with hematuria. However, clinical features of kidney calculi may be more difficult to interpret in pregnancy because frequent episodes of diffuse, poorly localized abdominal discomfort and lower urinary tract symptoms can occur in normal pregnancy. Some women with calculi have concomitant UTI. Increased serum calcium concentrations in pregnancy warrant exclusion of hyperparathyroidism, which can lead to adverse maternal and fetal outcomes in untreated women.

Pregnant women with kidney calculi are reported to have an increased risk for superimposed pyelonephritis and obstetric complications including preterm labor, hypertensive disorders, gestational diabetes, and cesarean delivery.[37] However, the true risk of kidney stones in pregnancy is difficult to determine from existing studies.

The diagnosis of kidney calculi in pregnancy is difficult because of the radiation exposure to the fetus with computed tomography (CT) imaging, which is the investigation of choice outside of pregnancy. The fetal radiation exposures from abdominal CT (and most other diagnostic imaging procedures in common use) is below the threshold at which there is risk of fetal death, malformation, growth restriction, or impaired mental development.[38] However, as the radiation exposure threshold that leads to an increased relative (though low absolute) risk of childhood cancer is unknown, alternative imaging modalities that do not use ionizing radiation should be used when possible. Ultrasound is therefore often the first-line investigation in pregnancy, although detection rates are lower than with CT, varying from 29% to 69%.[36] Ultrasound will also detect gestational dilation of the urinary tract, which can complicate the diagnosis. An absence of ureteric jets in the contralateral decubitus position may be helpful in the assessment of obstruction. Transvaginal ultrasound can be added to examine for distal ureteral stones. If symptoms persist and further diagnosis is required, magnetic resonance (MR) urography or limited intravenous urography (IVU) have been suggested. MR imaging findings include a signal void, perinephric or periureteral edema, and an abrupt ending of the ureter at the level of obstruction. Limited IVU has been reported to have better diagnostic accuracy (93%) compared with ultrasound (60%).[40]

Treatment

Approximately 64% to 84% of stones will pass spontaneously during pregnancy, and so initial management of kidney calculi is conservative, including appropriate hydration, antiemetics, analgesia, and antibiotics if infection is suspected. The woman should lie on her side, with the symptomatic side up, enabling relief of pressure on the ureter from the gravid uterus. The dose of nifedipine used for expulsion of stones outside of pregnancy is comparable to that used in pregnancy for both hypertension and tocolysis and so can be safely given if clinically indicated. Quantitation of urine calcium, uric acid, or other mineral excretion is not performed in pregnancy, as interpretation in the context of gestational change is not clear and specific pharmacologic agents are not used in pregnancy due to limited data. Such investigations can be completed postpartum.

Surgical intervention is considered only when stones cause persistent obstruction, deteriorating kidney function, intractable pain or infection. This is a rare situation in pregnancy. Percutaneous nephrostomy can be used as a temporizing measure until after delivery, although the likelihood of tubal blockage should be considered, and flushing and/or replacement may be required. Ureteroscopic stone removal is increasingly described in pregnancy, with complete stone removal achieved in 86% of 116 procedures.[41] Lithotripsy is contraindicated during pregnancy because of the presumed adverse effect of the shock waves on the fetus, with fetal damage and death reported in animal studies. Inadvertent exposure to extracorporeal shock wave lithotripsy has been reported, however, leading to a recommendation for further research on possible utility in pregnancy.[36] Rare cases of percutaneous nephrolithotomy are reported in pregnancy; however, prolonged fluoroscopy time and prone positioning mean that it is usually delayed until the postpartum period.[36] Women should be assessed for idiopathic hypercalciuria or other causes of kidney calculi after delivery. Clinicians should be aware that gestational calyceal and ureteral dilation may persist for months postpartum.

HYPERTENSION IN PREGNANCY

Definitions

Median BP falls to a nadir of 113/69 mm Hg at 18 to 19 weeks' gestation and peaks at 121/78 mm Hg at term with an upper reference limit (97th centile) of 136/86 mm Hg in midpregnancy and 144/95 mm Hg

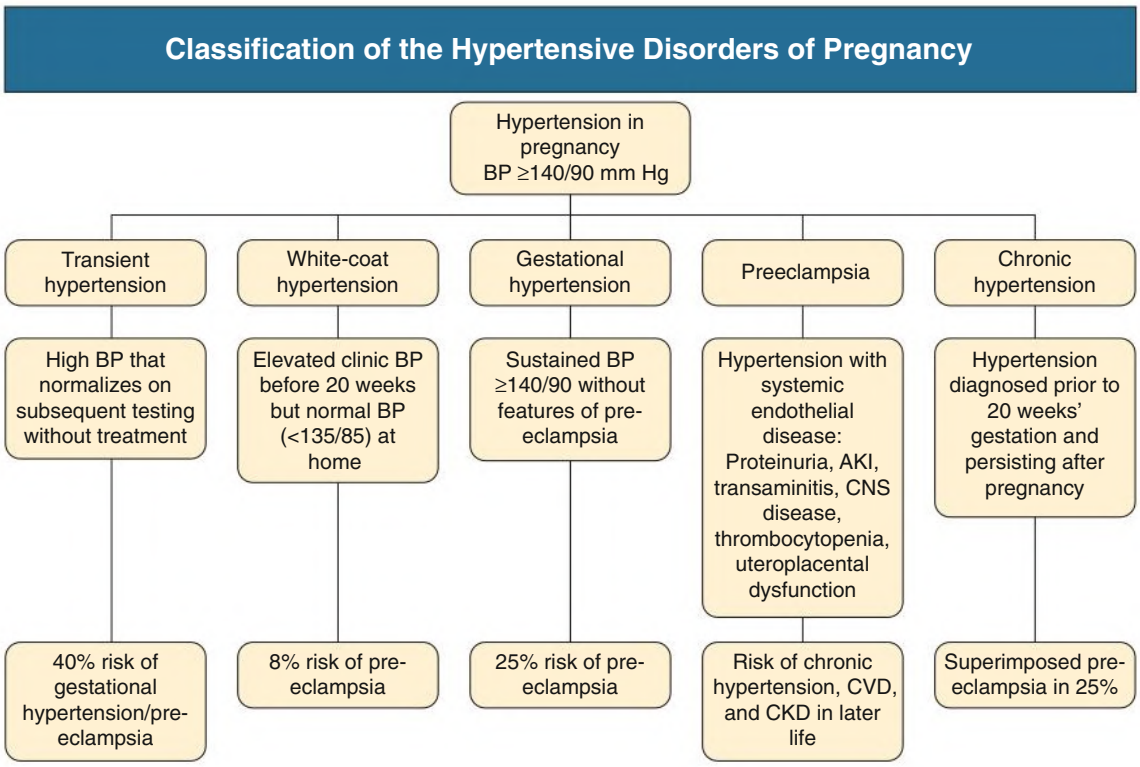

Fig. 44.3 Classification of the Hypertensive Disorders of Pregnancy. *AKI,* Acute kidney injury; *BP,* blood pressure; *CKD,* chronic kidney disease; *CNS,* central nervous system; *CVD,* cardiovascular disease.

at term,[15] supporting the use of 140/90 mm Hg as the upper threshold for normal BP in pregnancy. The different hypertensive disorders of pregnancy are shown in Fig. 44.3.

Gestational hypertension is the development of new hypertension after 20 weeks' gestation in the absence of features of preeclampsia. Approximately 25% will progress to develop preeclampsia. Gestational hypertension usually resolves by 12 weeks postpartum. If hypertension persists beyond that, the possibility of chronic hypertension should be considered.

Preeclampsia is new hypertension after 20 weeks' gestation either with maternal organ dysfunction (proteinuria, AKI, elevated transaminases, cerebral, hepatic or clotting abnormalities) or uteroplacental dysfunction (fetal growth restriction, abnormal umbilical artery Doppler waveform, or stillbirth). Proteinuria (uPCR >30 mg/mmol or uACR >8 mg/mmol) is not essential for the diagnosis of preeclampsia if other criteria exist[42] (Table 44.4).

Eclampsia is seizure activity in a woman with preeclampsia. It is uncommon in high-income countries, with a prevalence of about 0.3% of hypertensive pregnancies. In low- and middle-income countries, eclampsia is more common, with greater risks for maternal mortality and morbidity, as well as perinatal mortality.

Chronic hypertension is BP 140/90 mm Hg or higher that predates pregnancy or is detected before the 20th week of pregnancy on at least two occasions and persists beyond 12 weeks postpartum. This can be confirmed by home BP monitoring or 24-hr ambulatory BP monitoring. Superimposed preeclampsia is the new development of features outlined in Table 44.4 after 20 weeks' gestation in a woman with chronic hypertension.

White-coat hypertension is elevated office or clinic BP (≥140/90 mm Hg) but normal BP measured at home (<135/85 mm Hg). It is not an entirely benign condition with an increased (8%) risk of preeclampsia, which is about double the usual risk.

Epidemiology

Hypertension affects 10% to 12% of all pregnancies, and the global estimate for the incidence of preeclampsia is 4.6% of all pregnancies, though there is variation due to patient factors such as ethnicity and vascular risk, as well as nonstandardization of diagnostic criteria. The incidence of eclampsia is 1.4% of pregnancies globally, though this varies between countries from 0.02% to 2.9%. In low- and middle-income countries, mortality from preeclampsia accounts for nearly 30% of maternal deaths. Such mortality rates are 200 times higher than those of high-income countries that have universal access to health care, consistently applied national guidance for management, and a low threshold for the treatment of severe hypertension in pregnancy.[42] Chronic hypertension is estimated to affect 1% of pregnancies, which may increase due to advancing maternal age and rising rates of pregestational diabetes, obesity, and metabolic syndrome. Black, Asian, Hispanic, American Indian, Alaskan Native, and indigenous Australian populations have a higher risk for preeclampsia than non-Hispanic Whites, with a higher prevalence of hypertension, obesity, and diabetes contributing.

PREECLAMPSIA

Box 44.2 lists known risk factors for preeclampsia. The risk is highest in those with a history of preeclampsia, ranging from 15% to 65% depending on the gestation at which preeclampsia developed in a previous pregnancy. Early development of preeclampsia requiring delivery before 34 weeks is associated with the highest risk of recurrence. Antiphospholipid syndrome, diabetes, obesity, chronic hypertension, CKD, and assisted reproduction all confer an increased risk of preeclampsia.[43] In general, the risk of preeclampsia is higher in a first pregnancy compared with subsequent pregnancies. However, risk returns to that of a first pregnancy in women who have a new partner or an interpregnancy interval beyond 7 years.

TABLE 44.4 Diagnostic Criteria for Preeclampsia

Essential criteria	>20 weeks' gestation *and* New hypertension: systolic BP ≥140 mm Hg or diastolic BP ≥90 mm Hg on two occasions
Additional criteria	Proteinuria: • uPCR >30 mg/mmol (≥0.3 mg/mg) • >300 mg/24 h (not indicated if uPCR available) • Dipstick >2+ (if other methods unavailable) • uACR >8 mg/mmol (>70 mg/g) Serum creatinine: • An increase of serum creatinine to >1.0–1.1 mg/dL (>90–100 μmol/L)[a] • Doubling of serum creatinine in pregnancy (even if new serum creatinine <1.1 mg/dL)[a] Hematologic complications: • Platelets <150 × 10^9/L[a] • Hemolysis,[a] disseminated intravascular coagulation[a] Liver complications: • AST or ALT >40 U/L or double normal reference limit[a] • Epigastric/right upper quadrant pain (not attributable to alternate diagnosis)[a] Neurologic complications: • Eclampsia[a] • Altered mental status[a] • Blindness, persistent visual scotomata[a] • Stroke[a] • Clonus • New onset headache not attributable to alternate diagnosis[a] Respiratory complications: • Pulmonary edema[a] Uteroplacental dysfunction: • Fetal growth restriction, abnormal umbilical artery • Doppler waveform, stillbirth

Diagnosis requires one essential and one additional clinical feature for diagnosis.

BOX 44.2 Risk Factors for Preeclampsia

Maternal Factors

Obstetric
- Nulliparity
- Multiple-gestation pregnancy
- History of previous preeclampsia
- Prior intrauterine growth restriction
- Prior placental abruption
- Prior stillbirth
- Artificial reproductive technology
- Molar pregnancy
- Trisomy 13 or fetal hydrops
- Gestational diabetes
- First trimester biophysical/biochemical markers: uterine artery pulsatility index, uterine mean arterial pressure, serum pregnancy-associated plasma protein A and placental growth factor[a]

Comorbidity
- Chronic hypertension
- Chronic kidney disease
- Pregestational diabetes
- Prepregnancy body mass index >30 kg/m²
- Antiphospholipid antibody syndrome
- Systemic lupus erythematosus
- Polycystic ovarian syndrome

Genetic
- Thrombophilia
- Preeclampsia in first-degree relative

Other
- Age >40 years
- Having been born small for gestational age

Paternal Factors
- New partner
- Conception by intracytoplasmic sperm injection
- Father born from pregnancy affected by preeclampsia

[a]Hofmeyr GJ, Lawrie TA, Atallah AN, et al. Calcium supplementation during pregnancy for preventing blood pressure disorders and related problems. *Cochrane Database Syst Rev.* 2018;10(10):CD001059.

Pathogenesis

The placenta is likely to be key in the development of preeclampsia, secreting factors that cause systemic endothelial dysfunction (Fig. 44.4).[44] Hence, preeclampsia can occur in hydatidiform mole, where the fetus is absent, and it resolves after delivery and removal of the placenta.

Normal placental development is characterized by remodeling of the uterine spiral arteries within the endometrium that supply the placenta. The process is driven by cytotrophoblasts derived from the conceptus, which surround the walls of the spiral arteries, leading to destruction of smooth muscle and elastin within the arterial wall and replacement with inert fibrinoid material, thereby preventing vasoactivity and vasoconstriction. This conversion of the spiral arteries produces capacitance vessels capable of carrying blood at a reduced velocity and pulsatility to placental villi, allowing sufficient oxygen exchange between mother and fetus.

Although deficient spiral artery remodeling has also been described in normal pregnancies and in fetal growth restriction in the absence of preeclampsia, there is consensus that this finding is most marked in preeclamptic pregnancies. A failure of spiral artery remodeling results in uteroplacental ischemia (though this may not be the only mechanism producing an hypoxic placental environment), indicated by the finding of hypoxia-inducible factor 1α, a marker of cellular oxygen deprivation, in the placentas of women with preeclampsia.[45] Oxidative stress, activation of nuclear factor-κB, increased necrotic trophoblast shedding, and proinflammatory interleukin production have all been mechanistically linked to the hypoxic microenvironment. Pathologic inflammation is also evidenced by acute atheroma, which is seen in 10% of preeclamptic placentas.[46]

Placental hypoxia leads to an altered balance between angiogenic (placental growth factor [PlGF], vascular endothelial growth

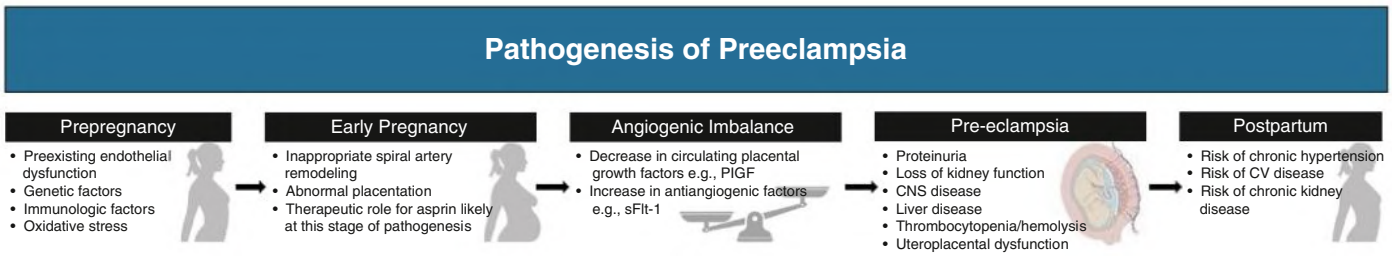

Fig. 44.4 Pathogenesis of Preeclampsia. Prepregnancy risk factors and hypothesized pathologic mechanisms contribute to the failure of trophoblast uterine interactions in early pregnancy. Stress to the syncytiotrophoblast leads to the release of a range of factors into the systemic circulation producing an imbalance between proangiogenic factors including placental growth factor (PlGF) and antiangiogenic factors including soluble fms-like tyrosine kinase-1 (sFlt-1), which is detectable before the clinical syndrome of preeclampsia manifests. Maternal endothelium dysfunction produces the clinical syndrome of preeclampsia. Preeclampsia confers a risk of chronic hypertension, and cardiovascular (CV) and kidney disease later in life. (Pre-eclampsia image from Maher GM, McCarthy FP, McCarthy CM et al. A perspective on pre-eclampsia and neurodevelopmental outcomes in the offspring: Does maternal inflammation play a role? Int J Dev Neurosci. 2019;77:69–76.)

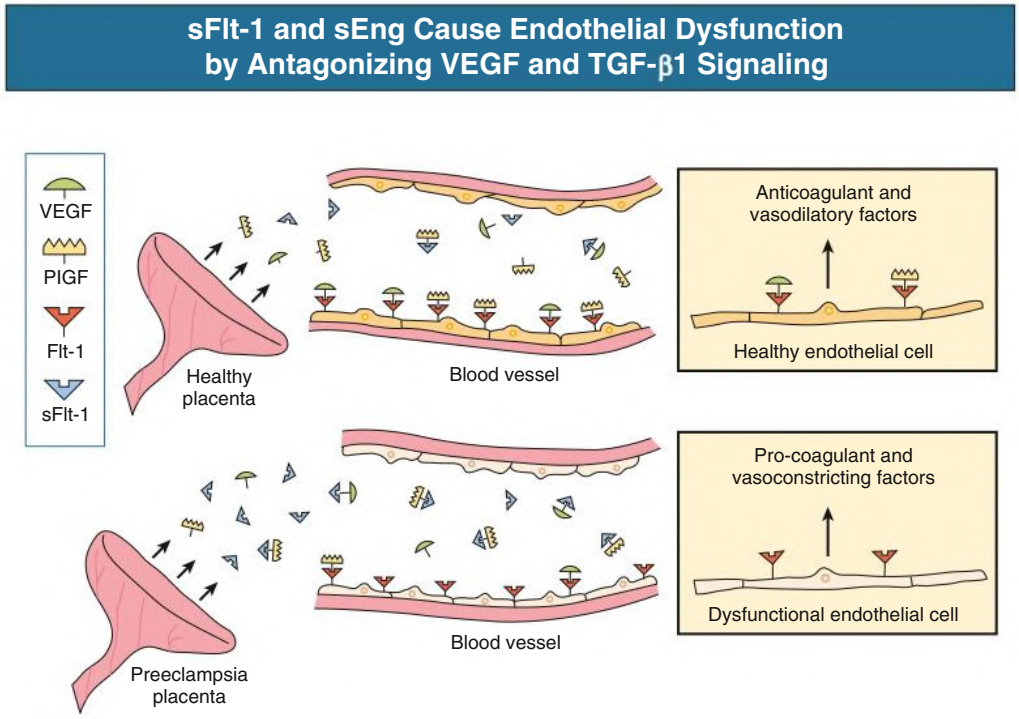

Fig. 44.5 Proteins Soluble fms-like Tyrosine Kinase 1 (sFlt-1) and Soluble Endoglin (sEng) Cause Endothelial Dysfunction by Antagonizing Vascular Endothelial Growth Factor (VEGF), Placental Growth Factor (PlGF), and Transforming Growth Factor β1 (TGF-β1) Signaling. There is mounting evidence that VEGF and TGF-β1 are required to maintain endothelial health in several tissues, including the kidney and perhaps the placenta. During normal pregnancy, vascular homeostasis is maintained by physiologic levels of VEGF and TGF-β1 signaling in the vasculature. In preeclampsia, excess placental secretion of sFlt-1 and sEng (two endogenous circulating antiangiogenic proteins) inhibits VEGF/PlGF and TGF-β1 signaling, respectively. This results in endothelial cell dysfunction, including decreased prostacyclin, nitric oxide production, and release of procoagulant proteins. *sFlt-1,* Soluble Fms-like tyrosine kinase 1; *PlGF,* placental growth factor. (Modified from Karumanchi SA, Epstein FH. Placental ischemia and soluble fms-like tyrosine kinase 1: cause or consequence of preeclampsia? *Kidney Int.* 2007;71[10]:959961.)

factor [VEGF], transforming growth factor beta [TGFβ]) and antiangiogenic (soluble fms-like tyrosine kinase 1 [sFlt-1] and soluble endoglin [sEng]) factors, which are measurable in the maternal circulation. sFlt-1 and sEng are syncytiotrophoblast-derived antiangiogenic factors, which bind to PlGF, VEGF, and TGFβ, preventing their interaction with endothelial receptors, thereby inducing endothelial dysfunction, with increased sensitivity to proinflammatory factors and inhibition of vasodilatory pathways (Fig. 44.5). Thus, insufficient placental function, the release of antiangiogenic placental factors into the maternal circulation, and an exaggerated maternal inflammatory response produce the preeclamptic phenotype of generalized endothelial dysfunction including clotting activation, glomerular endotheliosis, transaminitis, and cerebral and pulmonary edema.

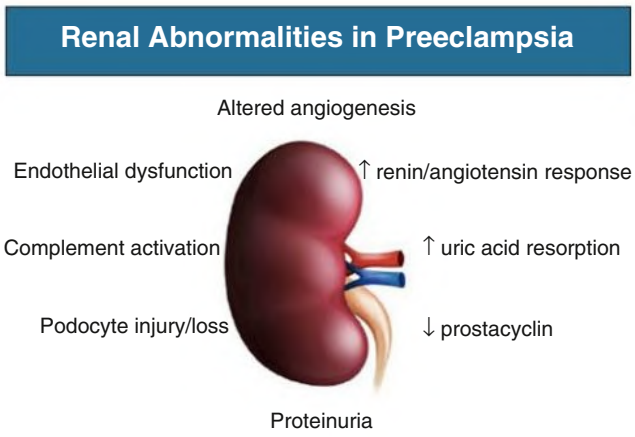

Fig. 44.6 Renal abnormalities in preeclampsia. *GFR,* Glomerular filtration rate. (Modified from Hoenig MP, Hladik GA. Overview of kidney structure and function. In: *National Kideny Foundation Primer on Kidney Diseases,* ed 8. 2022:2–18.)

The hypertensive phenotype can be explained by an exaggerated pressor response, possibly mediated by angiotensin II type 1 receptor (AT_1) autoantibodies. These antibodies are detected in some women with preeclampsia and can activate the AT_1 receptor, produce reactive oxygen species (ROS), increase thrombin generation, impair fibrinolysis, and cause endothelial cell damage.[45] However, the importance of AT_1 autoantibodies in the pathogenesis of preeclampsia remains to be determined.

The clinical presentation of preeclampsia depends on how maternal organ systems and the fetus are affected, but once begun, preeclampsia runs a progressive course until removal of the placenta at delivery, which remains the only definitive cure.

Kidney Abnormalities in Preeclampsia

Histologic changes in the kidney include diffuse *glomerular endotheliosis,* characterized by swelling and vacuolization of endothelial cells, capillary lumen occlusion, and glomerular enlargement (Fig. 44.6). The swollen endothelial cytoplasm encroaches on glomerular capillary lumina, contributing to tuft ischemia (Fig. 44.7). Immunofluorescence

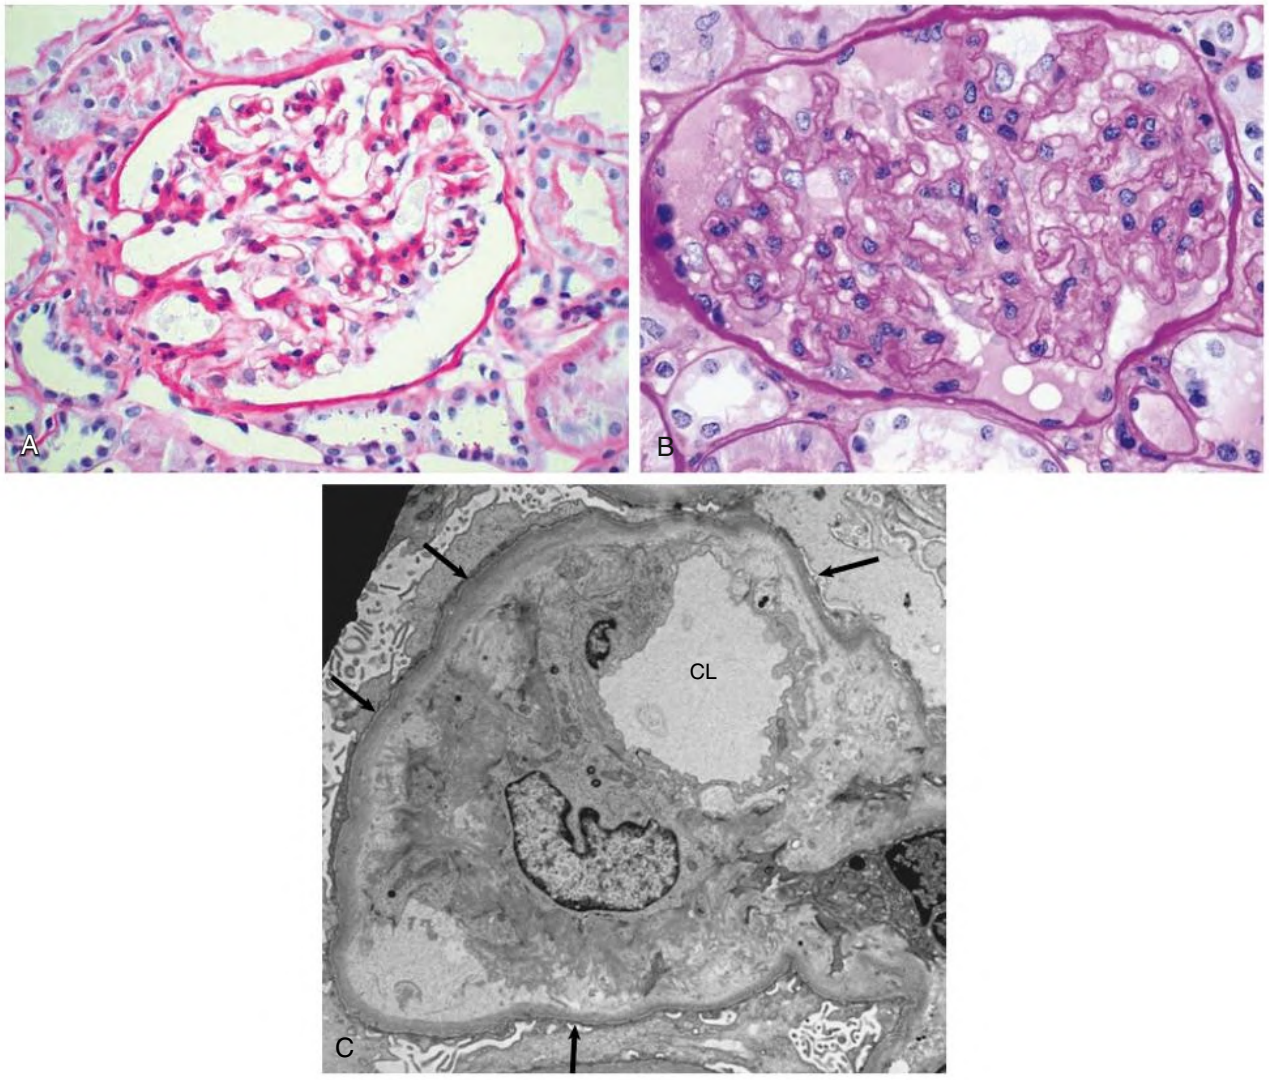

Fig. 44.7 Glomerular Endotheliosis. (A) Normal glomerulus on light microscopy. (B) Glomerulus from a patient with preeclampsia on light microscopy. Note occlusion of capillary lumina by swollen endothelial cells. (C) On electron microscopy, note glomerular basement membrane *(arrows)* and marked reduction of capillary lumen *(CL)* caused by swollen endothelial cell cytoplasm. (A–B, Periodic acid–Schiff reaction; magnification ×40; C, original magnification ×7500.) (Courtesy Prof. P. Furness, University of Leicester, UK.)

may reveal fibrin deposits. However, preeclampsia is a clinical diagnosis and kidney biopsy is not indicated.

Proteinuria

Proteinuria in preeclampsia may be part of the general capillary leak of preeclampsia or a consequence of glomerular endotheliosis. Both glomerular and tubular patterns of proteinuria are reported. Glomerular proteinuria is nonselective and varies from the diagnostic threshold of 300 mg/day up to the nephrotic range. Levels of proteinuria in women with preeclampsia do not consistently correlate with maternal and fetal outcomes.[47,48]

Decreased Glomerular Filtration Rate

GFR is decreased by approximately one-third in women with preeclampsia compared with normotensive late pregnancy. This reduction in GFR is greater than the measured reduction in blood flow, leading to the conclusion that glomerular endotheliosis is an important causative factor in addition to the hemodynamic changes of preeclampsia, including vasoconstriction, plasma volume contraction, and altered cardiac output.

Sodium Retention

Sodium retention occurs in preeclampsia, thought to be a renal tubular response to the perceived reduction in kidney perfusion, increased sympathetic nervous system activity, and/or altered expression of epithelial sodium channels.

Increased Uric Acid Reabsorption

Hyperuricemia in preeclampsia results primarily from increased renal uric acid retention in the kidney, perhaps with increased placental production. Though hyperuricemia has been correlated with fetal risk, serum uric acid concentrations are not a diagnostic criterion for preeclampsia.

Clinical Manifestations

A diagnosis of preeclampsia requires a combination of new onset of hypertension after the 20th week of pregnancy, with evidence of maternal endothelial dysfunction or uteroplacental compromise (see Table 44.4). Symptoms are not always present but may include headache, visual scotomata, seizures, focal neurologic deficit (manifestations of cerebral involvement), epigastric or right upper quadrant pain (reflecting hepatic disease), oliguria, abdominal pain (placental abruption), or reduced fetal movements (Box 44.3). Neurologic complications include seizures (eclampsia), ischemic and hemorrhagic stroke, retinal detachment, cortical blindness, and posterior reversible encephalopathy. Hepatic complications include transaminitis, subcapsular hematoma, and in rare cases liver rupture. AKI occurs, though requirement for dialysis is rare in the absence of significant hemodynamic complications at the time of delivery, or severe disease with thrombotic microangiopathy. Cardiorespiratory complications include myocardial ischemia and pulmonary edema.

Diagnosis and surveillance of preeclampsia require the following:

- Quantitation of proteinuria by uPCR or uACR (diagnostic only)
- Hemoglobin and platelet count
- Serum creatinine and electrolytes
- Serum transaminases
- Ultrasound assessment of fetal growth, amniotic fluid volume, and umbilical artery flow

Routine evaluation in preeclampsia should include BP measurement, assessment for pulmonary edema, assessment for clonus as a warning sign of impending eclampsia, fetal heart rate patterns measured by cardiotocography (CTG) and assessment of fetal growth.

BOX 44.3 Clinical Features of Preeclampsia

Primary Manifestation

- Hypertension

Kidney Involvement

- Significant proteinuria: spot ratio of urine protein to creatinine >30 mg/mmol (≥0.3 mg protein/mg creatinine)
- Acute kidney injury: serum creatinine >1.0–1.1 mg/dL (>90 mmol/L)
- Oliguria

Hematologic Involvement

- Thrombocytopenia
- Hemolysis
- Disseminated intravascular coagulation

Liver Involvement

- Raised serum transaminases
- Severe epigastric or right upper quadrant pain

Neurologic Involvement

- Seizures (eclampsia)
- Hyperreflexia with sustained clonus
- Severe headache
- Persistent visual disturbances (photopsia, scotomata, cortical blindness, retinal vasospasm)
- Cerebrovascular accident (stroke)

Other Major Features

- Pulmonary edema
- Fetal growth restriction
- Placental abruption

Eclampsia

Eclampsia is the occurrence of tonic-clonic seizures in a woman with preeclampsia. The majority, but not all, have premonitory signs and symptoms in the week before a first eclamptic seizure including headache (56%), visual disturbances (23%), epigastric pain (17%), hypertension (48%), proteinuria (46%), or concurrent hypertension and proteinuria (38%).[49] Risk for eclampsia is not directly related to the level of BP, and it can occur in treated hypertension and in the absence of proteinuria. Importantly, about half the cases of eclampsia occur after delivery, usually within the first 5 postpartum days.

HELLP Syndrome

HELLP syndrome (hemolysis, elevated liver enzymes, and low platelet count) is considered a severe form of preeclampsia in which hepatic and platelet abnormalities dominate, with thrombotic microangiopathy. Proteinuria may be absent. The diagnosis of HELLP syndrome is based on the following laboratory criteria:

- Microangiopathic hemolytic anemia: schistocytes (fragments) in a blood film, elevated serum bilirubin, high lactate dehydrogenase, low haptoglobin
- Increased liver transaminases: aspartate transaminase greater than 70 U/L or more than twice the upper limit of normal
- Platelet count: less than 100×10^9/L

Maternal mortality from severe HELLP syndrome is about 1% and perinatal mortality between 7% and 34%, largely depending on gestational age.[50] It is advisable to treat this as a severe variant of preeclampsia, for which iatrogenic delivery is usually indicated to prevent morbidity and mortality. Maternal steroid administration is therapeutic and is not recommended.

Natural History

In general, the prognosis is favorable for women with preeclampsia, but complications include abnormal liver function or thrombocytopenia (10%–20%), pulmonary edema (<0.5%), AKI (1%–5%), placental abruption (1%–4%), fetal growth restriction (10%–25%), neurologic damage (<1%), preterm birth, and perinatal death.[51] After delivery, clinical and laboratory derangements of preeclampsia resolve, but this may be delayed in some women, and it is critical to remain vigilant until there is definite improvement in the clinical picture and hematologic and biochemical parameters. Some patients require antihypertensives for the first time in the postnatal period, which we recommend for BPs in excess of 140/90 mm Hg. Hypertension may persist for days, weeks, or months but will eventually resolve if preeclampsia is responsible for the elevated BP and there is no underlying chronic hypertension.

Prediction

Combination screening, including maternal risk factors, late first-trimester uterine artery Doppler ultrasound, and various biomarkers, has been shown in some studies to predict early-onset preeclampsia with high sensitivity and specificity,[52,53] though clinical validation is awaited. The use of a combined first-trimester screen has shown that the detection of preeclampsia requiring delivery before 34 weeks' gestation, which is associated with the highest neonatal morbidity and mortality, can be predicted in 50% of cases using maternal characteristics, improved to 75% by the addition of biochemical markers (serum pregnancy-associated plasma protein-A and placental growth factor), to 90% by addition of biophysical markers (uterine artery pulsatility index, uterine mean arterial pressure), and to 95% if biochemical and biophysical markers are both used.[54] This strategy was used to detect high-risk women in a randomized controlled trial (RCT) of aspirin for the prevention of preeclampsia, with a detection rate of 77%.[55] Such screening may offer clinical utility for women who would not qualify for aspirin prophylaxis based on maternal characteristics alone, provided it is affordable, where standards in measuring pulsatility indices are met, and where appropriate counseling is available.

Changes in angiogenic (lower PlGF) and antiangiogenic (higher sFlt-1) factors are also predictive in preeclampsia. A PlGF concentration lower than 100 pg/mL before 35 weeks' gestation has been shown to rule out the need for delivery due to preeclampsia within the next 2 weeks with 98% probability.[56] Similarly, a ratio of sFlt-1:PlGF lower than 38 has a negative predictive value of 99% for the development of preeclampsia within 1 week and 95% for the next 4 weeks.[57] One RCT of revealed versus concealed PlGF testing showed that PlGF testing in suspected preeclampsia reduced the time to diagnosis and maternal adverse event rate, with no difference in perinatal outcomes.[58] There has been variable adoption of these markers in the assessment of women with placental insufficiency, including suspected preeclampsia, with the outcome of further studies awaited.

Prevention

The observation that preeclampsia is associated with increased platelet turnover and increased platelet-derived thromboxane levels led to several trials investigating the effect of aspirin in the prevention of preeclampsia. Low-dose aspirin (75–150 mg daily) has been shown to reduce the incidence of preeclampsia.[59-62] A recent RCT involving high-risk women was based on maternal risk characteristics and biophysical and biochemical markers. The trial, in which women were given 150 mg aspirin daily versus placebo for 11 to 14 weeks, demonstrated a 62% reduction in preterm preeclampsia.[63] We advocate starting aspirin in all high-risk women at a dose of 150 mg/day in early pregnancy (by 16 weeks' gestation) until 36 weeks.

Evidence that high-dose oral calcium supplementation reduces the risk of preeclampsia is of low quality.[64] The World Health Organization recommends calcium supplementation (1.5–2 g/day) after 20 weeks' gestation only in women with low dietary calcium intake, and calcium supplementation is not given routinely in most high-income countries. Nutritional supplements, including magnesium, folic acid, fish oils, antioxidants, and garlic, have no efficacy in preventing preeclampsia.[65] In particular, combined use of vitamins C and E has been associated with worse maternal and fetal outcomes. Anticoagulation is not recommended for reducing the risk of preeclampsia. Maternal obesity is associated with an increased risk for preeclampsia, and weight loss is recommended to reduce risk.

Management

All women with preeclampsia should be reviewed at the initial diagnosis to assess the severity of the condition and the well-being of the fetus. In some centers, PlGF-based testing is used to predict the risk of preterm delivery and serious maternal complications to guide decisions about the appropriate place of care. If BP is controlled in the absence of severe features, fetal compromise or other clinical concern, outpatient care may be appropriate provided resources, expertise, and regular repeat surveillance are available. Face-to-face clinical reviews should take place at least twice weekly, including platelet count, serum creatinine, liver function, and CTG as clinically indicated. Repeated quantification of proteinuria is not required once the protein-to-creatinine ratio has reached the diagnostic threshold of 30 mg/mmol, because the amount or rate of increase in proteinuria does not reliably predict adverse maternal or perinatal outcome. Ultrasound estimation of fetal growth, amniotic fluid volume, and umbilical artery blood flow should be done at diagnosis and at least every 2 weeks, though a higher frequency may be indicated according to the degree of uteroplacental dysfunction seen.

Blood Pressure Management

The main indication for antihypertensive therapy in preeclampsia is to prevent maternal severe hypertension with risk of intracerebral hemorrhage and placental abruption. Treatment of hypertension does not affect the disease course of preeclampsia, which continues to be driven by irreversible, abnormal placental function. However, control of maternal BP may allow pregnancy to be prolonged, with further fetal maturation.

The BP threshold at which antihypertensive treatment should be initiated is controversial. An RCT of "tight" (target diastolic 90 mm Hg) with "less tight" (target diastolic 100 mm Hg) BP control in pregnancy found that although the achieved BP differences between groups were less than intended (139/90 mm Hg vs. 133/85 mm Hg), tighter BP control was associated with a reduced incidence of severe maternal hypertension (28% vs. 41%) without fetal compromise.[66] A secondary analysis showed that in women with less tight BP, severe hypertension was associated with an increased risk of adverse maternal and fetal outcomes.[67] A systematic review of 59 trials and 4723 women with BPs in pregnancy between 140/90 and 169/109 mm Hg concluded that antihypertensive treatment halves the risk of severe maternal hypertension, with no adverse effects on maternal and fetal outcomes.[68] Such studies have led to a fall in the treatment targets for hypertension in pregnancy over recent years (Table 44.5). An outlier in this trend is the United States, where antihypertensive treatment is not recommended unless BP is higher than 160/110 mm Hg for women with gestational hypertension or preeclampsia[69] and 150/100 mm Hg in women with chronic hypertension and end organ damage.[70] Falling rates of maternal death from hypertensive disorders in the United Kingdom contrast with

TABLE 44.5 Recommended Blood Pressure Targets in Pregnancy

Professional Society	Blood Pressure for Treatment Initiation (mm Hg)	Treatment Target (mm Hg)
NICE, 2010	>150/100 >140/90 if target organ damage	<150/80–100
ACOG, 2013	≥160/110 ≥160/105 if chronic hypertension	120–160/80–105 for chronic BP
SOGC, 2014	>160/110 140–159/90–109 if comorbid conditions	130–155/80–105 <140/90 if comorbid conditions
SOMANZ, 2014	≥160/110 for mild/moderate BP ≥170/110 for severe BP	NA
ISSHP, 2014	160–170/110 for preeclampsia	NA
ISSHP, 2018	>140/90 (>135/85 home)	110–140/85 Reduce medication if diastolic <80
NICE, 2019	>140/90	110–135/70–85
ACOG, 2020	≥160/110 ≥150/100 if end organ damage	120–160/80–110 if chronic hypertension

Over the past 10 years, there has been a trend to reduce the target blood pressure in pregnancy due to evidence of maternal benefit in the absence of fetal harm.
ACOG, American College of Obstetricians and Gynecologists; *ISSHP,* International Society for the Study of Hypertension in Pregnancy; *NA,* not applicable; *NICE,* National Institute for Health and Care Excellence; *SOGC,* Society of Obstetricians and Gynaecologists of Canada; *SOMANZ,* Society of Obstetric Medicine of Australia and New Zealand.

global rates and those in the United States. This has been attributed to strict management protocols that include adequate treatment of hypertension to increasingly lower BP targets in addition to avoiding fluid overload, seizure prophylaxis, and planned delivery after 36 ± 6 weeks' gestation.[71] Our practice is to target treatment to achieve a BP of 110/70 to 135/85 mm Hg in pregnancy.

The choice of antihypertensive agent in pregnancy is determined by licensing, availability, and clinician experience, with no high-level evidence to guide prescribing. The dosing of antihypertensive medication for pregnancy is shown in Table 44.6. Where urgent blood control is needed, both IV (labetalol, hydralazine) and oral (nifedipine, labetalol, methyldopa)[72] agents can be used. Modified-release oral nifedipine is used in this situation to avoid the precipitous drop in BP that can occur with immediate release preparations before admission/monitoring is established llowing for additional treatment including IV preparations if needed. Fewer safety data are available for amlodipine and doxazosin/prazosin, although no adverse fetal effects are commonly reported. ACE inhibitors and angiotensin receptor antagonists are contraindicated due to fetotoxicity in the second and third trimesters. In the absence of pulmonary edema, diuretics are avoided because of concern regarding further intravascular volume depletion on top of the known volume contraction that exists in preeclampsia.

Eclampsia Prophylaxis and Treatment

Magnesium sulfate loading (4 g over 10–15 minutes) followed by an infusion (1 g/h) is used for eclampsia prophylaxis and treatment. Magnesium is a more effective anticonvulsant in eclampsia than diazepam and phenytoin. When used prophylactically, magnesium halves the risk of eclampsia and therefore likely reduces maternal death.[73] It should be continued for 24 hours after a seizure or until 24 hours after delivery when used as prophylaxis. Magnesium sulfate is excreted by the kidney, so caution is required in women with oliguria, AKI, or CKD. In these settings, we advocate that the full loading dose is given

TABLE 44.6 Antihypertensive Treatment in Pregnancy

Medication	Dose	Notes
Labetalol	Oral: 200–1200 mg/day IV: 50 mg every 10 min to a total 200 mg IV infusion: 20 mg/h, titrated as required	Avoid in asthma, heart block/bradycardia Short duration of action; consider oral dosing three times per day.
Nifedipine	Oral: 10 mg stat dose, 20–90 mg/day	Modified-release preparations are used to prevent a precipitous fall in BP and reflex tachycardia. Sublingual preparations are not recommended. Doses can be repeated after 30–60 min. May cause headache and peripheral edema.
Methyldopa	Oral: 250–750 mg three times per day	Wean after delivery due to exacerbation of postnatal depression. 1000 mg orally has been used in the treatment of severe hypertension, with less effect compared with nifedipine.[a]
Hydralazine	Slow IV: 5 mg over 5–10 min, repeated after 20–30 min Oral: 25–50 mg three times/day	IV is used for control of severe hypertension where labetalol is contraindicated or ineffective. Monitor for hypotension and tachycardia. Preloading with IV fluid may be indicated if volume deplete on clinical assessment (250 mL and review). Rarely used orally for acute BP lowering due to unpredictable hypotensive effect.
Clonidine	Oral: 0.05 mg two to three times per day, maximum 1.2 mg/day	
Prazosin	Oral: 0.5–5 mg once to three times/day	Can cause orthostatic hypotension Limited safety data
Amlodipine	Oral: 5–10 mg/day	Limited safety data

Oral dosing is recommended where adequate control can be achieved and expectant management is ongoing. IV dosing is recommended for urgent control in severe hypertension (>160/110 mm Hg), where oral agents do not achieve the desired clinical effect or for precise control at the time of delivery.
[a]Easterling T, Mundle S, Bracken H, et al. Oral antihypertensive regimens (nifedipine retard, labetalol, and methyldopa) for management of severe hypertension in pregnancy: an open-label, randomised controlled trial. *Lancet.* 2019;394:1011–1021.
BP, Blood pressure; *IV,* intravenous.

but the concentration of the ongoing infusion is reduced. Though a serum concentration 1.8 to 3.0 mmol/L has been suggested as therapeutic, monitoring is controversial as concentrations do not correlate with clinical toxicity. In the absence of kidney impairment, we do not routinely measure serum magnesium concentrations. Assessment of respiratory rate, oxygen saturation, examination for hyporeflexia, and electrocardiogram review are required. In our view, seizure prophylaxis should be given to women with preeclampsia and severe features, particularly if there is clinical evidence of cerebral involvement including clonus, severe headaches, and visual scotomata. These women should simultaneously have a plan made for delivery. Withholding seizure prophylaxis in women with preeclampsia without severe features is associated with an extremely low likelihood of seizure and avoids the potential for drug toxicity, which occurs in up to 25% of women treated with magnesium sulfate.[73,74]

Fluid Balance

Preeclampsia is a volume-contracted, not volume-depleted, state. In addition, increased capillary permeability means that IV volume expansion carries risk, particularly for pulmonary edema. Volume expansion is not warranted in most women with preeclampsia because of the risks of pulmonary edema, and fluid restriction (to ~85 mL/h) in women with preeclampsia with severe features reduces maternal morbidity and mortality. Invasive measures of central pressure are not indicated.

Other

Platelet transfusion is generally given for platelet counts less than 20–30 $\times$ 10^9/L to facilitate delivery. Platelet transfusion is avoided at higher counts, as the pathology of thrombocytopenia in preeclampsia is one of platelet consumption, not platelet deficiency. Coagulopathy should also be corrected. Caution is advised in the use of fresh frozen plasma because of the IV volume required, and the use of concentrated preparations should be considered. There is no evidence that plasma exchange or corticosteroids are of therapeutic benefit in HELLP syndrome. Therapeutic adsorption of sFlt-1 by dextran column apheresis is the subject of an ongoing prospective study.[75]

Delivery

The only definitive treatment for preeclampsia is delivery of the placenta. The decision to deliver weighs the risk of progressive maternal disease against the likelihood of complications in the infant due to preterm delivery. Assessment of fetal well-being helps to establish the benefit of further intrauterine time. Timing of delivery should be based on optimizing perinatal outcomes while avoiding maternal risks.

Indications for delivery include the following:

- Progressive evidence of maternal organ dysfunction: worsening kidney or hepatic function, progressive thrombocytopenia, neurologic symptoms or signs
- Inability to control BP
- Failure of fetal growth or concern about fetal status

The Hypertension and Preeclampsia Intervention Trial at Near Term (HYPITAT) showed that after 37 weeks' gestation, the maternal risks of preeclampsia are significantly reduced with delivery, without additional perinatal risks.[76] In contrast, prior to 34 weeks, the advantages of increased fetal maturity mean that, in the absence of the indications listed above, expectant management to prolong pregnancy is the norm. For women with preeclampsia between 34 to 37 weeks' gestation, the situation is less clear. A recent randomized trial of planned delivery versus expectant management for women with preeclampsia between 34 and 37 weeks showed that planned delivery reduced maternal morbidity and severe hypertension compared with expectant management, with three-quarters of expectantly managed women progressing to severe preeclampsia. Although there were more neonatal unit admissions related to prematurity with planned delivery, there was no increase in respiratory or other neonatal morbidity. This suggests that planned delivery for women with preeclampsia can be considered after 34 weeks. The trade-off of a reduced risk of severe hypertension and maternal morbidity, against higher neonatal unit admission without excess morbidity, should be discussed with the mother and the multidisciplinary team involved in her and her baby's care with shared decision-making regarding time of delivery.

Antenatal corticosteroids for fetal lung maturation are routinely given to women who are less than 34 weeks' gestation in whom delivery within the next 7 days is anticipated. Use of corticosteroids for fetal lung maturity after 34 weeks remains controversial with limited prospective, randomized trial data to guide practice. Many consensus protocols do recommend steroids at later gestations, particularly for cesarean delivery, which is associated with higher rates of neonatal respiratory distress compared with vaginal delivery.

The antepartum management of preeclampsia is summarized in Fig. 44.8.

Postpartum Management

Recovery should be anticipated over 5 to 7 days after delivery in most women. In many women, the condition may worsen in the first 3 to 5 days after delivery, and they should continue to be monitored and treated in the same way as antepartum. Persistent hypertension at 3 months postpartum warrants investigation for chronic hypertension. Proteinuria can persist for up to 6 months, though regression would be expected. Nonregression of proteinuria and persistent proteinuria at 6 months postpartum warrant renal referral to exclude the possibility of underlying CKD. Investigation to exclude underlying connective tissue, cardiovascular, kidney, and antiphospholipid disorders should be considered for women with early-onset preeclampsia requiring delivery in the second or early third trimester, before another pregnancy.

Preeclampsia has well-recognized long-term implications, including an increased risk for chronic hypertension, coronary heart disease, stroke, venous thromboembolism, and CKD (Box 44.4). Whether preeclampsia causes, accelerates, or reveals underlying endothelial dysfunction is not clear. It is appropriate to counsel women who develop hypertension in pregnancy on cardiovascular risk factor lifestyle modifications, along with interval BP, serum lipid, blood glucose, and kidney function surveillance.

ACUTE FATTY LIVER OF PREGNANCY

Acute fatty liver of pregnancy (AFLP) usually presents in the third trimester and has an incidence of 5 per 100,000 pregnancies,[77] but many milder cases may go unrecognized. Primiparity, twin pregnancies, and low body mass index (<20) are overrepresented in women who develop AFLP compared with the general obstetric population. AKI is a common complication of AFLP.

Pathogenesis and Pathology

AFLP is characterized by lipid microvesicle infiltration of hepatocytes without inflammation or necrosis, though biopsy is not required for clinical diagnosis. AFLP has been linked with rare disorders of mitochondrial fatty acid oxidation, which lead to variable clinical manifestations in those affected including hypoglycemia, hepatic dysfunction, encephalopathy, cardiomyopathy, peripheral neuropathy, and myopathy. Both AFLP and HELLP are described in pregnancies in which the fetus is affected by such a disorder of fatty acid oxidation, of which long-chain 3-hydroxyacyl-CoA dehydrogenase (LCHAD) deficiency is the best described. The mothers of babies affected by these recessive conditions are default heterozygotes for the same mutation. Although

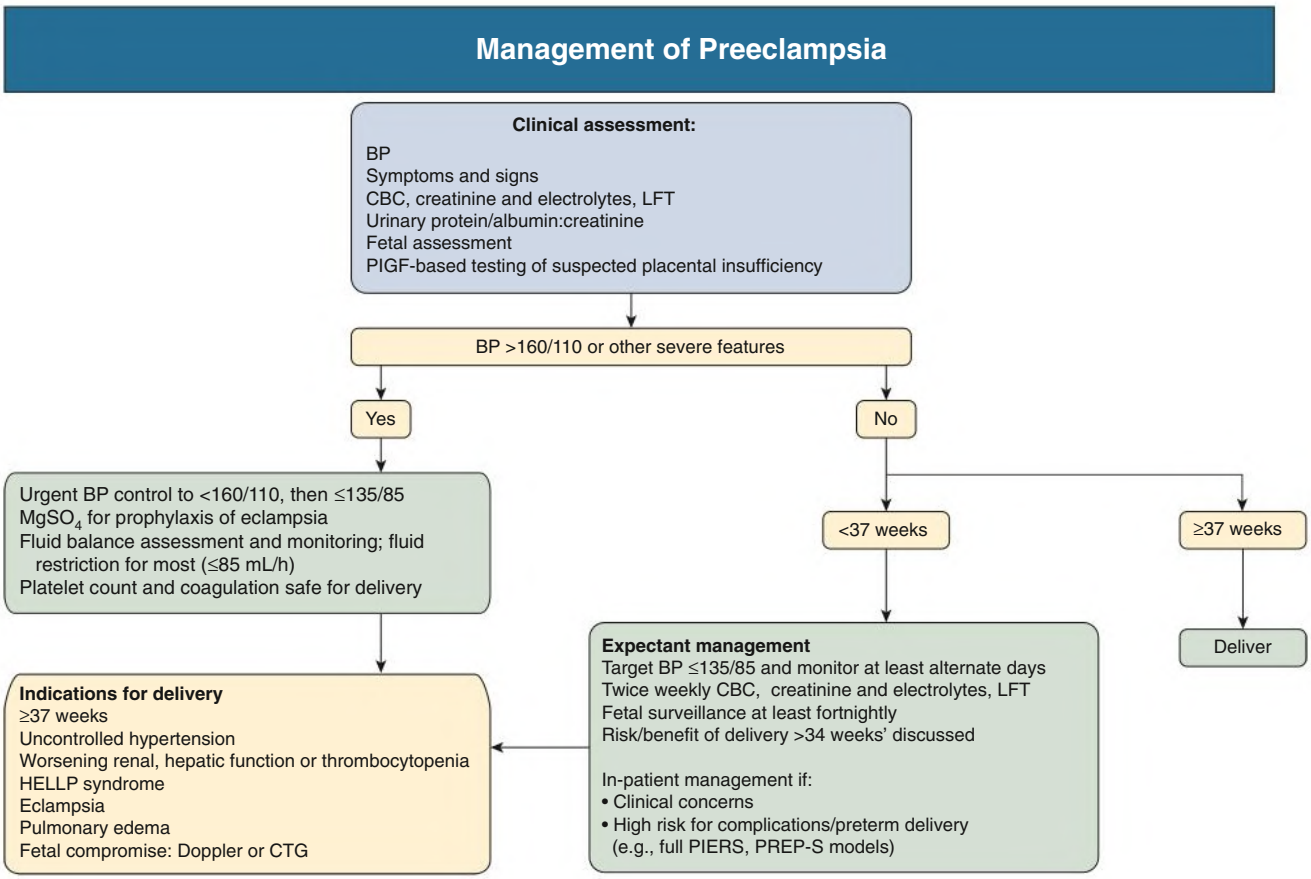

Fig. 44.8 Management of Preeclampsia. Management depends on disease severity and gestational age of diagnosis. *BP,* Blood pressure; *CBC,* complete blood count; *CTG,* cardiotocography; *HELLP,* hemolysis, elevated liver enzymes, and low platelet count; *$MgSO_4$,* magnesium sulfate; *LFT,* liver function test; *PIGF,* placental growth factor. (Modified from Chaiworapongsa T, Chaemsaithong P, Korzeniewski SJ, et al. Pre-eclampsia part 2: prediction, prevention and management. *Nat Rev Nephrol.* 2014;10[9]:531–540.)

BOX 44.4 Long-Term Consequences of Preeclampsia

- Fatal and nonfatal coronary heart disease
- Cerebrovascular accident (stroke)
- Hypertension
- Thromboembolism
- End-stage kidney disease
- Diabetes
- Cognitive dysfunction and white matter lesions on cerebral computed tomography scan
- Death from any cause

heterozygosity is insufficient for disease manifestation outside of pregnancy, the excess fetal fatty acid burden in pregnancy is thought to lead to hepatic deposition and overt maternal liver disease in pregnancy. The screening of infants born after pregnancies affected by AFLP for fatty acid oxidation disorders including LCHAD deficiency has been advocated but is not routine, and prospective data are warranted.[78]

Kidney disease in AFLP is likely to be multifactorial. Kidney biopsy and autopsy studies have shown mild glomerular hypercellularity with thick, narrow capillary loops and tubular free fatty acid accumulation, suggesting that abnormal fatty acid oxidation also may contribute to kidney dysfunction. Hemodynamic changes like those seen in the hepatorenal syndrome, thrombotic microangiopathy, and coexisting preeclampsia may also contribute to kidney injury.

Clinical Manifestations

A diagnosis of AFLP requires six or more clinical criteria (Box 44.5) in the absence of another explanation. The severity of liver involvement in women with AFLP is highly variable, ranging from a moderate isolated increase in transaminases to fulminant hepatic failure with encephalopathy and coagulopathy. Characteristic laboratory abnormalities include hyperbilirubinemia, increased transaminases, hypoglycemia, leukocytosis, and evidence of coagulopathy (hypofibrinogenemia, prolonged prothrombin time, depressed antithrombin III levels).

Differential Diagnosis

Viral hepatitis and biliary obstruction should be excluded. Distinguishing AFLP from HELLP can be challenging because the two disorders share many pathophysiologic and clinical features (Table 44.7). However, new vomiting in late pregnancy, polyuria, coagulopathy, and hypoglycemia increase clinical suspicion of AFLP.

Treatment and Outcome

Early diagnosis, supportive care (reversal of coagulopathy, correction of hypoglycemia and fluid status management), and prompt delivery are critical in the management of AFLP. One-third of cases require admission to intensive care. Kidney disease is described in 14% of women with AFLP, with temporary kidney replacement required in one-quarter of women with AKI.[77] In most women, there is complete liver and kidney recovery after delivery, although progressive liver disease requiring transplantation is described. AFLP has maternal and

perinatal mortality rates of 2% and 10%, respectively, in a high-income country with universal access to health care.[77]

THROMBOTIC MICROANGIOPATHY

Pregnancy-associated thrombotic microangiopathy (TMA) is defined by the presence of fibrin and platelet thrombi in the microcirculation, causing organ dysfunction, microangiopathic hemolysis, and thrombocytopenia. HELLP syndrome, atypical hemolytic uremic syndrome (aHUS), and thrombotic thrombocytopenic purpura (TTP) can all cause a pregnancy-associated TMA.

BOX 44.5 Criteria for the Diagnosis of Acute Fatty Liver of Pregnancy

Clinical
Vomiting
Abdominal pain
Polydipsia/polyuria
Encephalopathy

Laboratory Values
Bilirubin >0.8 mg/dL (>14 μmol/L)
Hypoglycemia <70 mg/dL (<4 mmol/L)
Uric acid >5.7 mg/dL (>340 μmol/L)
Leukocytosis >11 × 109/L
ALT or AST >42 U/L
Ammonia >47 μmol/L
Coagulopathy: PT >14 s or APTT >34 s

Other
Ascites or bright liver on ultrasound
Microvesicular steatosis on liver biopsy

Diagnosis requires six or more criteria in the absence of another explanation.
ALT, Alanine aminotransferase; *APTT,* activated partial thromboplastin time; *AST,* aspartate aminotransferase; *PT,* prothrombin time.
Modified from Knight M, Nelson-Piercy C, Kurinczuk JJ, et al. A prospective national study of acute fatty liver of pregnancy in the UK. *Gut.* 2008;57(7):951–956.

Clinical Manifestations and Differential Diagnosis

Diagnosis requires platelet count less than 100 × 10^9/L, hemoglobin less than 100 g/L, serum lactate dehydrogenase (LDH) more than 1.5 times the upper limit of normal, undetectable serum haptoglobin, a negative direct erythrocyte antiglobulin test, and either the presence of schistocytes (fragments) on blood smear or features of TMA on biopsy of an affected organ.

Women with atypical HUS typically present with AKI, most commonly at the end of pregnancy or in the first 3 months postpartum, although disease is described throughout pregnancy. Although kidney injury predominates in aHUS, cardiac and neurologic disease are also described, so distinction from TTP may be difficult on clinical grounds alone. TTP tends to present in the second and third trimesters at the same time as a physiologic decline in ADAMTS13, the deficiency of which leads to pregnancy-associated TTP.

In practice, it can be difficult to distinguish aHUS and TTP from preeclampsia with severe features (see Table 44.7). Preeclampsia with severe features is a far more common cause of pregnancy-associated TMA than both aHUS and TTP, which are rare. However, recovery of clinical parameters after delivery is expected in preeclampsia/HELLP, and persistent or progressive thrombocytopenia at 48 to 72 hours postpartum should raise clinical suspicion for alternative pathology. Postpartum hemorrhage is another complicating factor. The risk of postpartum hemorrhage is higher in women with thrombocytopenia at the time of delivery, and postpartum hemorrhage is a cause of both TMA and AKI, particularly if there is ischemic necrosis of the kidney cortex. Coagulation studies and liver function tests are usually normal in aHUS and TTP (with the exception of prehepatic hyperbilirubinemia), unlike in HELLP and AFLP. Whether PlGF-based testing offers utility in the distinction of antepartum disease is unknown.

Treatment

Delivery should be considered for all cases of pregnancy-associated TMA, depending on fetal maturity. Delivery is indicated if there is fetal compromise or progressive maternal disease. Delivery is sufficient to control TMA due to preeclampsia/HELLP and may help achieve a better response to treatment in TTP.

Plasma exchange should be commenced in atypical presentations of preeclampsia/HELLP with thrombocytopenia (<30 × 10^9/L) and either life-threatening neurologic features (seizures, altered

TABLE 44.7 Differential Clinical and Laboratory Features of Syndromes That Cause Acute Kidney Injury in Pregnancy

Clinical Features	PE	HUS/TTP	HELLP	AFLP

AFLP, Acute fatty liver of pregnancy; *ALT,* alanine aminotransferase; *AST,* aspartate aminotransferase; *CNS,* central nervous system; *HELLP,* hemolysis, elevated liver enzymes, and low platelet count; *HUS,* hemolytic uremic syndrome; *PE,* preeclampsia; *TTP,* thrombotic thrombocytopenic purpura.

consciousness, coma) or cardiac disease (persistently elevated troponin levels, electrocardiographic abnormalities, impaired cardiac function). Plasma exchange should be continued until ADAMTS13 tests results are available, which will allow confirmation or exclusion of TTP. In the absence of significant neurologic and cardiac disease, parameters can be monitored for postpartum recovery and plasma exchange commenced if anticipated improvements in hemolytic parameters, platelet count, and kidney function are not seen. Plasma exchange is continued only if TTP (or catastrophic antiphospholipid syndrome) is confirmed. If a diagnosis of aHUS is made by exclusion of preeclampsia, short-term treatment with eculizumab can be started and reviewed depending on response to treatment and the results of complement gene testing.[78] Though there are limited data on eculizumab exposure and pregnancy, the benefit in treating organ-threatening disease outweighs risk. Treatment can be ceased if no complement abnormality is demonstrated and clinical recovery occurs quickly after delivery.[33]

ACUTE KIDNEY INJURY

Definition

International criteria for the diagnosis and staging of AKI (e.g., Acute Kidney Injury Network [AKIN]; Risk, Injury, Failure, Loss of Kidney Function, and End-Stage Kidney Disease [RIFLE]; Kidney Disease: Improving Global Outcomes [KDIGO]; see Chapter 72) have not been validated for use in pregnancy. Diagnosis of AKI in pregnancy is therefore based on serum creatinine concentrations. Meta-analysis data show that the upper reference limits (97.5th centile) for serum creatinine in pregnancy are 85%, 80%, and 86% of the female nonpregnant reference range in the first, second, and third trimesters, respectively.[8] This means that for a female reference range for serum creatinine of 45 to 90 μmol/L outside of pregnancy, serum creatinine concentrations greater than 0.86 mg/dL (76 μmol/L), 0.81 mg/dL (72 μmol/L), and 0.87 mg/dL (77 μmol/L) in respective trimesters should trigger investigation for AKI (or undiagnosed CKD).

Epidemiology

AKI is associated with an increased morbidity and mortality regardless of the underlying cause, and it should be considered a serious complication of pregnancy. Audit data demonstrate that AKI complicates 1.4% of obstetric admissions in the United Kingdom. Most cases occur in women without preexisting kidney disease, and it is estimated that more than 40% may be unrecognized by the treating clinical team,[15] masked by gestational changes, the limitations of serum creatinine, and by physiologic oliguria in the immediate postpartum period.

The development of AKI in pregnancy follows a bimodal distribution with two incidence peaks: the first and third trimesters. Prerenal causes are more common in the first trimester because of hyperemesis gravidarum and septic abortion, which remains a common global cause of pregnancy-associated AKI. The most common etiologies in late pregnancy are preeclampsia and hemorrhage.

Etiology and Pathogenesis

The etiology of pregnancy-associated AKI can be considered according to the trimester in which it presents, which aids in establishing an appropriate differential (Table 44.8). Diagnosis may be complicated by the overlapping clinical phenotype of pregnancy-associated conditions. Table 44.7 outlines the differentiating clinical features of preeclampsia, HELLP syndrome, aHUS/TTP, and AFLP.

TABLE 44.8 Causes of Acute Kidney Injury in Pregnancy

Gestation	Diagnosis	Clinical Features
Early	Hyperemesis gravidarum	Nausea, vomiting, ptyalism
	Septic abortion/miscarriage	Abdominal pain, vaginal bleeding, hypotension
	Acute retention	Retroflexed uterus
Mid-late	Preeclampsia/HELLP	New-onset hypertension after 20 weeks' gestation plus evidence of maternal endothelial dysfunction and/or uteroplacental dysfunction
	Ureteral obstruction	Increased risk if single kidney (including transplant), autonomic neuropathy, polyhydramnios, multiple pregnancy, obstructed labor
	Placental abruption	Vaginal bleeding, abdominal pain, uterine tenderness
	AFLP	Vomiting, polydipsia, jaundice, elevated transaminases, hypoglycemia
	Microangiopathic hemolytic anemia (TTP/HUS)	Hemolysis and end organ damage including kidney failure, neurologic symptoms, heart disease
Peripartum	Chorioamnionitis	Tachycardia, fever, uterine tenderness, abnormal lochia, prolonged rupture of membranes
	Postpartum hemorrhage	Hemodynamic instability
	Ureteric injury	Operative delivery, fever, leucocytosis, pain, persistent ileus
	NSAIDs	Hyperkalemia, exacerbation of hypertension, fluid retention
Any	Urosepsis	Dysuria, back or flank pain, renal angle tenderness, hypotension
	Lupus nephritis	Proteinuria ± hematuria, malaise, joint pain, hair loss, rash, pancytopenia
	Glomerulonephritis	uPCR >30 mg/mmol or uACR >8 mg/mmol before 20 weeks warrants nephrology referral
	Interstitial nephritis	New drug exposure including antibiotics, NSAID, proton pump inhibitors, H_2 antagonists; systemic signs can include rash and fever
	Kidney stone disease	Renal colic; increased risk of AKI if single kidney
	Intravascular volume depletion	Sepsis, vomiting, cardiac failure, DKA

AFLP, Acute fatty liver of pregnancy; *AKI,* acute kidney injury; *DKA,* diabetic ketoacidosis; *HELLP,* hemolysis, elevated liver enzymes, and low platelet count; *HUS,* hemolytic uremic syndrome; *NSAID,* nonsteroidal antiinflammatory drug; *TTP,* thrombotic thrombocytopenic purpura *uACR,* urinary albumin/creatinine ratio; *uPCR,* urinary protein/creatinine ratio.

From Wiles KS, Banerjee A. Acute kidney injury in pregnancy and the use of non-steroidal anti-inflammatory drugs. *Obstet Gynaecol.* 2016;18:127–135.

Treatment

Fundamental to the management of AKI is supportive treatment to maintain kidney perfusion. However, assessment of the fluid state of the pregnant patient is complicated by physiologic reductions in blood and oncotic pressure. In addition, young pregnant women can compensate for hypovolemia and hypotension and may present with signs much later than expected. The significance of tachycardia and tachypnea in track and trigger systems, which should be based on parameters for pregnancy,[15] is important. Treatment specific to the etiology of AKI, such as antibiotics in sepsis, should be administered promptly.

If AKI leads to hyperkalemia, calcium salts for cardiac stabilization can be safely given in pregnancy. There are limited data on the use of oral potassium binders (patiromer and sodium zirconium cyclosilicate) in pregnancy, but systemic absorption is limited, so benefit in managing hyperkalemia is likely to outweigh any theoretical risk. Insulin with glucose can be used as a temporizing measure to increase intracellular potassium shift while definitive treatment of AKI is undertaken.

Drug doses may need to be adjusted in AKI, including antibiotics, anticoagulants, insulin, and opiate analgesia. The use of nonsteroidal antiinflammatory drugs, which often form part of a standard postpartum analgesic protocol, should be avoided in women with AKI.

Dialysis

Indications for kidney replacement in pregnancy mirror those in the nonpregnant population and include metabolic acidosis, hyperkalemia, and fluid overload refractory to medical treatment. Uremic symptoms (encephalopathy or pericarditis) are very rarely encountered in pregnancy, as dialysis is usually commenced in women with advanced CKD at lower serum urea concentrations than outside of pregnancy due to the risk of fetotoxicity. It is generally recommended to consider initiation of dialysis at blood urea nitrogen (BUN) greater than 42 mg/dL (serum urea >15 mmol/L) depending on etiology, trajectory, and plans for delivery. Both peritoneal dialysis and hemodialysis have been used in pregnancy. However, there are more data on the use of hemodialysis, which is preferentially used as it offers the capacity to increment dialysis provision as required, aiming for a predialysis BUN less than 35 mg/dL (urea <12.5 mmol/L) in contemporary cohorts.[33] Dialysis in pregnancy is discussed in more detail in Chapter 45.

OVARIAN HYPERSTIMULATION SYNDROME

Definition and Epidemiology

Ovarian hyperstimulation syndrome (OHSS) is an iatrogenic complication of ovarian stimulation therapy, which is used to increase the number of oocytes available for assisted reproductive technology. The clinical picture is of significant fluid shifts detectable as ascites and hemoconcentration. Thromboembolism, kidney injury, and pleural or pericardial effusions represent severe disease. OHSS is estimated to complicate between 0.5% and 5% of stimulatory cycles.

Pathogenesis

OHSS is thought to be due to the release of proinflammatory mediators including VEGF, cytokines, prostaglandins, and histamine, which are produced in response to human chorionic gonadotrophin (hCG) on a background of supraphysiologic ovarian stimulation. These factors increase vascular permeability, resulting in ascites, pleural and pericardial effusions, and edema. Women with severe OHSS are estimated to have lost 20% of their circulating volume.

Clinical Manifestations

Symptoms include abdominal bloating and pain, nausea and vomiting, peripheral edema, oliguria, breathlessness, and orthopnea. Venous thromboembolism can occur. The combination of elevated hematocrit, reduced serum osmolality, and hyponatremia is suggestive of OHSS. Patients should be investigated with full blood count and hematocrit; serum creatinine, electrolytes and osmolality; liver function tests; C-reactive protein; β-hCG; and coagulation profile. Abdominal ultrasound imaging may help clarify the diagnosis. OHSS is not a common cause of fever or peritonitis, in which case ovarian torsion or rupture, intraabdominal infection, and ectopic pregnancy should be excluded.

Management

OHSS is self-limiting, with an average duration of 7 days in nonpregnant women and 10 to 20 days in pregnant women. In the woman with moderate to severe OHSS, hospital admission is required for correcting volume depletion; monitoring and correcting electrolyte abnormalities (particularly hyperkalemia); and providing analgesia, nutrition and psychological support, prophylaxis of venous thromboembolism, and respiratory function support. If IV fluids are necessary, crystalloids are used first line, with close monitoring because of the possibility of third-space accumulation. Paracentesis is sometimes needed to improve symptoms and respiratory function, in which case human albumin solution as a plasma volume expander should be considered. Prophylactic anticoagulation is required because of the risk for thromboembolism.

Women with underlying kidney disease have a higher risk of adverse outcomes in the event of OHSS. In vitro fertilization cycles using gonadotrophin-releasing hormone (GnRH) antagonists have been found to have a lower incidence of OHSS compared with cycles where GnRH agonists are used. Incidence is also higher in cycles when conception occurs compared with cycles without conception, and higher still in cycles resulting in multiple pregnancy, highlighting the important role of endogenous hCG. Stimulation followed by later frozen-embryo transfer may therefore be opted for, rather than fresh-embryo transfer with stimulation and pregnancy in the same cycle.

SELF-ASSESSMENT QUESTIONS

1. Which of the following does not occur in normal pregnancy?
   - **A.** Lower serum osmolality
   - **B.** Hypernatremia
   - **C.** Elevated glomerular filtration rate
   - **D.** Glycosuria
   - **E.** Reduced serum albumin

2. Which of the following is not an indication for delivery in preeclampsia?
   - **A.** Proteinuria 2 g/day
   - **B.** Gestation 37 weeks or more
   - **C.** Pulmonary edema
   - **D.** Rising serum creatinine

E. Hemolysis, elevated liver enzymes, and low platelet count (HELLP)

3. Which one of the following syndromes causing acute kidney injury is least likely to recover after delivery?
   A. Preeclampsia
   B. HELLP syndrome
   C. Hemolytic uremic syndrome
   D. Acute fatty liver of pregnancy
   E. Acute urinary retention
4. Which of the following can be used to predict the need for delivery in suspected preeclampsia?
   A. Proteinuria
   B. Placental growth factor concentrations
   C. Relaxin concentration
   D. Renin concentration
   E. Angiotensin receptor antibody concentration
5. Which of the following can be given in early pregnancy to reduce the risk of preeclampsia?
   A. Folic acid
   B. Vitamin D
   C. Iron
   D. Aspirin
   E. Hydralazine
6. Which of the following is *not* a risk factor for preeclampsia?
   A. First pregnancy
   B. Previous preeclampsia
   C. Interbirth interval less than 1 year
   D. Chronic kidney disease
   E. Antihypertensive requirement before 20 weeks' gestation

Pregnancy With Preexisting Kidney Disease

Kate Wiles, Mark A. Brown, Kate Bramham

Historically, kidney disease was considered a contraindication to pregnancy, but now many pregnant patients with chronic kidney disease (CKD) have successful outcomes. To achieve this, nephrologists and obstetricians need to be skilled in disease optimization before pregnancy, counseling regarding possible pregnancy outcomes, and antenatal and postpartum management of such patients.

ADVERSE EFFECTS OF CHRONIC KIDNEY DISEASE ON PREGNANCY OUTCOMES

CKD affects up to 6% and 9% of women of reproductive age in high- and low-income countries, respectively, approximately one-third of whom have stages 3 to 5 CKD.[1] Pregnancy rates are lower in women with CKD. In Australia and New Zealand, women with kidney transplants and on dialysis had severalfold fewer births compared with the general population (21.4 vs. 5.8 vs. 61.9 live births/1000 women/year: in transplant, dialyzed, no kidney replacement therapy).[2]

More recent studies report an increase in live birth rates even in those with more advanced CKD,[3,4] with considerable improvements in outcomes compared with historic data, likely in part because of enhanced fetal surveillance and neonatal intensive care. The following key prepregnancy factors are the main predictors of pregnancy outcomes:

- Degree of reduction in glomerular filtration rate (GFR)/elevation in serum creatinine
- Presence of coexisting hypertension
- Amount of proteinuria

In most circumstances, these features are more important in predicting outcome than the mother's specific kidney disease etiology.

Traditionally, most women with mild kidney impairment (serum creatinine < 1.5 mg/dL [130 μmol/L]) and controlled hypertension were thought to have a good pregnancy outcome. However, even CKD stages 1 and 2 are associated with a higher rate of preeclampsia and perinatal mortality, preterm delivery, and small for gestation age rates.[4,5] Development of superimposed preeclampsia appears higher in women with a preconception creatinine value of less than 1.4 mg/dL (124 μmol/L) but greater than 0.9 mg/dL (80 μmol/L) in early pregnancy and, indeed, even in women with normal GFR but dipstick-positive proteinuria and one or more other risk factors for preeclampsia.[6] Those with serum creatinine greater than 1.5 mg/dL (133 μmol/L), particularly when accompanied by hypertension and heavy proteinuria, have a higher chance of preterm deliveries and maternal complications, including loss of kidney function. Pregnancy outcomes according to severity of kidney dysfunction are presented in Boxes 45.1 and 45.2.

Severity of Hypertension

Preexisting hypertension is associated with significantly higher risk for adverse pregnancy outcomes than the general population[7] and in pregnant women with CKD.[8] Preexisting hypertension conferred an approximate doubling of risk for severe neonatal outcome (early preterm delivery, requirement for neonatal intensive care, and/or small for gestational age infant) in a prospective Italian cohort study.[3,9] In a contemporary cohort of women with CKD stages 3 or higher, chronic hypertension was the strongest predictor of preterm delivery before 34 weeks and was associated with a greater decline in maternal kidney function in pregnancy.

Proteinuria

Preexisting proteinuria is another risk factor for poor pregnancy outcome.[3,10] Women with prepregnancy CKD stages 3 to 5 and a urine protein creatinine ratio greater than 100 mg/mmol (>0.9 mg/mg) before pregnancy or prior to 20 weeks' gestation are more than twice as likely to deliver a baby weighing less than the 10th percentile compared with women with CKD and less proteinuria.

MANAGEMENT COMMON TO ALL PREGNANCIES WITH PREEXISTING KIDNEY DISEASE

The general principles of management of pregnancy in women with CKD are summarized in Box 45.3.

Prepregnancy Counseling

All women with CKD should receive prepregnancy counseling, especially those with CKD stages 3 to 5, but women with CKD 1 or 2 may also have worse pregnancy outcomes than the general population.[4] Issues that should be covered in counseling are shown in Box 45.4, including relevant information on pregnancy outcomes in CKD shown in Boxes 45.1 and 45.2.

Pregnancy may be unplanned in women with CKD, and detailed discussion regarding maternal and fetal outcomes should be provided in early pregnancy. Furthermore, pregnancy may be the first opportunity for identification of CKD; for example, in a prospective cohort study 16% of women with CKD were diagnosed in pregnancy.[11]

Fertility Assessment

Fertility is reduced in women with moderate to severe CKD. Some individuals have raised prolactin, luteinizing hormone, and lower antimüllerian hormone concentrations, suggesting altered pituitary axis response and/or reduced ovarian follicle reserve.[12,13] With the advent of assisted conception, nephrologists may be approached for advice regarding hormone stimulation therapies and embryo transfer. There is no evidence that hormonal manipulation has additional adverse consequences in women with CKD unless they develop ovarian hyperstimulation syndrome (see Chapter 44), which may further compromise kidney function. Single embryo transfer is recommended because of the additional maternal and neonatal risk for multiple fetal pregnancies.

BOX 45.1 Maternal Kidney Outcomes According to Prepregnancy CKD Stage

CKD Stage 1 to 2
- Permanent loss of GFR in <10% of cases
- Greatest risk if GFR is <40 mL/min and proteinuria is >1 g/day
- Major determinant of progressive kidney loss is hypertension
- 40% risk for preeclampsia if baseline proteinuria is >500 mg/day

CKD Stage 3
- Decline or permanent loss of GFR in 30% of cases
  - Increased to 50% if uncontrolled hypertension
  - 10% ESKD soon after pregnancy
  - Accelerated decline in GFR because of pregnancy by 1.7–2.1 years

CKD Stage 4
- Progression to ESKD highly likely during or soon after pregnancy
  - Accelerated decline in GFR because of pregnancy by up to 4.9 years

Note that the Modification of Diet in Renal Disease (MDRD) formula and Chronic Kidney Disease-Epidemiology (CKD-Epi) formula for estimation of glomerular filtration rate are not valid in pregnancy.
CKD, Chronic kidney disease; *ESKD,* end-stage kidney disease; *GFR,* glomerular filtration rate.

BOX 45.2 Fetal Outcomes According to Maternal Prepregnancy CKD Stage[3]

Outcomes After Accounting for First-Trimester Miscarriage

CKD Stage 1 to 2
- Live births in most pregnancies
- Up to 50% preterm delivery, up to 18% small for gestational age

CKD Stage 3
- Live births in most pregnancies
- Up to 60% preterm delivery (mainly iatrogenic due to superimposed preeclampsia/fetal growth restriction)

CKD Stage 4 to 5
- Live births in most pregnancies
- 90% preterm delivery, two-thirds small for gestational age, 50% admission to neonatal unit

CKD, Chronic kidney disease.
Note that the Modification of Diet in Renal Disease (MDRD) formula and Chronic Kidney Disease-Epidemiology (CKD-Epi) formula for estimation of glomerular filtration rate are not valid in pregnancy.

BOX 45.3 Principles of Antenatal Care With CKD[68]

- Management of hypertension aiming for BP < 135/85 mm Hg
- Aspirin (75–150 mg daily) for all women with CKD
- Regular medication review: Discontinue statins, ACE inhibitors, ARBs
- Correct interpretation of gestational changes in serum creatinine
- Clinical assessment and maintenance of volume homeostasis
- Interpretation and management of proteinuria, including nephrotic syndrome
- Identification of superimposed preeclampsia
- Identification and management of urinary tract infection
- Consideration of the primary kidney disease
- Assessment for fetal well-being and consider if delivery is indicated (see Box 43.5)

ACE, Angiotensin-converting enzyme; *ARBs,* angiotensin receptor blockers; *BP,* blood pressure; *CKD,* chronic kidney disease.

BOX 45.4 Prepregnancy Counseling for Women With Chronic Kidney Disease

Maternal Risks
- Accelerated decline in glomerular filtration rate, sometimes precipitating dialysis during pregnancy or soon after in women with advanced chronic kidney disease
- Severe maternal hypertension with risk for stroke
- Superimposed preeclampsia with kidney, hepatic, thrombotic, or bleeding and neurologic risks
- Exacerbation of proteinuria, including nephrotic syndrome with risks for thrombosis

Fetal Risks
- Fetal growth restriction or intrauterine fetal death from placental insufficiency
- Preterm delivery, with both short-term and long-term consequences
- Teratogenicity and/or fetotoxicity of some drug therapies for kidney disease
- Inheritance of a kidney disorder

Contraception should be offered to women with CKD of reproductive age who do not wish to conceive, including those on dialysis and with kidney transplants. For the majority, estrogen-containing preparations are contraindicated because of exacerbation of hypertension or thrombotic risk, and progesterone methods including the progesterone-only pill, implant, and intrauterine device are preferred. Women taking immunosuppression have historically been advised against intrauterine devices because of concerns related to failure and pelvic inflammatory disease, although there is no robust evidence to support this recommendation.[14]

Urinalysis: Proteinuria

Preexisting proteinuria is often exacerbated during pregnancy because of increased glomerular permeability and plasma blood flow and stopping renin-angiotensin system blockade. However, when there is an increase in protein excretion during pregnancy in women with kidney disease, there are few therapeutic options apart from ensuring blood pressure (BP) control (see later discussion) and managing thrombotic risk. Isolated nonnephrotic proteinuria may develop de novo during pregnancy, which usually indicates one of the following scenarios and usually does *not* require antenatal kidney biopsy:

1. Developing preeclampsia (after 20 weeks of gestation).
2. No pregnancy complications occur, proteinuria resolves postpartum *(gestational proteinuria).*
3. Intrinsic glomerular disease has developed either before or during pregnancy and remains postpartum (uncommon). Management of glomerulonephritis (GN) in pregnancy is discussed in more detail later.

Serum albumin falls in most pregnancies as a result of volume expansion and may be less than 30 g/L even in healthy women, thus hypoalbuminemia is not a reliable indicator of nephrotic syndrome. Similarly, peripheral edema and a rise in serum cholesterol are commonly seen in healthy pregnancy. A spot urine protein-to-creatinine ratio (uPCR) greater than 300 mg/mmol (or >3 mg/mg) generally indicates protein excretion is greater than 3 g/day. Diuretics are rarely needed but are indicated for pulmonary edema.

Nephrotic syndrome in pregnancy may create a prothrombotic state and a propensity for intravascular volume contraction (see Chapter 16) that may lead to reduced uteroplacental compromise and worsening maternal kidney function. Treatment requires prophylaxis of thromboembolism with low-molecular-weight heparin, and

maternal kidney function surveillance. Thresholds for commencing heparin are undefined, but most clinicians initiate treatment at higher serum albumin and/or lower proteinuria concentrations than in the nonpregnant state because of the prothrombotic nature of pregnancy. We recommend prophylaxis of venous thromboembolism for all pregnant women with uPCR greater than 300 mg/mmol in pregnancy in the absence of contraindications and where delivery is not anticipated within 12 hours. Lesser degrees of proteinuria (uPCR 100–300 mg/mmol) are considered a risk factor for thromboembolic events, and prophylaxis may be warranted if there are additional risk factors. Low-molecular-weight heparins are safe during pregnancy and do not cross the placenta. Dose adjustment may be indicated for women with CKD. Warfarin is teratogenic and should be avoided during pregnancy.

Hypertension

Many pregnant patients with CKD will not exhibit the usual first-trimester fall in BP, and, in many women, BP increases as the pregnancy progresses. Normal pregnancy is accompanied by significant volume expansion, which does not induce hypertension. However, in CKD, there is often inability to excrete a sodium load with accompanying hypertension. Other potential contributory factors include stimulation of the renin-angiotensin and sympathetic nervous systems; alterations in endothelial factors such as prostacyclin, nitric oxide, and endothelin; and drugs such as calcineurin inhibitors and corticosteroids. Regardless of its cause, persistence of hypertension is an adverse factor in pregnancy outcome and inadequate use of antihypertensives in pregnancy has been associated with poorer pregnancy outcomes, at least in women with kidney transplants.[15] BP often rises after delivery and should be monitored postpartum and treated according to nonpregnant targets, with agents that are safe in lactation.

Hypertension in pregnancy is defined as BP of 140/90 mm Hg or greater (see Chapter 44). A large randomized controlled trial comparing tight BP control (target diastolic blood pressure [DBP], 85 mm Hg) or less tight control (target DBP, 100 mm Hg) reported no difference in neonatal outcomes, but a reduction in episodes of severe maternal hypertension including requirement for intravenous (IV) antihypertensive treatment and associated liver and platelet abnormalities in those with tighter BP control[16]; thus tight blood pressure control is recommended for pregnant women with hypertension.

BP targets for nonpregnant proteinuric women with CKD are lower than pregnancy recommendation. Although there is no direct evidence for optimum BP in pregnant women with CKD, BP less than 130/80 mm Hg may be recommended to avoid prolonged periods with suboptimal control, while avoiding sustained blood pressures less than 110/70 mm Hg. Suitable antihypertensive agents include labetalol, nifedipine, methyldopa, hydralazine, and prazosin in conventional doses (see Chapter 44). Choice of first-line agent is based on availability, licensing, and clinician preference and experience. The frequency of dosing may need to be increased because of altered drug metabolism in pregnancy. Diltiazem may have a small benefit in reducing proteinuria, but this has not been addressed specifically among pregnant patients. Diuretics are not recommended during pregnancy because any reduction in maternal plasma volume may have adverse effects on uteroplacental or kidney perfusion but are indicated for the treatment of pulmonary edema or where substantial peripheral edema leads to skin breakdown.

Angiotensin-converting enzyme (ACE) inhibitors or angiotensin receptor blockers (ARBs) cannot be used in pregnancy because of fetotoxicity in the second and third trimesters. It had previously been recommended to cease ACE inhibitors in advance of pregnancy; however, population studies have shown no increased risk compared with women exposed to other antihypertensive agents in the first trimester.[17] Women with kidney or cardiac indications can therefore continue ACE inhibitors during the unknown length of time it will take to conceive, provided they are counseled to undertake regular pregnancy testing and stop at a positive pregnancy test. There are less data supporting ARB safety, so these agents are usually discontinued in advance of pregnancy. Enalapril or captopril may be used in patients after delivery for those who wish to breastfeed. Aldosterone antagonists should be avoided in pregnancy, and atenolol is associated with fetal growth restriction.

KIDNEY BIOPSY IN PREGNANCY

It is rare to require kidney biopsy in pregnancy except for:

1. De novo onset of nephrotic syndrome or unexplained kidney injury with abnormal urine sediment in the first and early second trimester when the risks of kidney biopsy are lower[18] and when a histologic diagnosis will change management in pregnancy. Nephrotic syndrome after this stage can generally be managed until delivery, with postpartum investigations for those with persistent proteinuria/nephrosis that cannot be attributed to preeclampsia.
2. Where the clinical picture warrants exclusion of acute rejection in a female with a kidney transplant.

Complications of kidney biopsy in pregnancy are more common in the late second and third trimester of pregnancy compared with those in general nephrology practice; a systematic review reported bleeding complications in 7% of biopsies performed in pregnancy compared with 1% performed postpartum.[18]

SUPERIMPOSED PREECLAMPSIA

Preeclampsia (see Chapter 44) is a placental disorder that presents after 20 weeks of gestation and has several predisposing risk factors, including an association with increasing severity of CKD.[19] Superimposed preeclampsia in a female with CKD frequently leads to exaggerated hypertension and proteinuria with risks for nephrotic syndrome, progression of maternal kidney impairment, fetal growth restriction, preterm delivery, and perinatal mortality.

Superimposed preeclampsia is challenging to diagnose in a patient with preexisting hypertension, elevated serum creatinine, and/or proteinuria; however, when accompanied by additional features such as clonus, abnormal liver transaminases, or new-onset thrombocytopenia, superimposed preeclampsia is likely, although few patients with superimposed preeclampsia present with extrarenal manifestations[11] and delivery decisions may be required without waiting for other severe systemic features to develop. Proposed criteria for diagnosis of superimposed preeclampsia in patients with CKD are highlighted in Table 45.1.

Placental growth factor (PlGF) testing (reduced in isolation or increased as a ratio to soluble fms-like tyrosine kinase 1 [sFlt-1]) can be used to predict the need for delivery due to preeclampsia (see Chapter 44). PlGF-based testing has been shown to distinguish preeclampsia without CKD from pregnant patients with CKD without preeclampsia in a small cohort.[20] A larger, prospective cohort including patients with chronic hypertension or kidney disease reported comparable diagnostic performance for superimposed preeclampsia and preeclampsia without preexisting disease.[11] PlGF-based testing offers a quantitative assessment of placental function and, at gestational concentrations, will not measure maternal endothelial disease caused by CKD. A recent prospective cohort study has shown increased surveillance for need for delivery should take place in patients with CKD and plasma PlGF less than 150 pg/mL after 20 weeks' gestation, compared with a threshold of less than 100 pg/mL in women without CKD. However, this testing

TABLE 45.1 Diagnostic Criteria for Preeclampsia[a]

Diagnostic Criteria	Preeclampsia	Preeclampsia in Women With CKD
Essential	>20 weeks' gestation New hypertension: systolic BP ≥ 140 mm Hg or diastolic BP ≥ 90 mm Hg on two occasions	Hypertension: • In women without chronic hypertension: as for preeclampsia • In women with chronic hypertension: no diagnostic threshold, de novo severe BP (systolic BP > 160 or diastolic BP > 110 mm Hg) or an increase in treatment to maintain BP < 160/110 mm Hg used in research cohorts[6,8]
Additional	Proteinuria: • uPCR > 30 mg/mmol (or 0.3 µg/mg) • uACR > 8 mg/mmol (or >800 µg/mg) • > 300 mg/24 h (not indicated if uPCR available) • Dipstick > 2+ (if other methods unavailable) Serum creatinine: • Serum creatinine>1.0[b] to 1.1[c] mg/dL (90–100 µmol/L)[d] • Doubling of serum creatinine less than 1.1 mg/dL (100 µmol/L)[c,d]	Proteinuria: • In women with nonproteinuric CKD: as for preeclampsia • In women with proteinuric CKD: no diagnostic threshold, > 100% increase and UPCR ≥ 0.3 mg/mg (> 30 mg/mmol) used in research cohorts[6,8] Serum creatinine: • In women with CKD and preserved excretory function: as for preeclampsia • In women with CKD and abnormal prepregnancy function: no consensus on diagnostic threshold for change in creatinine, > 50% increase within 7 days used in research cohorts[8]

[a]Diagnosis requires one essential and one additional clinical feature.[84–87]
[b]Modified from Mills KT, Xu Y, Zhang W, et al. A systematic analysis of worldwide population-based data on the global burden of chronic kidney disease in 2010. *Kidney Int*. 2015;88:950–957.
[c]Modified from Bramham K, Briley AL, Seed PT, et al. Pregnancy outcome in women with chronic kidney disease: A prospective cohort study. *Reprod Sci*. 2011;18:623–630.
[d]Severe features.
BP, Blood pressure; *CKD*, chronic kidney disease; *uACR*, urinary albumin/creatinine ratio; *uPCR*, urinary protein/creatinine ratio.

is not needed if increased surveillance is already planned and decisions regarding delivery should not be made on the basis of PlGF results alone. The indications for delivery in patients with preeclampsia are the same in women with or without underlying CKD (Box 45.5). PlGF can be a useful adjunct to interpreting gestational changes in hypertension, proteinuria, and creatinine in patients with CKD.

Limited studies suggest that aspirin is of benefit in reducing the risk of superimposed preeclampsia and perinatal death in patients with underlying kidney disease.[21] Our practice is to use low-dose aspirin (75–150 mg/day) for all patients with CKD, using data generalized from high-risk cohorts (see Chapter 44).

ASSESSMENT OF FETAL WELL-BEING

Preterm delivery, fetal growth restriction, and stillbirth are the major concerns for women with kidney disease, particularly if superimposed preeclampsia develops. Avoidance of preterm delivery reduced both short-term and lifelong complications, including higher mortality in later life.

Early pregnancy ultrasound between 11 and 14 weeks is advised to estimate accurately the expected date of delivery and to offer trisomy screening, followed by fetal morphology scan at 18 to 20 weeks of gestation to screen for fetal anomalies, assess fetal well-being, and check placental function and position. Blood human chorionic gonadotropin (hCG) levels are often elevated in patients with kidney impairment and may overestimate the risk for fetal abnormalities.[22]

Additional ultrasound scans should be offered at 2- to 4-weekly intervals from 28 weeks of gestation in women with CKD to assess fetal growth and amniotic fluid volume, with Doppler studies of umbilical artery blood flow. Absent end-diastolic flow on umbilical artery velocimetry is usually an indication for the need for delivery, depending on gestation. The development of reversed end-diastolic flow indicates a high risk for fetal hypoxia, acidosis, and death.

BOX 45.5 Indications for Delivery in Women With Preeclampsia and Chronic Kidney Disease

- Gestation ≥37 weeks
- Inability to control blood pressure
- Deteriorating kidney function
- Neurologic abnormalities, such as eclampsia, headaches with accompanying clonus and hyperreflexia, or repeated visual scotomata
- Worsening thrombocytopenia
- Increasing liver transaminase levels
- Failure of fetal growth
- Reversed or absent end-diastolic flow on cardiotocography

The decision to deliver is based on a global clinical assessment rather than on specific thresholds for each parameter.

TIMING OF DELIVERY

In patients with stable CKD and no evidence of fetal compromise, pregnancies should be continued to term and spontaneous labor awaited. The method of delivery, either vaginal or by cesarean delivery, is determined by obstetric issues rather than CKD. Indications for delivery are described in Box 45.5.

The goal is to time delivery such that the risks of prematurity are less than the risks of the pregnancy continuing, which requires multidisciplinary consultation among obstetrician, neonatologist, nephrologist, or obstetric medicine physician and midwife. Decision making regarding the timing of iatrogenic preterm delivery is a balance between the need for fetal maturity and concern regarding maternal health, which for patients with CKD is usually the development of superimposed preeclampsia or worsening kidney function.

Final pregnancy outcomes for patients with CKD are usually successful for both mother and baby, although there may be long-term implications

for childhood development and maternal health. Clinicians can take a positive approach, at all times emphasizing the need for diligence and assessment for potential complications, and aim to relieve some of the stress that accompanies pregnancy for patients with CKD.

COURSE OF CHRONIC KIDNEY DISEASE DURING AND AFTER PREGNANCY

For most women with CKD, the risk for progression of kidney disease during pregnancy is determined by the severity of kidney disease prior to pregnancy, chronic hypertension, and the development of superimposed preeclampsia, rather than the underlying cause of CKD.

Rapid deterioration during a pregnancy is unlikely in patients with mild CKD (prepregnancy CKD stage 1 to 2), other than lupus nephritis, which may flare. However, 50% of patients with moderate baseline kidney impairment (serum creatinine > 1.5 mg/dL [130 µmol/L]) or worse have a significant rise in serum creatinine in the third trimester or early postpartum, and almost 1 in 5 of these will require kidney replacement within 6 months.[23] In a series of 49 women with stage 3 to 5 CKD before conception whose pregnancy proceeded beyond 20 weeks, GFR was lower after pregnancy than before conception, and this fall was predicted by the combination of preconception GFR less than 40 mL/min/1.73 m^2 and proteinuria greater than 1 g/day, but not by GFR alone.[24] In a more recent study of 179 pregnancies in women with prepregnancy CKD stages 3 to 5 not on dialysis, 46% of women had lost 25% of their prepregnancy eGFR or required kidney replacement therapy by 1 year postpartum. There was a measurable loss of GFR associated with pregnancy, equating to 1.7, 2.1, and 4.9 years of prepregnancy kidney disease for women with prepregnancy CKD stages 3a, 3b, and 4 to 5, respectively. Chronic hypertension was a significant predictor of pregnancy-associated loss of kidney function, and absence of an early fall in maternal serum creatinine was a significant predictor of delivery before 34 weeks' gestation and further loss of maternal kidney function.[3]

The course of kidney disease postpartum is unpredictable. Some women with stable antenatal kidney function acutely deteriorate postpartum. Surveillance and hypertension control should continue postpartum. ACE inhibitors (captopril or enalapril if breastfeeding) or ARBs (after lactation) can be commenced after delivery for their antiproteinuric effect.[25]

Norwegian women with biopsy-proven kidney disease had slightly faster progression to a requirement for kidney replacement if their pregnancy required preterm delivery but not if they had preeclampsia.[26] A neglected issue is the association between preterm birth, low birth weight, and later-life cardiovascular and kidney disease. This may transmit an increased risk for kidney disease to offspring even if the kidney disease is not hereditary. On balance, it is prudent to consider both preeclampsia and preterm delivery as risk factors for later kidney disease.

MANAGEMENT OF COMMON KIDNEY DISORDERS DURING PREGNANCY

Immunoglobulin A Nephropathy

Pregnancy outcomes for patients with immunoglobulin A (IgA) nephropathy are generally positive, and comparable to other causes of CKD. Long-term follow-up of women with IgA nephropathy diagnosed in childhood showed that pregnancy was complicated by hypertension in half of them and preterm delivery in one-third.[27] A Swedish cohort study comparing pregnancy outcomes in women with and without IgA nephropathy described an increased risk of preterm birth (adjusted odds ratio [OR], 2.69), preeclampsia (adjusted OR, 4.29), and small for gestational age (adjusted OR, 1.84), but no reduction in live birth[28] rates, although stratification according to CKD stage was not possible. Pregnancy in IgA nephropathy did not accelerate kidney dysfunction in those with CKD stage 1 or 2,[29–31] but proteinuria may increase in the third trimester.[32] However, there is limited evidence that women with proteinuria before pregnancy[33] and those with preterm delivery, low birth weight, and preeclampsia[34] have a more rapid decline in function postpartum.

Diabetic Kidney Disease

In the United Kingdom, more pregnant women have type 2 than type 1 diabetes, and 8% of pregnant women with type 1 diabetes and 5% with type 2 diabetes have diabetic kidney disease (DKD).[35] Diabetes per se increases risks for congenital abnormality, preterm birth, cesarean section, and perinatal mortality. The presence of overt nephropathy more than doubles the risk for fetal death after 20 weeks. There is an added risk for congenital abnormalities if blood sugar was not adequately controlled at the time of conception, which is not uncommon. For example, the UK National Audit reported that 7 out of 8 women were not well prepared for pregnancy according to national guidelines.[35] A large cohort study indicated that the presence of DKD is an independent risk factor for congenital abnormalities.[36]

The Diabetes Control and Complications Trial and EURODIAB trial both concluded that pregnancy does not increase progression to albuminuria. It is likely that women with DKD have worse pregnancy outcomes than women with other causes of CKD and comparable kidney function. For example, a retrospective cohort study of women with type 1 diabetes and DKD (median prepregnancy serum creatinine 0.8 mg/dL [70 µmol/L]) reported high complication rates (e.g., preeclampsia 42%, preterm before 34 weeks 21%, neonatal care admission 49%).[37] In a recent cohort of women with moderate and advanced CKD, none of the 11 women with DKD had a normal pregnancy course.[3]

The outcome of DKD during pregnancy depends on the usual factors of severity of kidney impairment and hypertension. Specialist-led meticulous control of blood glucose and BP during pregnancy is required. One study showed that failure to achieve mean arterial pressure (MAP) less than 100 mmHg was associated with increased risk for early delivery, even after adjusting for glucose control.[38] Risk for permanent decline in kidney function for women with more severe DKD has not been formally evaluated. Ideally, ACE inhibitors (enalapril or captopril if breastfeeding) should be introduced soon after delivery for prevention of progression of DKD.

Having gestational diabetes mellitus (GDM) without developing overt diabetes after the pregnancy is still associated with approximately 10% risk for microalbuminuria by age 50, an intermediate risk between that of nondiabetic and diabetic women.[39] This means that women with a history of GDM, not just those with type 1 or 2 diabetes, should be followed after pregnancy because of their risk for later developing diabetes.

Lupus Nephritis

Women with active disease at conception are more likely to have active lupus nephritis during pregnancy, which is then associated with high fetal risk, with approximately 1 in 5 pregnancies ending in miscarriage, stillbirth, or neonatal death.[40] Ideally, women with lupus should be in remission for at least 6 months before conception on medications known to be safe in pregnancy. Prepregnancy assessment may include cessation of renin angiotensin blockade to allow assessment of proteinuria, with repeat kidney biopsy before attempts to conceive if active disease is suspected.

In addition to low-dose aspirin to reduce the risk of superimposed preeclampsia, all women with previous lupus nephritis should receive hydroxychloroquine.[41] Hydroxychloroquine in pregnancy is associated with reduced risks of lupus flare and fetal growth restriction.[42–44]

Lupus nephritis flares are described in 30% of women during pregnancy and in 15% of women immediately postpartum,[45] but a prophylactic postpartum increase in corticosteroid dosing is not indicated. Although rare, the major cause of maternal death in lupus nephritis is sepsis, so immunosuppression should be maintained at the lowest possible dose to control disease.[46] New onset or a flare of lupus nephritis, evidenced by increasing proteinuria, active urine sediment, and rising serum creatinine, is a major concern. Distinguishing a flare of lupus nephritis from preeclampsia can be challenging because the phenotype of both conditions includes hypertension, proteinuria, kidney injury, and thrombocytopenia. A kidney biopsy can be arranged in the first and early second trimester when bleeding risks are lower, and only if a histologic diagnosis will change management in pregnancy. Serological markers of disease, including complement and double-stranded DNA antibody concentrations, may also be clinically helpful.

Lupus nephritis can be treated with corticosteroids and azathioprine in pregnancy. Tacrolimus is an alternative agent that has been used with increasing success in women with active lupus nephritis in pregnancy.[47] Cyclophosphamide and mycophenolate mofetil (MMF) are contraindicated in pregnancy because of teratogenicity and should be ceased at least 6 weeks before conception. MMF is associated with microtia (underdeveloped external ear), auditory canal atresia, cleft lip and palate, and micrognathia. Although cyclophosphamide has been used successfully in a few cases of lupus nephritis in later pregnancy after the period of fetal organogenesis, its use is not routinely recommended. Rituximab is not teratogenic but crosses the placenta and causes B-cell depletion in the fetus as in the mother[48] and is therefore not recommended for use in pregnancy, where other treatment options exist.[49] The use of belimumab in pregnancy is described in isolated case reports, with insufficient data to confirm safety.[50] There are no pregnancy-specific contraindications to the use of IV immunoglobulin and plasma exchange in pregnancy if clinically indicated.

Prior histologic class of lupus nephritis has no influence on pregnancy outcome. Predictors of poor pregnancy outcome include baseline creatinine greater than 0.9 mg/dL (79 μmol/L), proteinuria greater than 0.5 g/24 hours, antiphospholipid syndrome, hypertension, non-White ethnicity, and maternal disease flare.[51] A prospective cohort study of women with lupus, including those with mild nephritis, recently reported that pregnancy outcomes were favorable for women without adverse risk factors (including lupus anticoagulant, antihypertensive use, active disease, or low platelets), with 92% having uncomplicated pregnancies. However, when counseling about future pregnancies, women should be advised that even if their lupus nephritis has been well treated, they appear to have a greater risk for maternal complications and lupus flare in their next pregnancy than do women with systemic lupus erythematosus (SLE) who have never had nephritis; this is only partly explained by increased activity of the SLE at conception. Fortunately, fetal outcomes are not affected adversely in this group and postpartum GFR appeared unaffected.[52] This means that such patients need more surveillance during pregnancy than usual, to detect a kidney flare or preeclampsia, their two biggest maternal risks.

Women with anti-Ro and anti-La antibodies should be counseled regarding the risk for fetal heart block and neonatal cutaneous lupus, respectively. Hydroxychloroquine may reduce the risk for recurrent fetal heart block in patients with a previously affected infant, and this is indicated in pregnancy in women with lupus nephritis.[53] There is debate as to the optimum monitoring for congenital heart block with variable recommendations for fetal heart rate monitoring and echocardiography in the second trimester. Even if surveillance detects early-stage fetal heart block, the optimum treatment is unclear.

Reflux Nephropathy

Pregnancy outcomes in women with reflux nephropathy depend predominantly on preexisting kidney function and BP control as for other kidney diseases. An analysis of contemporary data (2000–2016) including 434 women with 879 pregnancies showed an increased risk of pregnancy-related hypertension (OR, 5.55) and preeclampsia (OR, 6.04), but no difference in preterm delivery compared with unmatched control pregnancies. A higher incidence of stillbirth has been reported, which warrants further analysis.

Women with reflux are more predisposed to urinary tract infection (UTI) throughout pregnancy, as are women who have had surgically corrected reflux in childhood. Around 20% of women with reflux nephropathy will develop UTI in pregnancy, with a 6% incidence of pyelonephritis in historical studies. Urine culture should be performed throughout pregnancy in those with underlying reflux nephropathy and treatment offered for confirmed bacteriuria. In the absence of evidence of harm, antibiotic prophylaxis is recommended to those with reflux nephropathy after a single confirmed infection, informed by urine culture, antimicrobial sensitivities, and patient preference.[49] Management of UTI in pregnancy is further discussed in Chapter 44.

Vesicoureteric reflux may be a familial disorder, estimated to affect 20% of infants with a positive parental family history, compared with a 1% to 2% frequency in the general population.[54] However, not all vesicoureteric reflux results in kidney parenchymal damage, and 80% of mild cases resolve in childhood (see Chapter 62).[55] Data are inadequate to define an evidence-based screening strategy for the offspring of women with reflux nephropathy. Expert consensus, based on observational data, is that infants of mothers with urinary tract abnormalities who had normal urinary tracts on antenatal ultrasound scans do not need further follow-up unless features of UTI are identified in childhood.[49]

Inherited Kidney Disorders

Although chronic hypertension is a risk factor for adverse pregnancy outcomes in autosomal dominant polycystic kidney disease (ADPKD),[56] normotensive women with ADPKD have comparable pregnancy outcomes to those of unaffected family members. A study of 54 women with ADPKD compared with 92 women with simple cysts showed increased rates of hypertension and preeclampsia but no difference in neonatal outcome.[57] Case reports suggest that there is no change in kidney volume in ADPKD because of pregnancy and uterine growth is not compromised.

Very few pregnancies have been described in women with Alport syndrome, but substantial gestational proteinuria with clinical nephrosis is recognized.[58]

Inherited kidney disorders are likely to have been diagnosed before pregnancy, and specific implications for the offspring should be discussed. For single-gene disorders, preimplantation diagnosis may be available, and referral for specialist counseling is recommended.

HEMODIALYSIS IN PREGNANCY

Significant improvements in outcomes of pregnant patients requiring dialysis during pregnancy have occurred over the past two decades, with fetal survival rising from less than 50% to almost 85%.[59] Pregnancy rates have also risen, with a 71% increase in delivery rate among women of reproductive age undergoing hemodialysis reported in the United States[60] from 2002 to 2015. Pregnancy rates in non-White women

treated with maintenance dialysis are also reported to be higher.[61] Improved outcomes have been associated with more intensive hemodialysis regimens, and advances in neonatal care have enabled survival for premature and growth-restricted infants. A Canadian cohort study reported significant improvement in birth weight and length of gestation in women who received prolonged dialysis (43 ± 6 hr/wk) compared with those with a more modest increment (17 ± 5 hr/wk).[62] A meta-analysis of 574 pregnancies in 543 patients reported that fewer dialysis hours per week was strongly associated with preterm delivery before 37 weeks.[63] Recommendations for managing hemodialysis during pregnancy are listed in Box 45.6.

Women of childbearing age undergoing dialysis have low rates of conceiving,[59] but increments in dialysis dose, such as nocturnal home hemodialysis, appear to be associated with increased fertility.[62] Women of childbearing age on maintenance dialysis who do not wish to conceive should therefore have access to safe and effective contraception (progesterone-only pill, progesterone implant, intrauterine device).

Initiating Dialysis for Progressive Chronic Kidney Disease

Dialysis should be commenced in pregnancy for the standard indications of hyperkalemia, acidosis, uremic symptoms and/or fluid overload. However, it is more common to initiate dialysis in pregnancy because of potential fetotoxicity of urea. The optimum serum urea concentration at which dialysis offers benefit in pregnancy is unknown and practice varies from routine commencement of dialysis at maternal blood urea nitrogen (BUN) 48 mg/dL[64] (or urea > 17 mmol/L) to dialysis only when BUN is consistently greater than 56 mg/dL (or urea > 20 mmol/L). We recommend that in progressive kidney disease, BUN greater than 42 mg/dL (or serum urea > 15 mmol/L) should initiate conversations about the risks, benefits, and logistics of hemodialysis in pregnancy, weighed with the risks of preterm delivery before dialysis initiation if the gestation is approaching or exceeds 34 weeks.[49] Dialysis initiated during pregnancy is probably associated with greater likelihood of successful pregnancy than for those on maintenance dialysis, perhaps because of the benefits of residual kidney function,[65] although this is not a consistent finding.[62]

Dialysis Regimens in Pregnancy

Differences in residual kidney function means that intensification of dialysis may not show the same benefit for women initiating dialysis in pregnancy as it does for women established on hemodialysis before pregnancy. Meta-analysis data demonstrating improved outcomes with intensification of dialysis do not include women starting dialysis after 20 weeks' gestation.[63] In a study of intensive dialysis in pregnancy, a very small subgroup analysis of women starting hemodialysis after conception showed no significant difference in gestational age at delivery between those receiving 33 ± 6 hours per week ($n = 4$) compared with 15 ± 4 hours per week ($n = 13$).[62]

A graded increase in dialysis guided by residual kidney function and biochemical parameters has been described with initial weekly hours of hemodialysis determined according to residual urine output and time on dialysis before pregnancy, with dialysis provision then adjusted according to midweek predialysis serum urea, BP, weight gain, and polyhydramnios. In this cohort, linear regression identified a midweek predialysis BUN 35 mg/dL (or serum urea 12.5 mmol/L) as discriminatory in determining successful pregnancy outcome.[66] We therefore recommend initiating hemodialysis at 2 to 3 hours, 3 times per week in women newly starting dialysis in pregnancy for a fetal rather than maternal indication, and adjusting provision to achieve midweek predialysis urea less than 12.5 mmol/L (BUN 35 mg/dL).

BOX 45.6 Managing Hemodialysis During Pregnancy[49]

Prepregnancy

Discuss risks of pregnancy (miscarriage, fetal death, fetal growth restriction, preterm delivery, preeclampsia)
Ensure all medications are safe in pregnancy
Aspirin: 75–150 mg daily
Folic acid: 5 mg daily

During Pregnancy

Dialysis
- Aim for midweek predialysis BUN <35 mg/dL (serum urea 12.5 mmol/L)
- Heparin requirement may increase because of hypercoagulability of pregnancy

Anemia
- Intravenous iron to maintain iron stores
- Dose ESA to achieve hemoglobin 10–11 g/dL

Bicarbonate
- Adjust dialysate bicarbonate to achieve normal serum bicarbonate for pregnancy (18–22 mmol/L)

Nutrition
- Dietician advice to ensure adequate protein and nutrient intake.
- Supplement oral or dialysate phosphate to maintain postdialysis serum phosphate in normal range.

Calcium
- Maintain normal serum calcium with vitamin D/vitamin D analogues and appropriate dialysate calcium.

Phosphate
- Supplement oral or dialysate phosphate to maintain postdialysis serum phosphate in normal range.

After Pregnancy

Return to usual dialysis schedule.
Readjust dry weight and antihypertensives weekly for 6–12 weeks.

BUN, Blood urea nitrogen; *ESA,* erythropoiesis-stimulating agents.

In addition to augmentation of dialysis dose as practically possible, ensuring the aforementioned biochemical goals are achieved, and weekly surveillance, the following also should be considered:

- Control of maternal BP, generally to less than 110 to 140/70 to 90 mm Hg. This is difficult to achieve in many cases. Volume expansion is often evident in women on maintenance hemodialysis who become pregnant, as evidenced by anemia and fall in serum albumin. There are no data supporting assessment of volume status in pregnant patients on dialysis using ultrasound measurement of inferior vena cava diameter or bioimpedance.
- IV iron and erythropoiesis-stimulating agents aiming for a hemoglobin level of 10 to 11 g/dL. No adverse consequences in pregnancy have been reported with either IV iron or erythropoiesis-stimulating agents, although there is a paucity of data on IV iron preparation use in the first trimester and a theoretic risk for exacerbation of hypertension with the latter agents. Transfusion should be avoided to minimize sensitization but may be required if hemoglobin levels are low, especially before delivery.
- Phosphate monitoring and supplementary phosphate in the dialysate if required.
- Fetal monitoring with at least 2- to 4-weekly ultrasound scanning from the time of fetal viability, around 24 weeks of gestation.

Peritoneal Dialysis and Pregnancy

There is little information concerning specific requirements of women on peritoneal dialysis (PD) during pregnancy. A systematic review and meta-analysis compared pregnancy outcomes in women on hemodialysis (HD) with PD and reported a higher incidence of infants who are small for gestational age in those receiving PD.[63] Pregnancy rates in Medicare-insured women with ESKD (2000–2015) were only 2.8% (0.5–1.4 deliveries per 1000 patient-years), and, unlike the number of pregnancies in women receiving hemodialysis or kidney transplants, have not increased over the last 2 decades.[60] A major risk is that PD peritonitis may provoke premature labor or preterm rupture of membranes. Although some women have had successful outcomes remaining on PD throughout pregnancy, we recommend switching to HD to allow augmentation of dialysis dose in a controlled manner. This recommendation is predicated on the greater available evidence for HD in pregnancy and may change when more data emerge about PD in pregnancy.

KIDNEY TRANSPLANTATION AND PREGNANCY

Successful kidney transplantation is an excellent way of restoring fertility in women with ESKD. It is surprising therefore that the pregnancy rate among female transplant recipients more than halved between 1990 and 2003, which is unexplained by a change in the age of women being transplanted but may be related to the introduction of MMF, which is teratogenic.[67] Women with transplants appear less likely to conceive if ESKD is caused by diabetes compared with women without diabetes and overall pregnancy rates among kidney transplant recipients are only one-third of the general population.[2]

Timing of Pregnancy

Women are recommended to wait at least 12 months after a successful kidney transplant before embarking on pregnancy to ensure stable transplant function and maintenance immunosuppression,[49] although evidence is conflicting. A meta-analysis of pregnancy outcomes in women with kidney transplants reported that cesarean section rate was higher and live birth rate lower in those who conceived in the interval of 2 to 3 years than greater than 3 years and less than 2 years (68% vs. 75% vs. 74%, and 73% vs. 65% vs. 42%, respectively). Maternal complications of preeclampsia were higher in the 2- to 3-year interval, and the greater than 3-year interval compared to the less than 2-year interval (24% vs. 23% vs. 13%). Spontaneous abortion rates were highest in the greater than 3-year interval followed by the 2- to 3-year interval, and the less than 2-year interval (16% vs. 14% vs. 10%).[68] However, in a study in the United States, rates of preeclampsia, gestational diabetes, cesarean section, and preterm delivery also were higher than for the general population in those who conceived within 2 years.[69] One to 2 years after transplantation seems a practical time for ensuring clinical stability and having optimal BP control, absence of cytomegalovirus (CMV) viremia, and stable immunosuppression.

Immunosuppression in Pregnancy

There are usually opportunities to ensure that conception is carefully planned, immunosuppression and vaccination status optimized, and folic acid commenced, but, unfortunately, many pregnancies in women with kidney transplants are still unplanned. Discussion regarding restoration of fertility with transplantation and contraception should take place before transplantation.[70] Immunosuppressive drugs considered safe in pregnancy include prednisolone, azathioprine, cyclosporine, and tacrolimus. Tacrolimus has been associated with neonatal hyperkalemia, but overall data support its safety. MMF is associated with teratogenic effects and should be avoided in pregnancy, as should sirolimus and everolimus. We suggest ceasing such drugs 3 to 6 months before pregnancy to ensure clinical stability on an alternative agent (usually azathioprine).

Gestational diabetes occurs in 3% to 12% of pregnancies of patients with kidney transplants but no more frequently in tacrolimus-treated patients than in those receiving cyclosporine. Screening for gestational diabetes is recommended for all transplant recipients at 12 and 28 weeks.

Dosing of tacrolimus in pregnancy remains problematic until assays for free tacrolimus become readily available. During pregnancy, tacrolimus shows increased metabolism but altered protein binding.[71] Our practice is to change dose from prepregnancy doses when trough levels are less than normal, with increments targeting the lower end of the prepregnancy range, but with return to prepregnancy doses immediately after delivery, with ongoing close monitoring.

Azathioprine, tacrolimus, cyclosporine, and prednisone appear safe to use for patients who are breastfeeding, but the decision to breastfeed remains an individual one. Patients can be informed that breastfeeding may have considerable advantages, particularly in preterm and growth-restricted babies.

Pregnancy Outcomes

A favorable view of pregnancy in patients who have undergone successful kidney transplantation was supported by observations in over 3000 pregnancies from 2000 women mostly receiving azathioprine and prednisone.[72] About 15% of these pregnancies miscarried spontaneously, and of those going past the first trimester, pregnancy was successful in over 90% of cases, provided that hypertension or a decline in GFR had not occurred before 28 weeks of gestation, in which case successful pregnancy outcome was reduced to about 70%. Patients with preconception serum creatinine of 1.4 mg/dL (125 μmol/L) had 96% pregnancy success, whereas those with higher serum creatinine had a 75% success rate. In keeping with the data for all women with CKD, long-term decline in kidney function occurred significantly more often (27%) in those with preconception serum creatinine greater than 1.4 mg/dL (125 μmol/L).

A recent systematic review of 78 studies reporting 6712 pregnancy outcomes in 4174 kidney transplant recipients reported the following pregnancy outcomes: live birth rate of 72.9%, miscarriage rate of 15.4%, termination of pregnancy in 12.4%, stillbirth rate of 5.1%, and ectopic pregnancies in 2.4%. Maternal complications included preeclampsia in 21.5%, cesarean section in 62.6%, gestational diabetes in 5.7% (US mean, 9.2%), and gestational hypertension in 24.1%. Neonatal outcomes included preterm birth (<37 weeks) in 43.1% with mean gestational age at delivery of 34.9 weeks; neonatal mortality was 3.8%.[68]

Graft and patient survival are similar in those with and without any pregnancy over a follow-up as long as 15 to 20 years, based on 577 pregnancies in the Australian and New Zealand Data registry, most of whom had GN or reflux nephropathy as their primary diagnosis.[73] A more recent meta-analysis including 2453 recipients with pregnancies confirmed stable serum creatinine postpartum, with no differences in rates of graft loss compared with nulliparous controls,[74] and a Norwegian population study has confirmed reduced rates of graft loss and death in women with kidney transplants after pregnancies compared with nonpregnant women despite adjustment for possible confounders.[75]

More recently, small studies have also reported longer-term outcomes for children of women with kidney transplants with normal development at 12 and 24 months in 94%, despite low birth weights and prematurity[76] (Box 45.7).

BOX 45.7 Maternal and Fetal Outcomes in Kidney Transplant Pregnancies

Maternal

- Decline in glomerular filtration if preconception serum creatinine >1.4 mg/dL (125 µmol/L); rate of decline not usually different from female transplant recipients who have not given birth
- Graft loss in 5% to 10% at 2 years postpartum
- Hypertension in about two-thirds
- Rejection reported in 2% to 9% (risk not thought to be increased by pregnancy)
- Infection in 20% to 35%
- Gestational diabetes mellitus in 6%

Fetal

- Overall live birth rate: 75% to 80%
- Spontaneous miscarriage: 15%
- Preterm delivery: 45%
- Growth restriction: 50%
- Birth defects in about 5%, comparable to the general population
- Long-term consequences of preterm delivery, although most infants have normal postnatal growth and development

Transplant Rejection

Acute transplant rejection is uncommon—reported in fewer than 1 in 20 cases in older series,[69] but a recently systematic review reported the overall acute rejection rate during pregnancy among 822 kidney transplant recipients to be 9.4% (95% confidence interval [CI], 6.4–13.7), which is comparable to the U.S. mean of 9.1%. The clinical presentation of acute graft dysfunction is not different in pregnancy but differentiation from preeclampsia may be challenging. A recent case control study using Transplant International Pregnancy Registry data identified that acute rejection is associated with higher creatinine concentrations, whereas patients with preeclampsia had much higher levels of proteinuria.[77] Kidney biopsy is required to confirm the diagnosis. Treatment is limited to IV methylprednisolone and increments in oral immunosuppression because safety of more potent agents (e.g., antithymocyte globulin) is unproven in pregnancy and likely to cause harm to the developing fetus. Delivery may need to be considered at more advanced gestations to facilitate therapies with unknown fetal safety.

Infection in Pregnant Transplant Recipients

There is an increased risk for infection (20%–35%), particularly UTI but also CMV infection, with attendant maternal and fetal risks. The consequences of any infection can include preterm labor and preterm rupture of membranes. CMV can cause congenital malformations and fetal demise, but delay in conception to after at least 1 year posttransplantation makes new infection or reactivation unlikely. Valganciclovir prophylaxis is not advised because of teratogenicity in animals, but there are case reports of successful use in women with severe CMV infection in pregnancy.

Recommendations for management of pregnancy in patients with a kidney transplant are summarized in Box 45.8.

Male Transplant Recipients

Outcomes of pregnancies fathered by male transplant recipients showed mean gestational age and mean birth weight similar to those of the general population. There have been recent concerns about teratogenicity of MMF in the offspring of fathers with kidney transplants,

BOX 45.8 Management of Kidney Transplant Patients During Pregnancy

Prepregnancy

- Stable graft function at least 1 year after transplantation
- Discuss risks with transplant recipient and partner
- Best pregnancy outcome will occur if:
  - Prepregnancy serum CKD stage 1 to 2
  - Proteinuria < 1 g/day
  - Blood pressure < 130/80 mm Hg
- Replace all medications that are not safe in pregnancy
- Eradicate UTI before pregnancy; consider prophylactic antibiotics if there has been recurrent UTI in the past year or a single confirmed UTI in pregnancy
- Stable cyclosporine or tacrolimus blood levels
- Test for and control diabetes

During Pregnancy

- Aspirin (75–150 mg daily) for all women with kidney transplant unless contraindicated.
- Assess fetal growth by ultrasound at least every 4 weeks from 28 weeks of gestation.
- Consider increase in CNI dose during pregnancy if drug level is significantly lower than the nonpregnant target range.
- Screen for gestational diabetes according to local protocol with additional early screening if taking steroids or calcineurin inhibitor.
- At each visit, assess BP (goal 110–135/70–85 mm Hg), proteinuria (dipstick, then uPCR or uACR if dipstick result is positive), urine culture, electrolytes, creatinine, full blood count, predose CNI level, and fetal growth.
- Reassess at each visit whether there is an impending indication for delivery (see Box 45.5).

During Delivery

- Vaginal delivery is generally possible, and indications for caesarean delivery are usually obstetric.
- Prophylactic antibiotics are not required.

Postpartum

- Control blood pressure.
- Monitor CNI and serum creatinine levels.
- CNI drugs, azathioprine, and corticosteroids are safe in breastfeeding.
- Higher level of clinical surveillance for the first 3 months.

BP, Blood pressure; *CKD,* chronic kidney disease; *CNI,* calcineurin inhibitor; *uACR,* urinary albumin/creatinine ratio; *uPCR,* urine protein/creatinine ratio; *UTI,* urinary tract infection.

and the manufacturers have advised switching to a different agent before conception. However, these recommendations are largely theoretical, and should be balanced against the risk for inadequate immunosuppression for a prolonged period in males with higher risk transplants. A recent French survey reported no increased risk of congenital malformations in offspring of males with kidney transplants compared with the general population.[78] Similarly, the ANZDATA registry recently reported no increase in congenital abnormalities in offspring of fathers taking MMF or derivatives.[79]

PREGNANCY IN THE KIDNEY DONOR

It is usually stated that being a kidney donor does not adversely affect future pregnancy outcomes in terms of fetal birth weight, stillbirth, or prematurity, although recent studies suggest there may be an increased risk for preeclampsia in pregnancy after organ donation, and some

reports suggest that fetal outcomes also may be slightly worse.[80,81] A large Canadian study also reported a higher incidence of preeclampsia and gestational hypertension in women after donation compared with controls but there were no differences in neonatal outcomes, including gestation at delivery or birth weight, and thus placental insufficiency is unlikely to be severe.[82]

More recently, a U.S. case-control study also demonstrated an increased risk of preeclampsia in primiparous kidney donors compared with age- and race-matched primiparous controls, but this was only significant for women up to 30 years old,[83] and in keeping with preexisting studies there were no differences in neonatal outcomes. These studies have some limitations in their design, and pregnancy should not be discouraged in women who have been kidney donors; rather, the key message is that all such women should be treated as at-risk pregnancies and have a higher number of clinical reviews, focusing on maternal BP and urinalysis and fetal growth, than in low-risk pregnancies. Aspirin prophylaxis may be considered, especially if women have additional risk factors for preeclampsia.

SUMMARY

A summary of factors to be considered in managing a pregnant patient with kidney disease is shown in Box 45.9. Attention to these issues from preconception to postpartum can result in good pregnancy outcomes with preservation of maternal health. These patients and, in many cases, their offspring require lifelong assessment for progressive kidney and/or cardiovascular disease.

BOX 45.9 Managing Women With Preexisting Kidney Disease During Pregnancy

- Women with chronic kidney disease (CKD) should be managed by a team made up of the obstetrician, nephrologist or expert physician, and experienced midwife or specialty nurse, preferably in a high-risk pregnancy clinic.
- Main determinants of pregnancy outcome are prepregnancy GFR, proteinuria, blood pressure (BP), medication, and previous obstetric history. These should be the focus in counseling.
- Kidney function should be monitored using serum creatinine in pregnancy.
- Proteinuria is quantified using spot uPCR or uACR.
- Low-dose aspirin should be given to reduce the risk for preeclampsia.
- Low-molecular-weight heparin for VTE prophylaxis if uPCR > 300 (uACR > 200). Assess VTE risk if uPCR > 100 (uACR > 30); may need dose adjustment for kidney function.
- Primary issues during pregnancy are BP control, surveillance for preeclampsia, and regular assessment of fetal well-being.
- Fetal assessment by ultrasound
  - At 20 weeks: Uterine artery pulsatility index
  - Monthly from 28 weeks: fetal growth, blood flow, amniotic fluid index
- Plans for obstetric, nephrology, and neonatal review determined at postpartum discharge. Increased nephrology surveillance recommended for 3 months. Pre-pregnancy counseling recommended in advance of a future pregnancy.

GFR, Glomerular filtration rate; *uACR*, urinary albumin/creatinine ratio; *uPCR*, urine protein-to-creatinine ratio; *VTE*, venous thromboembolism.

SELF-ASSESSMENT QUESTIONS

1. A 32-year-old woman with ADPKD wishes to become pregnant. Her GFR is 110 mL/min/1.73 m^2. Her BP is 142/89 mm Hg, and she has no proteinuria. She is taking amlodipine 5 mg once daily. Which of the following is correct advice about a future pregnancy?
   A. Her pregnancy will be low risk.
   B. She should be offered preimplantation genetic testing.
   C. She should take aspirin daily in advance of pregnancy.
   D. She should stop amlodipine when she becomes pregnant.
2. A 39-year-old woman with ESKD secondary to lupus nephritis received a kidney transplant from her partner 9 months ago and wishes to conceive. She has had no episodes of rejection. Her GFR is 84 mL/min/1.73 m^2, and her BP is 124/77 mm Hg. She is currently taking prednisolone, tacrolimus, MMF, and aspirin. What would you recommend to achieve the best outcome?
   A. She should not conceive until at least 24 months after transplantation.
   B. Breastfeeding is not recommended with immunosuppressant medication.
   C. MMF should be stopped.
   D. Anti-Ro and La antibody should be assessed to inform fetal monitoring.
3. A 28-year-old woman with IgA nephropathy is at 32 weeks of gestation. Her prepregnancy GFR is 45 mL/min/1.73 m^2 and uPCR is 120 mg/mmol. She presents with headache and peripheral edema; her BP is 166/100 mm Hg and uPCR is 245 mg/mmol. Her serum creatinine has increased from 70 µmol/L 4 weeks ago to 84 µmol/L. What is the best approach to management?
   A. Admit for BP control and assess by fetal artery Doppler to determine timing of delivery.
   B. Admit for BP control and urgent cesarean section delivery to preserve kidney function.
   C. Give IV magnesium sulfate to prevent eclampsia, then plan delivery within 24 hours.
   D. Start aspirin 75 mg daily and labetalol 200 mg three times daily with escalation to IV antihypertensives if no response.

Autosomal Dominant Polycystic Kidney Disease

Vicente E. Torres, Peter C. Harris

DEFINITION

Autosomal dominant polycystic kidney disease (ADPKD) is a multisystem disorder characterized by multiple, bilateral kidney cysts and associated with cysts in other organs, such as the liver, pancreas, and arachnoid membranes.[1] It is a genetic disorder caused mainly by mutations in either of two major genes and inherited in an autosomal dominant pattern, with variable expression. Although benign (nongenetic) kidney cysts are common with aging, an underlying inherited disease should be suspected in patients with multiple bilateral kidney cysts, even if the kidney function is normal.

ETIOLOGY AND PATHOGENESIS

The common ADPKD proteins, polycystin-1 and polycystin-2, play a critical role in the normal function of the primary cilium that is essential to maintaining the differentiated phenotype of tubular epithelium.[2]

Genetic Mechanisms

ADPKD is genetically heterogeneous with two common genes identified (Fig. 46.1): *PKD1* (chromosome 16p13.3) and *PKD2* (4q21). Recently, three additional genes have been identified in pedigrees with an atypical ADPKD presentation: *GANAB,*[3] *DNAJB11,*[4] and *ALG9*[5]; the encoded proteins are involved in the maturation and processing of polycystins. Autosomal dominant polycystic liver disease (ADPLD) also exists as an independent entity and is genetically heterogeneous; the first two genes identified (*PRKCSH* in chromosome 19 and *SEC63* in chromosome 6) account for about one-third of isolated ADPLD cases. More recently, mutations to *GANAB, ALG8, SEC61B,* and *LRP5* have also been shown to cause ADPLD.[6]

Evidence from animal models of ADPKD and analysis of cystic epithelia have shown that kidney cysts may develop from loss of functional polycystin with somatic inactivation of the normal allele. However, cysts can develop even if the protein is not completely lost, as demonstrated by animal models expressing incompletely penetrant alleles.[7]

Polycystic Kidney Disease Proteins

Polycystin-1 (PC1; PKD1 protein) and polycystin-2 (PC2; PKD2 protein) belong to a subfamily of transient receptor potential (TRP) channels. PC1 (~440 kDa) has the structure of a receptor or adhesion molecule and contains a large extracellular N region, 11 transmembrane regions, and a short intracellular C region (see Fig. 46.1). PC1 interacts with PC2 through a coiled-coil domain in the C-terminal portion and with multiple other proteins at different extracellular and intracellular sites. PC1 is found in the primary cilia, plasma membrane at focal adhesions, desmosomes, adherens junctions, and possibly endoplasmic reticulum (ER) and nuclei. PC2 (TRPP2; ~110 kDa) contains a short N-terminal cytoplasmic region, six transmembrane domains, and a short C-terminal portion. PC2 is localized predominantly to the ER but also to the plasma membrane, primary cilium, centrosome, and mitotic spindles in dividing cells.[2] A cryo-EM structure indicates 1 PC1 to 3 PC2 molecules.[8] PC1 and PC2 are also found at high concentrations in exosomes, which are shed into the urine and physically interact with primary cilia, possibly exerting an effect on other cells in the nephron.

Mechanisms of Cyst Formation

Experimental data indicate that the timing of ciliary loss or *Pkd1* inactivation determines the rate of development of cystic disease. Inactivation in the developing kidney results in rapid progression.[9] Interestingly, the loss of *Pkd1* and cilia results in less severe polycystic kidney disease (PKD) than loss of *Pkd1* alone.[10]

The polycystins are involved in the detection of extracellular cues at primary cilia, cell-cell contacts, and cell-matrix contacts and are essential to maintain the differentiated phenotype of the tubular epithelium. Reduction in one of the polycystins to below a critical threshold results in inability to maintain planar polarity, increased rates of proliferation, expression of a secretory phenotype, and remodeling of the extracellular matrix.[2] PC1 and PC2 in the primary cilium may be required for the increase in cytosolic calcium that occurs in response to ciliary bending.[11] PC2 is a TRP channel (TRPP2) and functions as a calcium release channel in the ER.[12] PC1 interacts with and modulates the maturation and function of PC2, and vice versa.[13] PC1 and PC2 also interact with additional calcium channel proteins. Precisely how intracellular calcium homeostasis is altered in ADPKD remains uncertain, but many studies show reduced resting intracellular calcium, ER calcium stores, and store-operated calcium entry in primary cell cultures or microdissected samples from human and rodent polycystic tissues[2] (Fig. 46.2).

A common finding in animal models of PKD is increased levels of cyclic adenosine monophosphate (cAMP), not only in the kidney but also in the liver and vascular smooth muscle.[14] Tissue levels of cAMP are determined by the activities of membrane-bound and soluble adenylyl cyclases and cAMP phosphodiesterases (PDEs), themselves subject to complex regulatory mechanisms. Reduced intracellular calcium

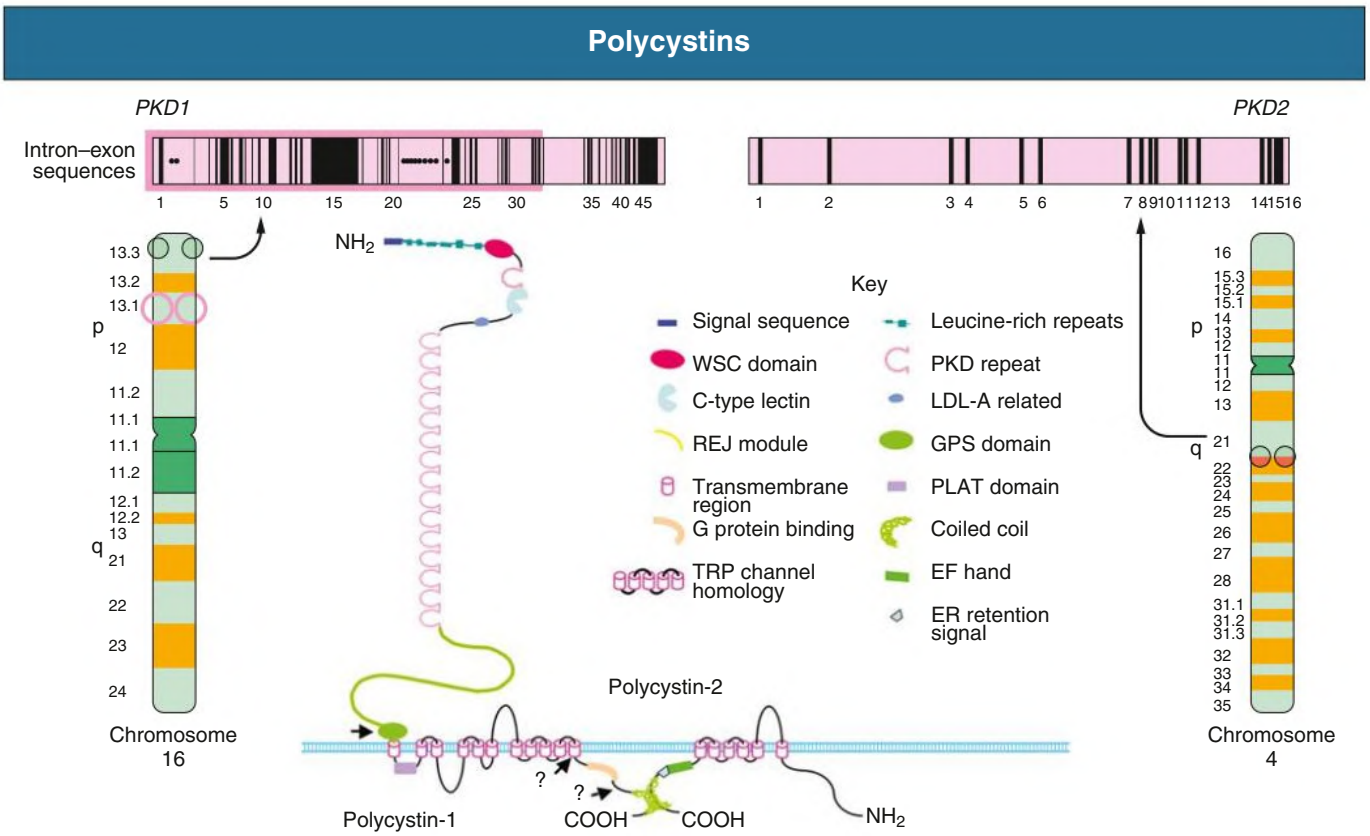

Fig. 46.1 Polycystins: Genes, Messenger RNAs, and Proteins. Diagrammatic representation of chromosome 16 *(left)* and chromosome 4 *(right)*. Intron-exon sequences of *PKD1 (upper left)* and *PKD2 (upper right)*. Diagram of proposed structural features of the polycystin-1 and polycystin-2 proteins *(center)*. *ER*, Endoplasmic reticulum; *GPS*, G-protein-coupled receptor proteolytic site; *LDL*, low-density lipoprotein; *PKD*, polycystic kidney disease; *PLAT*, polycystin-1, lipoxygenase, alpha-toxin; *REJ*, receptor for egg jelly; *TRP*, transient receptor potential; *WSC*, wall integrity and stress response component.

in PKD may activate calcium inhibitable AC6 or AC5, directly inhibit calcium/calmodulin-dependent PDE1, and indirectly inhibit cGMP inhibitable PDE3, thereby accounting for the accumulation of cAMP and activation of protein kinase A (PKA), which, in turn, contributes to the development and progression of PKD by stimulating cystic fibrosis transmembrane conductance regulator (CFTR)-driven chloride and fluid secretion and cell proliferation (see Fig. 46.2).

Chloride enters across basolateral Na^+-K^+-$2Cl^-$ cotransporters, driven by the sodium gradient generated by basolateral Na^+,K^+-ATPase, and exits across apical PKA-stimulated CFTR. Basolateral recycling of potassium occurs through the KCa3.1 channel.

cAMP exerts opposite effects on cell proliferation in different cell types. cAMP and PKA signaling enhance several proproliferative pathways (extracellular signal–regulated kinase [ERK]) in cells derived from polycystic kidneys and inhibit proliferation in cells derived from normal human kidney cortex.[15,16] Treatment of normal human kidney or murine collecting duct cells with calcium channel blockers replicates the proliferative response of the ADPKD cells to cAMP, thus linking this response to the reduction in intracellular calcium that results from disrupting the polycystin pathway.[17] Conversely, treatment of ADPKD cyst–derived cells with calcium channel activators or calcium ionophores restores the normal antimitogenic response to cAMP (see Fig. 46.2).

Liver Cyst Development

Liver cysts arise by excessive proliferation and dilation of biliary ductules and peribiliary glands. Estrogen receptors, insulin-like growth factor 1 (IGF-1), IGF-1 receptors, and growth hormone receptors are expressed in the epithelium lining the hepatic cysts, and estrogens and IGF-1 stimulate hepatic cyst–derived cell proliferation. Cyst growth is also promoted by growth factors and cytokines secreted into the cyst fluid.

Hypertension

Hypertension is a major clinical manifestation and predictor of outcome in ADPKD (see Clinical Manifestations). Several factors contribute to the development of hypertension in ADPKD. Activation of the intrarenal renin-angiotensin system (RAS) likely plays an important role, but whether the circulating RAS is inappropriately activated is controversial. The expression of PC1 and PC2 in vascular smooth muscle and endothelium, along with enhanced vascular smooth muscle contractility and impaired endothelium-dependent vasorelaxation in ADPKD, suggest that disruption of polycystin function directly contributes to hypertension. Other factors include increased sympathetic nerve activity and plasma endothelin-1 levels and insulin resistance.[1]

Endothelial vasodilation and constitutive nitric oxide synthase activity are reduced in subcutaneous resistance vessels from patients with ADPKD and normal glomerular filtration rate (GFR). Flow-induced vasodilation of the brachial artery is inconsistently impaired, whereas pulse wave reflection is amplified, suggesting a predominant involvement of small resistance vessels. Reduced coronary flow velocity reserve and increased carotid intima-media thickness in normotensive patients with normal GFR suggest that atherosclerosis starts early in the course of ADPKD.

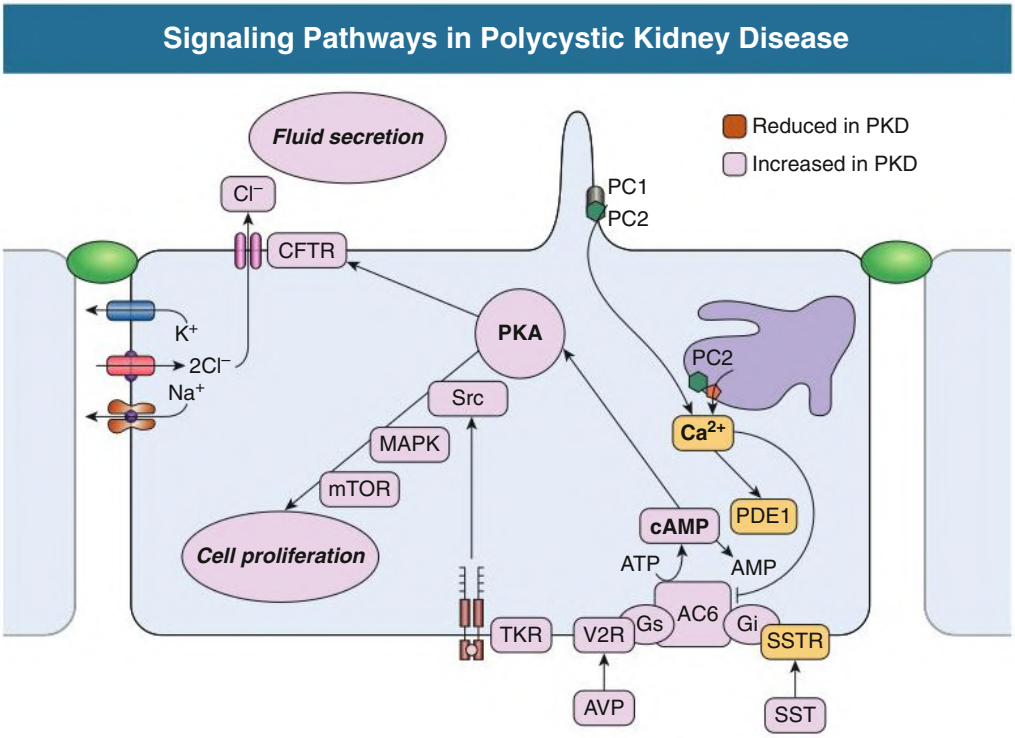

Fig. 46.2 Signaling Pathways in Polycystic Kidney Disease (PKD). Pathways that are upregulated or downregulated in PKD and the rationale for potential therapies. Dysregulation of intracellular calcium homeostasis leads to intracellular accumulation of cyclic adenosine monophosphate (cAMP), activation of protein kinase A (PKA), cystic fibrosis transmembrane conductance regulator (CFTR) phosphorylation, and stimulation of chloride-driven fluid secretion. In the setting of reduced intracellular calcium, PKA activates Src, mitogen-activated protein kinase (MAPK)/extracellular signal–regulated kinase (ERK), and mammalian target of rapamycin (mTOR) signaling. Activation of tyrosine kinase receptors (TKR) for several growth factors contributes to the activation of Src and downstream proproliferative pathways. Therapies currently under clinical investigation target G protein–coupled receptors (modulating activity of adenylyl cyclase 6 [AC6] and generation of cAMP), Src, mTOR, and TKRs. *AVP,* Arginine vasopressin; *PDE1,* phosphodiesterase-1; *SST,* somatostatin; *SSTR,* somatostatin receptor.

Reduced nitric oxide endothelium-dependent vasorelaxation in ADPKD may be caused by increased plasma levels of asymmetric dimethylarginine, a mechanism common to all hypertension associated with kidney disease.

Altered polycystin function in cardiac fibroblasts likely accounts for the increased frequency of valvular heart disease in ADPKD.

EPIDEMIOLOGY

ADPKD occurs worldwide and in all races, with a prevalence of genetically affected individuals at birth estimated at 1 in 400 to 1 in 1000. In most patients the diagnosis is made decades later, and some patients are never diagnosed. Therefore, at any point in time, only a fraction of genetically affected individuals are aware of having the disease. Clinical registry data suggest point prevalence rates of diagnosed cases ranging from 1 in 543 to 1 in 4000. The proportion of end-stage kidney disease (ESKD) caused by ADPKD is less among Blacks than among Whites because of a higher incidence of other causes of ESKD. Yearly incidence rates for ESKD caused by ADPKD in males and females, respectively, are 8.7 and 6.9 per 1 million (1998–2001, United States), 7.8 and 6.0 per million (1998 and 1999, Europe), and 5.6 and 4.0 per million (1999 and 2000, Japan). Age-adjusted sex ratios greater than unity (1.2–1.3) and recent genotype/phenotype studies suggest more progressive disease in males than in females.[18–20] In recent studies, the age of onset of ESKD has increased in both sexes, and all-cause mortality has decreased, possibly because of improved detection and control of hypertension.[1]

PHENOTYPIC VARIABILITY

Genic, allelic, and gene-modifier effects contribute to the high phenotypic variability of ADPKD. *PKD1*-associated disease is more severe than *PKD2*-associated disease (age at ESKD, 58 years vs. 79 years for *PKD1* and *PKD2,* respectively).[21] The greater severity of *PKD1* is caused by development of more cysts at an early age, not faster cyst growth.[1] Both *PKD1* and *PKD2* can be associated with severe polycystic liver disease (PLD) and vascular abnormalities.[22] Because of the lesser severity of the kidney involvement, the prevalence of *PKD2*-associated disease has likely been underestimated in clinical studies.

Mutations in *PKD1* and *PKD2* are highly variable and often "private" (unique to a kindred). The ADPKD Mutation Database (http://pkdb.mayo.edu) lists 1621 likely pathogenic *PKD1* mutations identified in 2417 families with a total of 2905 variants, including silent polymorphisms. Also, 256 likely pathogenic *PKD2* mutations are listed in 553 families, with a total of 358 different variants. A much smaller number of patients with mutations to *GANAB, DNAJB11,* and *ALG9* have been described.[3]

Allelic factors have an effect on the severity of ADPKD. Recent studies in large cohorts have shown that the type of *PKD1* mutation, but not its position, correlates strongly with kidney survival. The median

age at onset of ESKD was 55 years for carriers of a truncating mutation and 67 years for carriers of a nontruncating mutation.[21] Hypomorphic or incompletely penetrant *PKD1* or *PKD2* alleles have been described. These alleles alone may result in mild cystic disease; two such alleles cause typical to severe disease and, in combination with an inactivating allele, may be associated with early-onset disease that mimics autosomal recessive PKD (ARPKD).[1] A prognostic score (PRO-PKD score) based on the gene mutated and type of mutation helps predict kidney outcomes and enable the personalization of therapeutic management in patients with ADPKD.[2,23]

The large intrafamilial variability of ADPKD highlights a role for genetic background in disease presentation. Age at onset of clinical manifestations in ADPKD is less variable within than between families, which suggests a common familial modifying background for early and severe disease expression (e.g., mutations or variants in genes encoding other cystoproteins). The contiguous deletion of the adjacent *PKD1* and *TSC2* is characterized by childhood PKD with additional clinical signs of tuberous sclerosis complex. Other modifying loci are likely to account for more common and subtle intrafamilial variability.

DIAGNOSIS

Only individuals who have been properly informed about the advantages and disadvantages of screening should be offered presymptomatic screening. If ADPKD is diagnosed, the patient should receive appropriate genetic counseling, and risk factors such as hypertension can be identified and treated early. If ADPKD is absent, the patient can be reassured. Disadvantages of presymptomatic screening relate to insurability and employability. Presymptomatic screening of children is not recommended until more effective therapy for the disease becomes available.

Kidney Imaging

Kidney ultrasound is used for presymptomatic testing because of cost and safety. Revised criteria have been proposed to improve the diagnostic performance of ultrasound in ADPKD (Table 46.1). At least three (unilateral or bilateral) kidney cysts are sufficient for diagnosis of at-risk individuals 15 to 39 years of age; two cysts in each kidney are sufficient for diagnosis for ages 40 to 59 years.[24] For at-risk individuals age 60 and older, four or more cysts in each kidney are required.

The specificity and positive predictive value (PPV) of ultrasound are close to 100% using these criteria, but their sensitivity and negative predictive value (NPV) when applied to PKD2 patients age 15 to 59 years are low. This is a problem in the evaluation of potential kidney donors, in which exclusion of the diagnosis is important. Different criteria have therefore been proposed to exclude a diagnosis of ADPKD in an individual at risk from a family with an unknown genotype. An ultrasound finding of normal kidneys or one kidney cyst in an individual aged 40 years or older has an NPV of 100%. The absence of any kidney cysts provides near certainty that ADPKD is absent in at-risk individuals aged 30 to 39 years, with a false-negative rate of 0.7% and NPV of 98.7%. A normal or indeterminate ultrasound scan does not exclude ADPKD with certainty in an at-risk individual younger than 30 years. A study of 73 affected and 82 nonaffected individuals suggested that finding fewer than five cysts by magnetic resonance imaging (MRI) is sufficient to exclude the diagnosis of ADPKD in potential living related kidney donors.[25] Contrast-enhanced computed tomography (CT) scanning with thin slices likely provides similar information, but this has not been proven.

Genetic Testing

Genetic testing can be performed when a precise diagnosis is needed and the results of imaging are indeterminate, although a case can now be made for broader screening to obtain a firm diagnosis. Molecular diagnosis of ADPKD is complicated by duplication of the *PKD1* gene, which means it may not be efficiently screened by whole-exome sequencing. For diagnostic purposes, next-generation sequencing panels of PKD genes are now generally employed that allow for higher throughput screening and lower costs.[26] Molecular testing by direct DNA sequencing is now informative in at least 90% of patients. However, because many mutations are unique and up to one-third of *PKD1* changes are missense, the pathogenicity of some changes is difficult to prove. De novo mutations and mosaicism also can complicate interpretation of results.[27]

In preimplantation genetic diagnosis (PGD), genetic analysis is performed on single blastomeres from preimplantation embryo biopsy specimens obtained after in vitro fertilization (IVF), and only embryos unaffected by the disease are selected for transfer. PGD for ADPKD is complicated by the genetic heterogeneity of the disease and the large size and complex structure of the *PKD1* gene but has been performed for ADPKD. PGD should be included in the discussion of reproductive choices with patients with ADPKD, but it is only available in certain countries and the acceptance of this technique is influenced by personal values and by the severity of the disease.[1]

TABLE 46.1 Ultrasound Criteria for the Diagnosis of Autosomal Dominant Polycystic Kidney Disease

Age (y)	Criteria	PPV	NPV
Original Ravine's PKD1 Diagnostic Criteria			
15–29	≥2 cysts, unilateral or bilateral	99	88
30–39	≥2 cysts in each kidney	100	88
40–59	≥2 cysts in each kidney	100	95
≥60	≥4 cysts in each kidney	100	100
Revised Unified Diagnostic Criteria			
15–29	≥3 cysts, unilateral or bilateral	100	86
30–39	≥3 cysts, unilateral or bilateral	100	86
40–59	≥2 cysts in each kidney	100	95
≥60	≥4 cysts in each kidney	100	100
Revised Diagnostic Criteria (when diagnosis needs to be excluded)			
15–29	≥1 cyst	97	91
30–39	≥1 cyst	94	98
40–59	≥2 cysts	97	100
≥60	≥3 cysts in each kidney	100	100

NPV, Negative predictive value; *PPV,* positive predictive value.

DIFFERENTIAL DIAGNOSIS

Kidney cysts can be a manifestation of many other systemic diseases. Conditions to consider when presentation is not typical of ADPKD include ARPKD, tuberous sclerosis complex, von Hippel–Lindau disease, kidney cysts and diabetes from *HNF1B* mutations, and oro-facio-digital syndrome type I, as well as medullary sponge kidney and simple kidney cysts. These are discussed further, including differential diagnosis, in Chapter 47. If the patient has ESKD, acquired cystic disease also should be considered (see Chapter 92).

CLINICAL MANIFESTATIONS

ADPKD is a multisystem disorder. Multiple kidney and extrarenal manifestations of ADPKD can cause significant complications.

BOX 46.1 Kidney Manifestations of Autosomal Dominant Polycystic Kidney Disease

Functional Manifestations
- Concentrating defect
- Reduced kidney blood flow

Hypertension → Target Organ Damage
- Cardiac
- Cerebrovascular
- Arteriolosclerosis and glomerulosclerosis
- Peripheral vascular disease

Pain, Caused by
- Cyst hemorrhage
- Gross hematuria
- Nephrolithiasis
- Infection
- Kidney enlargement

Reduced Glomerular Filtration Rate, Possibly Caused by
- Interstitial inflammation
- Apoptosis of tubular epithelial cells
- Hypertensive glomerulosclerosis
- Compression atrophy

Kidney Manifestations

A number of clinical features that result from kidney damage can be identified (Box 46.1). Reduction in urinary concentrating capacity and glomerular hyperfiltration are early functional abnormalities that can be observed in some children and adolescents with ADPKD.

Kidney Size

Kidney size increases with age, and kidney enlargement eventually occurs in 100% of patients with ADPKD. The severity of the structural abnormality correlates with the manifestations of ADPKD, such as pain, hematuria, hypertension, and kidney impairment.[1] Massive kidney enlargement can lead to compression of local structures, resulting in such complications as inferior vena cava (IVC) compression and digestive symptoms. Most manifestations are directly related to the development and enlargement of kidney cysts. The Consortium for Radiologic Imaging Studies of Polycystic Kidney Disease (CRISP), a prospective study of 241 patients by annual MRI, has shown that total kidney volume (TKV) and cyst volumes increased exponentially.[28] Rates of growth were relatively constant, averaging 5.3% per year, but were highly variable from patient to patient. Baseline TKV predicted the subsequent rate of increase in kidney volume and decline in GFR.[29] An imaging classification of ADPKD based on height-adjusted TKV and age may facilitate the selection of patients with rapidly progressive disease (class 1C–E) for enrollment into clinical trials and for disease-modifying treatments.[30]

Pain

Episodes of acute kidney pain are seen frequently; causes include cyst hemorrhage, infection, stone, and, rarely, tumor, and these must be investigated thoroughly. A few patients with ADPKD with kidney enlargement and structural distortion develop chronic flank pain without an identifiable cause.

Hematuria and Cyst Hemorrhage

Visible hematuria may be the initial presenting symptom and occurs in up to 40% of patients with ADPKD over the course of the disease. Many have recurrent episodes. Differential diagnosis includes cyst hemorrhage, stone, infection, and tumor. Cyst hemorrhage is a frequent complication and produces gross hematuria when the cyst communicates with the collecting system. Frequently, the cyst does not communicate with the collecting system, and flank pain without hematuria occurs. It can manifest with fever, raising the possibility of cyst infection. On occasion, a hemorrhagic cyst will rupture, resulting in a retroperitoneal bleed that can be significant, potentially requiring transfusion. In most patients, cyst hemorrhage is self-limited, resolving within 2 to 7 days. If symptoms of hematuria or flank pain last longer than 1 week or if the initial episode of hematuria occurs after age 50 years, neoplasm should be excluded.

Urinary Tract Infection and Cyst Infection

Urinary tract infection (UTI) is common in ADPKD, but its incidence may have been overestimated because sterile pyuria is common in these patients. UTI presents as cystitis, acute pyelonephritis, cyst infection, and perinephric abscesses. As in the general population, females are affected more frequently than males. Most infections are caused by *Escherichia coli, Klebsiella* and *Proteus* species, and other Enterobacteriaceae. The route of infection in acute pyelonephritis and cyst infection is usually retrograde from the bladder; therefore cystitis should be promptly treated to prevent complicated infections.

Both CT and MRI are sensitive to detect complicated cysts and can provide anatomic definition, but the findings are not specific for infection. Nuclear imaging, especially indium-labeled white blood cell scanning, is useful, but false-negative and false-positive results are possible. F-Labeled fluorodeoxyglucose (FDG) positron emission tomography (PET) has recently been used for detection of infected cysts.[1] FDG is taken up by inflammatory cells because of their high metabolic rate but is filtered by the kidneys, is not reabsorbed, and appears in the collecting system, which may limit its use in diagnosis of kidney cyst infections; its present role is for diagnosis of infected liver cysts. FDG-PET is expensive and not widely available, but it provides rapid imaging with high spatial resolution, high target-to-background ratio, low radiation burden, and high interobserver agreement.

When there is fever and flank pain with suggestive diagnostic imaging but blood and urine cultures are negative, cysts should be aspirated under ultrasound or CT guidance to culture the organism and inform the selection of antimicrobial therapy.

Nephrolithiasis

Kidney stone disease occurs in about 20% of patients with ADPKD. Most stones are composed of uric acid, calcium oxalate, or both. Uric acid stones are more common in ADPKD than in stone formers without ADPKD. Urinary stasis secondary to distorted kidney anatomy may play a role in the pathogenesis of nephrolithiasis. Predisposing metabolic factors include decreased ammonia excretion, low urinary pH, and low urinary citrate concentration.

Stones can be difficult to diagnose on imaging in ADPKD because of cyst wall and parenchymal calcification. The distorted anatomy can cause difficulty in localizing stones to the collecting system on plain radiographs. Intravenous (IV) urography has the advantage of specifically localizing stone material to the collecting system and may provide clues to stone composition. IV urography also can detect precalyceal tubular ectasia, found in 15% of patients with ADPKD. CT urography has replaced IV urography in many centers; it is more sensitive in detecting small or radiolucent stones and for differentiating stones

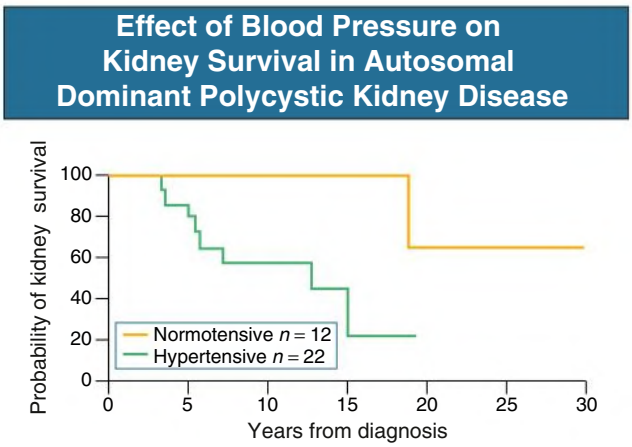

Fig. 46.3 Patients with polycystic kidney disease and hypertension at diagnosis have less probability of kidney survival than those with normal blood pressure.

from tumor, clot, and cyst wall or parenchymal calcification. Dual-energy CT is increasingly used to distinguish between calcium and uric acid stones.

Hypertension

Hypertension is the most common manifestation of ADPKD and a major contributor to kidney disease progression and cardiovascular morbidity and mortality (Fig. 46.3). Albuminuria and hematuria are more common in hypertensive patients with ADPKD and correlate with the rate of kidney function loss. Hypertension also may increase morbidity from valvular heart disease and intracranial aneurysms, which are common in ADPKD.

Ambulatory blood pressure (BP) monitoring of children or young adults without diagnosed hypertension often reveals elevated BP, attenuated nocturnal BP dipping, and exaggerated BP response during exercise. A study stratified 65 children by BP into three cohorts: hypertensive (≥95th percentile), borderline hypertensive (75th to 95th percentile), and normotensive (≤75th percentile).[31] Both the hypertensive and the borderline hypertensive children had significantly higher left ventricular (LV) mass indices than the normotensive children. Among normotensive children, indices were significantly higher in those within the upper quartile of normal BP. These observations suggest that target organ damage develops early in ADPKD and that antihypertensive treatment may be indicated in children with ADPKD and borderline hypertension.

End-Stage Kidney Disease

In most patients, kidney function is maintained within the normal range, despite relentless growth of cysts, until the fourth to sixth decade of life. By the time kidney function starts declining, the kidneys usually are greatly enlarged and distorted with little recognizable parenchyma on imaging studies. At this stage, the average rate of GFR decline is 4.4 to 5.9 mL/min per year. Nevertheless, ESKD is not inevitable in ADPKD. Up to 77% of patients are alive with preserved GFR at age 50 years and 52% at age 73 years. Males tend to progress to kidney failure more rapidly and require kidney replacement therapy at a younger age than females. Other risk factors for kidney failure include Black race, diagnosis of ADPKD before age 30 years, first episode of hematuria before age 30 years, onset of hypertension before age 35 years, hyperlipidemia, low level of high-density lipoprotein cholesterol, sickle cell trait, and *PKD1* truncating mutations. Recently, a post hoc analysis of the HALT PKD clinical trials showed an association of dietary sodium with the rate of kidney growth in patients with ADPKD with estimated GFR (eGFR) >60 mL/min/1.73 m^2 and with the rate of decline in kidney function in those with eGFR between 25 and 60 mL/min/1.73 m^2.[32]

Several mechanisms account for loss of GFR. The CRISP study confirmed that kidney and cyst volumes are the strongest predictors of declining GFR[29] and also found that kidney blood flow (or vascular resistance) is an independent predictor.[33] The latter suggests that vascular remodeling may account for cases in which the decline of kidney function seems disproportionate to the severity of the cystic disease, particularly in patients reaching ESKD in the seventh decade of life or later.[34] Other factors, such as heavy use of analgesics, may contribute to chronic kidney disease (CKD) progression in some patients.

Extrakidney Manifestations

Polycystic Liver Disease

PLD is the most common extrarenal manifestation of ADPKD. PLD is associated with both *PKD1* and *PKD2* genotypes. In contrast to the kidney phenotype, the ADPKD genotype is not associated with the severity or growth rate of PLD in patients with ADPKD.[22] In addition, PLD also occurs as a genetically distinct disease in the absence of kidney cysts (ADPLD). Most simple hepatic cysts are solitary, and PLD should be suspected when four or more cysts are present in the hepatic parenchyma. The liver in PLD contains multiple microscopic or macroscopic cysts that result in hepatomegaly (Fig. 46.4), but typically there is preservation of normal hepatic parenchyma and liver function.

Hepatic cysts are exceedingly rare in children with ADPKD. Their frequency increases with age and may have been underestimated by ultrasound and CT studies. Their prevalence by MRI in the CRISP study was 58%, 85%, and 94%, respectively, in participants age 15 to 24, 25 to 34, and 35 to 46 years. Females develop more cysts at an earlier age than males. Females who have multiple pregnancies or who have used oral contraceptives (OCs) or estrogen replacement therapy (ERT) in the postmenopausal period may have worse disease. After menopause, the volume of polycystic livers often remains stable or may even decrease.[22]

Typically, PLD is asymptomatic, but reported symptoms have become more frequent as the life span of patients with ADPKD is prolonged with dialysis and transplantation. Symptoms result from mass effect or from complications related to the cysts themselves.[35] Symptoms include dyspnea, orthopnea, early satiety, gastroesophageal reflux, mechanical low back pain, uterine prolapse, and even rib fracture. Other complications caused directly by mass effect include hepatic venous outflow obstruction, IVC compression, portal vein compression, and bile duct compression presenting as obstructive jaundice. Hepatic venous outflow obstruction is an uncommon condition caused by severe extrinsic compression of the intrahepatic IVC and hepatic veins by cysts, rarely with superimposed thrombosis. Symptomatic cyst complications include cyst hemorrhage, which occurs less frequently than kidney cyst hemorrhage, cyst infection, and the rare occurrence of torsion or rupture of cysts. Hepatic cyst infection can be a serious complication and typically presents with localized pain, fever, leukocytosis, elevated sedimentation rate, and often elevated alkaline phosphatase. Enterobacteriaceae are the most common microorganisms causing cyst infection. The same imaging techniques discussed for the investigation of kidney cyst infections may be useful for the localization of infected cysts in the liver.

Congenital hepatic fibrosis, always found in association with ARPKD, can rarely coexist with ADPKD. Contrary to PKD, which affects members of several generations in these families, congenital hepatic fibrosis is seen in only one generation and is not transmitted vertically, suggesting the importance of modifier genes. These patients present with manifestations of portal hypertension, but hepatocellular function is normal.

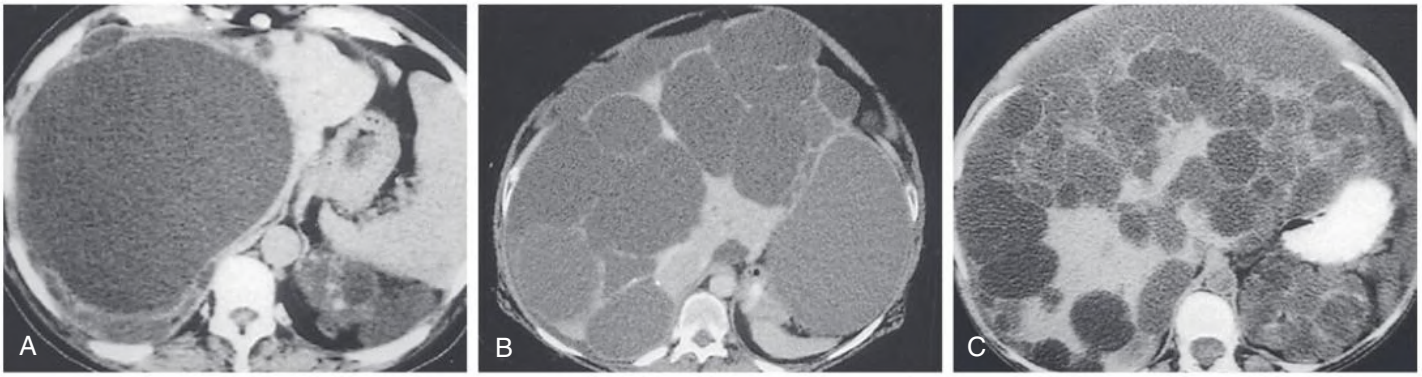

Fig. 46.4 Variable Presentation of Symptomatic Polycystic Liver Disease. (A) Hepatomegaly caused by a very large, isolated, dominant cyst. (B) Hepatomegaly caused by several large cysts. (C) Hepatomegaly caused by multiple smaller cysts throughout the hepatic parenchyma.

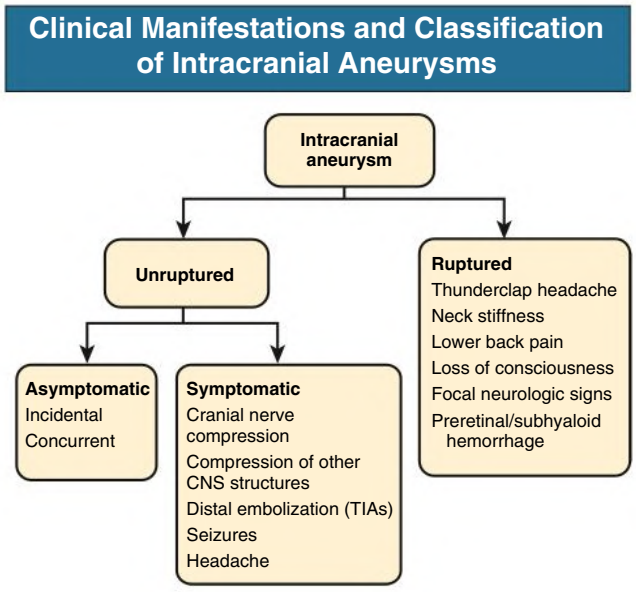

Fig. 46.5 Clinical manifestations and classification of intracranial aneurysms. *CNS,* Central nervous system; *TIAs,* transient ischemic attacks.

Intracranial Aneurysms

Intracranial aneurysms occur in about 8% of patients with ADPKD. There is some familial clustering; intracranial aneurysms occur in 6% of patients with a negative family history and 16% of those with a positive family history. Most are asymptomatic. Focal findings, such as cranial nerve palsy and seizure, may result from compression of local structures by an enlarging aneurysm (Fig. 46.5). Yearly rupture rates increase with size, ranging from less than 0.5% for aneurysms <5 mm in diameter to 4% for aneurysms >10 mm. Rupture carries a 35% to 55% risk for combined severe morbidity and mortality. The mean age at rupture in ADPKD is 39 years (vs. 51 years in the general population), with a range of 15 to 69 years. Most patients have normal kidney function, and up to 29% have normal BP at rupture.

Although still controversial, the largest follow-up study of asymptomatic, unruptured intracranial aneurysms discovered by presymptomatic imaging and a review of the literature suggest that widespread screening is not indicated for all patients with ADPKD because most intracranial aneurysms found by presymptomatic imaging are small, have a low risk for rupture, and require no treatment because the risks of intervention exceed any risk for rupture.[36] Indications for targeted imaging in patients with a good life expectancy include family history of intracranial aneurysm or subarachnoid hemorrhage, previous aneurysmal rupture, preparation for elective surgery with potential hemodynamic instability, high-risk occupations (e.g., airline pilots), and significant patient anxiety despite adequate information about the risks. Magnetic resonance angiography is the modality of choice for presymptomatic imaging because it is noninvasive and does not require IV contrast administration. CT angiography is a satisfactory alternative if there is no contraindication to IV contrast. Repeated imaging of patients with a strong family history of intracranial aneurysms or aneurysmal rupture after 5 to 10 years is recommended.

Other Vascular Abnormalities

In addition to intracranial aneurysms, ADPKD is associated with other vascular abnormalities, such as thoracic aortic and cervicocephalic arterial dissections, coronary artery aneurysms, and retinal artery and vein occlusions (Fig. 46.6). Thoracic aortic dissection is seven times more common in ADPKD than in the general population in autopsy series, but reported cases are rare. Rare patients with coronary aneurysms can present with cardiac ischemia and thrombus in the aneurysm in the absence of atherosclerotic disease. Several case reports describe abdominal aortic aneurysms in ADPKD. However, a prospective ultrasound study showed neither a wider aortic diameter nor a higher prevalence of abdominal aortic aneurysms in patients with ADPKD compared with an unaffected kindred in any age group.

Valvular Heart Disease and Other Cardiac Manifestations

Mitral valve prolapse is the most common valvular abnormality and has been demonstrated in up to 25% of patients with ADPKD by echocardiography. Mitral regurgitation, tricuspid regurgitation, and tricuspid prolapse also occur more frequently in ADPKD than in unaffected kindreds. Aortic regurgitation may be associated with dilation of the aortic root. On histologic examination, valvular tissue shows myxoid degeneration with disruption of collagen, as seen in Marfan and Ehlers-Danlos syndromes. Although the lesions may progress with time, they rarely require valve replacement. Echocardiography is not indicated unless a murmur is detected on physical examination. Coexistence of ADPKD and idiopathic cardiomyopathies (dilated, hypertrophic, and LV noncompaction) appears to be higher than expected by chance.[37] Small, hemodynamically insignificant pericardial effusion can be detected by CT scanning in up to 35% of patients with ADPKD.

(B) Gross specimen demonstrating a thoracic aortic dissection extending into the abdominal aorta in a patient with ADPKD.

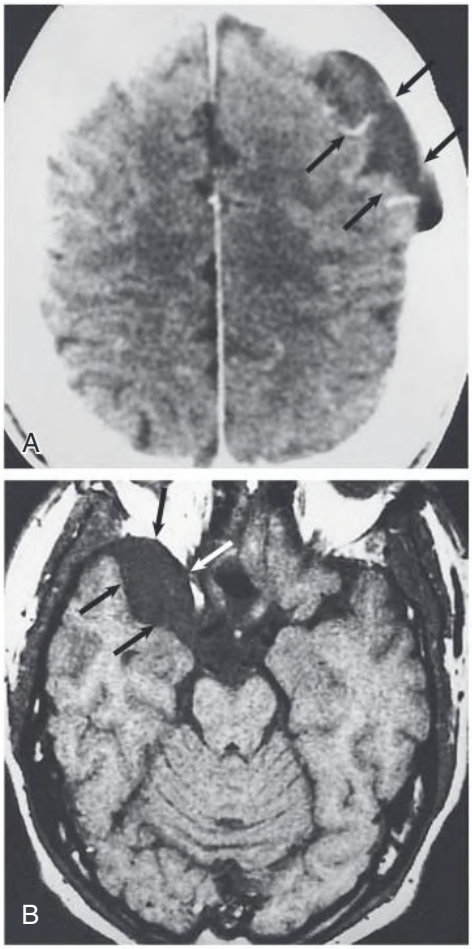

Fig. 46.7 Extrakidney Manifestations of Autosomal Dominant Polycystic Kidney Disease (ADPKD). Computed tomography (A) and magnetic resonance imaging (B) scans demonstrate cysts in the arachnoid membrane *(arrows)* in ADPKD.

Other Associated Conditions

Cyst formation has been described in such diverse organs as the pancreas, seminal vesicles, and arachnoid membrane (Fig. 46.7). Seminal vesicle cysts, usually multiple and bilateral, are found in 40% of ADPKD compared with 2% of nonaffected males. Ovarian cysts are not associated with ADPKD. Pancreas and arachnoid membrane cysts are present in 5% and 8% of patients, respectively. Pancreatic cysts are almost always asymptomatic, with rare occurrences of recurrent pancreatitis and possibly chance associations of intraductal papillary mucinous tumor or carcinoma. Epididymal and prostate cysts also may occur with increased frequency. Sperm abnormalities with defective motility are common in ADPKD and rarely may be a cause of male infertility. Spinal meningeal diverticula may occur with increased frequency and rarely manifest with intracranial hypotension (orthostatic headache, diplopia, hearing loss, ataxia) caused by cerebrospinal fluid leak. The prevalence of colonic and duodenal diverticula also may be increased.

Fig. 46.8 Polycystic Kidneys. Greatly enlarged polycystic kidneys from a patient with autosomal dominant polycystic disease compared with a normal kidney *(middle)*.

PATHOLOGY

Polycystic kidneys are diffusely cystic and enlarged (Fig. 46.8). Size varies from normal to weighing more than 4 kg. The outer and cut surfaces show numerous spherical cysts of varying size, which are distributed evenly between cortex and medulla. The epithelium lining the cysts is characterized by hyperplastic changes, including flat nonpolypoid hyperplasia, polypoid hyperplasia, and microscopic adenomas (Fig. 46.9), as well as increased rates of cell proliferation and apoptosis. Despite the frequency of hyperplastic lesions and microscopic adenomas, the incidence of renal cell carcinoma is not increased.

Cysts arise from all segments of the nephron and collecting ducts. As they grow, cysts dissociate from the parent tubule and eventually become isolated, fluid-filled sacs. There is no agreement on whether

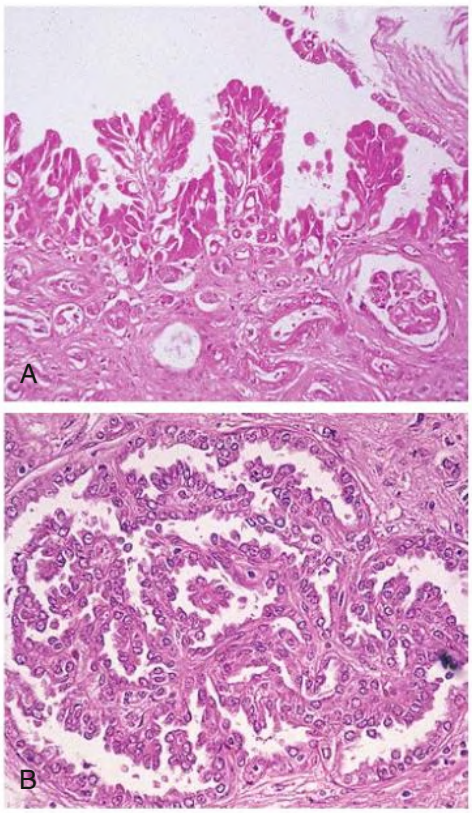

Fig. 46.9 Kidney Cyst Histology in Autosomal Dominant Polycystic Kidney Disease (ADPKD). (A) Papillary hyperplasia of cyst epithelium. (B) Papillary microscopic adenoma in kidney of patient with ADPKD. (Magnification ×200.)

the cysts originate preferentially from particular tubular segments. Most studies indicate that cysts are predominantly of distal nephron and collecting duct origin. Studies in advanced kidney disease showing proximal tubular cysts may be confounded by the effects of obstruction and acquired kidney cystic disease.

Polycystic kidneys demonstrate advanced sclerosis of preglomerular vessels, interstitial fibrosis, and tubular epithelial hyperplasia, even in patients with normal GFR or early kidney failure. Sclerosis involves both afferent arterioles and interlobular arteries. Interstitial fibrosis is also prominent, even in early disease. It is associated with an interstitial infiltrate of macrophages and lymphocytes.

TREATMENT

Therapy is directed toward the kidney and extrarenal complications of ADPKD in an effort to limit morbidity and mortality. Advances in the understanding of the genetics of ADPKD and mechanisms of cyst development and growth have raised hopes for treatments specifically directed toward limiting the development and progression of the disease, and some of these treatments are now being evaluated in clinical trials, with one treatment now approved (see Novel Therapies).

Flank Pain

Causes of flank pain that may require intervention, such as infection, stone, and tumor, should be excluded. Care should be taken to avoid long-term administration of nephrotoxic agents, such as combination analgesics and nonsteroidal anti-inflammatory drugs. Narcotic analgesics should be reserved for the management of acute pain. Patients with chronic kidney pain are at risk for narcotic and analgesic dependence, and a psychological evaluation and a supportive attitude by the physician are essential. Reassurance, lifestyle modification, and avoidance of aggravating activities may be helpful. Tricyclic antidepressants are helpful as in other chronic pain syndromes, with a generally well-tolerated side effect profile. Splanchnic nerve blockade with local anesthesia or corticosteroids results in pain relief prolonged beyond the duration of the local anesthetic.

When distortion of the kidneys by large cysts is deemed responsible for the pain and conservative measures fail, cyst decompression should be considered. Cyst aspiration, under ultrasound or CT guidance, is a relatively simple procedure. To prevent the reaccumulation of cyst fluid, sclerosing agents such as 95% ethanol, acidic solutions of minocycline, sodium tetradecyl sulfate, and, more recently, sodium tetradecyl sulfate mixed with room air (foam sclerotherapy),[38] may be used. Minor complications include microhematuria, localized pain, transient fever, and systemic absorption of the alcohol. More serious complications, such as pneumothorax, perirenal hematoma, arteriovenous fistula, urinoma, and infection, are rare. Complications from aspiration of centrally located cysts are more common, and the morbidity of the procedure is proportional to the number of cysts treated.

If multiple cysts are contributing to pain, laparoscopic or surgical cyst fenestration may be of benefit. Surgical decompression is effective in 80% to 90% of patients at 1 year, and 62% to 77% have sustained pain relief for over 2 years (Fig. 46.10A). Surgical intervention does not accelerate the decline in kidney function but does not appear to preserve declining GFR either (see Fig. 46.10B). Laparoscopic fenestration is as effective as open surgical fenestration in short-term follow-up in patients with limited disease, and there is a shorter, less complicated recovery period compared with open surgery. Previous abdominal surgery with possible adhesion formation is a relative contraindication.

Other interventions are available for the management of pain in ADPKD whose roles have not been fully defined. Laparoscopic kidney denervation has been used in combination with cyst fenestration and may be considered, particularly in polycystic kidneys without large cysts. Thoracoscopic sympatho-splanchnicectomy is effective in some patients but has significant morbidity. Catheter-based kidney denervation has been reported to be successful in a few patients, but a prospective protocolized evaluation of this approach is needed. Laparoscopic and retroperitoneoscopic nephrectomy and arterial embolization have been used to treat symptomatic polycystic kidneys in patients with ESKD.

Cyst Hemorrhage

Episodes of cyst hemorrhage are self-limited, and patients respond well to conservative management with bed rest, analgesics, and increased fluid intake to prevent obstructing clots. Rarely, bleeding is more severe, with extensive subcapsular or retroperitoneal hematoma causing significant decrease in hematocrit and hemodynamic instability. This requires hospitalization and transfusion. The antifibrinolytic agent tranexamic acid has been successfully used in some patients, but no controlled studies have been performed.[39] The dose should be reduced at lower levels of eGFR. Potential adverse effects of tranexamic acid therapy include glomerular thrombosis and ureteral obstruction from clots. In patients with unusually severe or persistent hemorrhage, segmental arterial embolization can be successful. If not, surgery may be required to control bleeding.

Urinary Tract and Cyst Infection

Because most kidney cyst infections begin as cystitis, prompt treatment of symptomatic cystitis and asymptomatic bacteriuria is indicated to prevent retrograde seeding of the kidney parenchyma. Antibiotics that require glomerular filtration, such as highly polar aminoglycosides, are

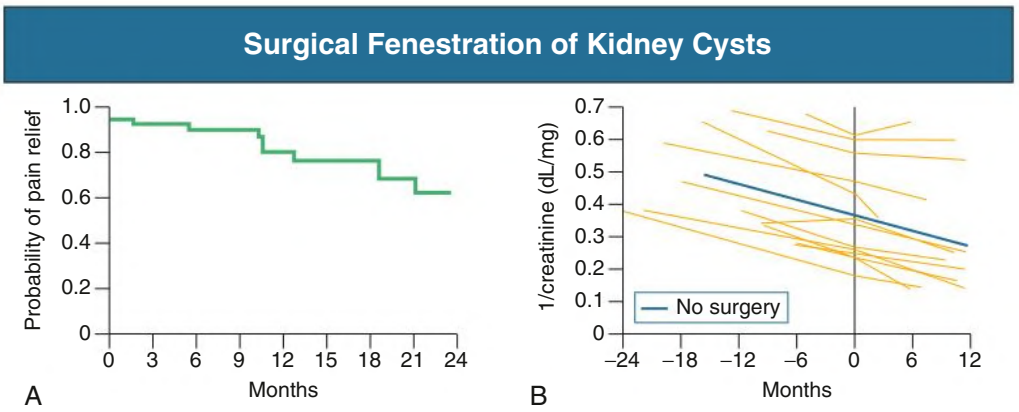

Fig. 46.10 Surgical Cyst Fenestration for Symptomatic Autosomal Dominant Polycystic Kidney Disease. (A) Effects on relief of pain. (B) Rate of decline of kidney function. *Orange lines* indicate the course of kidney function in individual patients who underwent cyst fenestration at month 0. The *green line* represents the mean rate of decline for all patients in the study.

not effective for upper UTI in severe kidney impairment. Cyst infection is often difficult to treat despite prolonged therapy with an antibiotic to which the organism is susceptible. Treatment failure occurs if antibiotics do not penetrate the cyst epithelium and achieve therapeutic concentrations within the cysts. Lipophilic agents have been shown to penetrate cysts reliably and have an acid dissociation constant (pK_a) that allows for favorable electrochemical gradients into acidic cyst fluid. Therapeutic agents of choice include trimethoprim-sulfamethoxazole and fluoroquinolones, both of which have favorable intracystic therapeutic concentration gradients at physiologic pH in gradient and nongradient cysts.

If fever persists after 1 to 2 weeks of appropriate antimicrobial therapy, infected cysts should be drained percutaneously or surgically. In the case of end-stage polycystic kidneys, nephrectomy should be considered. If fever recurs after stopping antibiotics, complicating features such as obstruction, perinephric abscess, and stone should be excluded. If no such complicating features are identified, the antibiotic course should be extended and may require several months to fully eradicate infection.

Nephrolithiasis

Treatment of nephrolithiasis in patients with ADPKD is the same as that in patients without ADPKD (see Chapter 60). Potassium citrate is the treatment of choice in the three stone-forming conditions associated with ADPKD: uric acid lithiasis, hypocitraturic calcium oxalate nephrolithiasis, and distal acidification defects. Extracorporeal shock wave lithotripsy and percutaneous nephrostolithotomy are reported to be 82% and 80% successful, respectively, without increased complications compared with patients without ADPKD.[1] Flexible ureterorenoscopy with laser fragmentation also has been used safely and effectively and cannot cause traumatic nephron loss.[1]

Hypertension

Control of hypertension is essential because uncontrolled hypertension accelerates the decline in kidney function and aggravates extrarenal complications. Antihypertensive agents of choice and optimal BP targets in ADPKD have not been established. Angiotensin-converting enzyme (ACE) inhibitors or angiotensin receptor blockers (ARBs) increase kidney blood flow in ADPKD, have a favorable side effect profile, and may have renoprotective properties that go beyond BP control. The HALT PKD study, a recent double-blind, placebo-controlled randomized clinical trial (RCT), examined the role of RAS blockade in both early and advanced ADPKD.[40,41] Monotherapy with ACE inhibitors gave good BP control in the majority of patients. In early ADPKD (15–49 years of age, GFR >60 mL/min/1.73 m^2), rigorous BP control (target range 95–110/60–75 mm Hg) was associated with slower increase in TKV, faster eGFR decline during the first 4 months of treatment followed by a slower eGFR decline thereafter without an overall eGFR effect, a lesser increase in kidney vascular resistance, and a greater decline in LV mass index, after 8 years of follow-up.[42] Patients with more severe ADPKD, determined by age-adjusted kidney volume, were more likely to benefit from rigorous BP control.[42] Dual RAS blockade with lisinopril and telmisartan had no beneficial effect compared with lisinopril alone in these patients, nor in more advanced ADPKD (aged 18–64 years with GFR between 25 and 60 mL/min/1.73 m^2). The HALT PKD study therefore supports the use of an ACE inhibitor or ARB as the antihypertensive medication of choice in most patients with ADPKD and a rigorous BP target (95–110/60–75 mm Hg) in young patients with ADPKD with normal kidney function and without other significant comorbidities.

Progressive Kidney Failure

General strategies to delay progression of CKD are discussed in Chapter 82. Hypertension plays an important role in the progression of ADPKD to ESKD. In addition to the HALT PKD clinical trials, long-term follow-up of participants in the Modification of Diet in Kidney Disease (MDRD) study suggested that individuals with ADPKD randomized to a low BP target (mean arterial pressure [MAP] < 92 mm Hg) experienced significantly less ESKD and combined ESKD/death than those randomized to the usual BP target (MAP < 107 mm Hg).[1]

Preclinical studies, and evidence suggesting the increased vasopressin effect on the kidney and cAMP levels are involved in cyst progression, have led to the ingestion of supplemental water sufficient to achieve a urinary osmolality below 250 mOsm/kg H_2O (~3 L in most patients) being recommended for patients with ADPKD with eGFR >30 mL/min, although no RCTs support this approach.[43] Exclusions would include severe protein or sodium restriction, reduced effective intravascular volume, taking diuretics or drugs enhancing the release of arginine vasopressin (AVP), or abnormal voiding. Serum sodium concentration should be monitored.

Patients with ADPKD have reduced morbidity and mortality on dialysis compared with patients with ESKD from other causes. Females appear to do better than males. The good outcome in ADPKD may result from higher endogenous erythropoietin production, better maintenance of hemoglobin, or lower comorbidity. Rarely, hemodialysis can be complicated by intradialytic hypotension if there is IVC

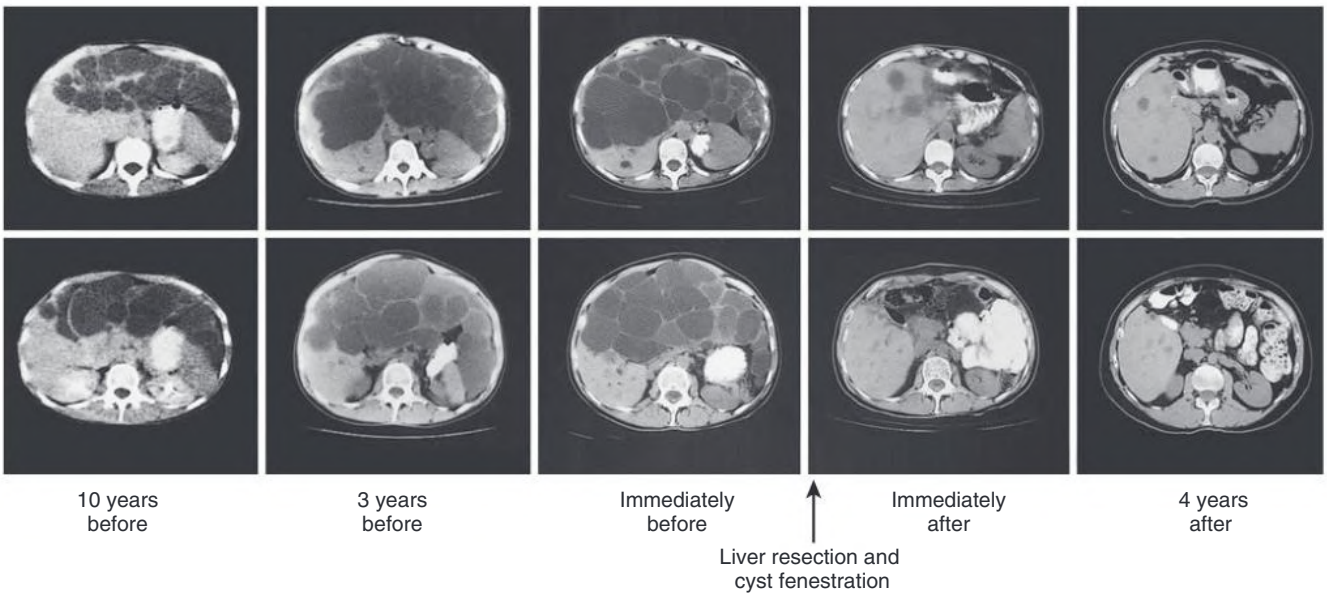

Fig. 46.11 Hepatic Resection in Autosomal Dominant Polycystic Kidney Disease (ADPKD). Computed tomography scans of the abdomen from two patients with ADPKD obtained are 10 years before *(column 1),* 3 years before *(column 2),* immediately before *(column 3),* immediately after *(column 4),* and 4 years after *(column 5)* liver resection and cyst fenestration, demonstrating long-term, sustained reduction in liver size after the procedure.

compression by a medially located kidney cyst. Despite kidney size, peritoneal dialysis can usually be performed in ADPKD, although there is increased risk for inguinal and umbilical hernias, which require surgical repair.

Polycystic Liver Disease

Usually asymptomatic, PLD requires no treatment. When symptomatic, therapy is directed toward reducing cyst volume and hepatic size. Noninvasive measures include avoiding excessive use of ethanol, other hepatotoxins, and possibly cAMP agonists (e.g., excessive caffeine), which have been shown to stimulate cyst fluid secretion in vitro. Histamine-2 blockers and somatostatin may reduce secretion of secretin and secretory activity of cyst walls. Estrogens are likely to contribute to cyst growth, but the use of OCs and postmenopausal ERT are contraindicated only if the liver is significantly enlarged and the risk for further hepatic cyst growth outweighs the benefits of estrogen therapy. Rarely, symptomatic PLD may require invasive measures to reduce cyst volume and hepatic size. Options include percutaneous cyst aspiration and sclerosis, laparoscopic fenestration, and open surgical fenestration. Cyst aspiration is the procedure of choice if symptoms are caused by one or a few dominant cysts or by cysts that are easily accessible to percutaneous intervention. To prevent the reaccumulation of cyst fluid, sclerosis with minocycline, 95% ethanol, or foam sclerotherapy with sodium tetradecyl sulfate is often successful. Laparoscopic fenestration can be considered for large cysts that are more likely to recur after ethanol sclerosis, or if several cysts are present that would require multiple percutaneous passes to be treated adequately. Partial hepatectomy with cyst fenestration is an option because PLD often spares a part of the liver with adequate preservation of hepatic parenchyma and liver function[44] (Fig. 46.11). In the rare case in which no segments are spared, liver transplantation may be necessary. When no better options are available, long-acting somatostatin analogs can be effective in reducing, and in some cases, reversing the growth of polycystic livers (see under Novel Therapies).

When a hepatic cyst infection is suspected, any cyst with unusual appearance on an imaging study should be aspirated for diagnostic purposes. The best management is percutaneous cyst drainage in combination with antibiotic therapy. Long-term oral antibiotic suppression or prophylaxis should be reserved for relapsing or recurrent cases. As for kidney cyst infection, antibiotics of choice are trimethoprim-sulfamethoxazole and the fluoroquinolones.

Intracranial Aneurysm

Ruptured or symptomatic intracranial aneurysm requires surgical clipping of the neck of the aneurysm. Asymptomatic aneurysms measuring <5 mm, diagnosed by presymptomatic screening, can be observed with repeated magnetic resonance angiography at 6 months, then annually and less frequently after stability of the aneurysm has been established. If the size increases, surgery is indicated. Definitive management of aneurysms between 6 and 9 mm remains controversial. Surgical intervention is usually indicated for all unruptured aneurysms that are at least 10 mm in diameter. For patients with high surgical risk or technically difficult lesions, endovascular treatment with detachable platinum coils may be indicated.[45]

NOVEL THERAPIES

A better understanding of the pathophysiology and the availability of animal models have facilitated the development of promising candidate drugs for clinical trials (see Fig. 46.2). Of the candidates, only tolvaptan has so far been approved by regulatory agencies for the treatment of rapidly progressive ADPKD[46] and has entered clinical practice.

Vasopressin Antagonists

The effect of vasopressin, through V_2 receptors, on cAMP levels in the collecting duct, the major site of cyst development in ADPKD, and the role of cAMP in cystogenesis provided the rationale for successful preclinical trials of vasopressin V_2 receptor antagonists.[2] High

water intake by itself also exerted a protective effect on the development of PKD in a rat model of PKD (PCK rat), probably because of suppression of vasopressin. Genetic elimination of AVP in these rats yielded animals born with normal kidneys that remained relatively free of cysts unless an exogenous V_2 receptor agonist was administered.[47]

The Tolvaptan Efficacy and Safety in Management of Autosomal Dominant Polycystic Kidney Disease and its Outcomes (TEMPO) 3:4 trial, a phase III, double-blind, 3-year RCT of a split daily dose of tolvaptan in 1445 patients with rapidly progressive disease and relatively preserved GFR (18–50 years old, estimated creatinine clearance > 60 mL/min, TKV > 750 mL), showed a reduction in the rates of kidney growth (from 5.5% to 2.8% per year) and of eGFR decline (from 3.70 to 2.72 mL/min/1.73 m^2 per year), and in the frequency of ADPKD-related adverse events (kidney pain, hematuria, UTI).[48] However, tolvaptan was associated with a higher frequency of aquaresis-related adverse events (polyuria, thirst, urinary frequency, nocturia) that led to drug discontinuation in 8.3% of tolvaptan-treated patients. In addition, clinically significant increases in liver enzymes (>2.5 times the upper limit of normal) were seen in 4.9% of tolvaptan-treated versus 1.2% of placebo-treated patients, and two patients had severe hepatocellular toxicity. Small increases in serum sodium and uric acid levels were also seen more frequently in the patients taking tolvaptan. The Replicating Evidence of Preserved Renal function: an Investigation of Tolvaptan Safety and Efficacy (REPRISE) trial, a phase III, randomized withdrawal, double-blind, 1-year trial, in 1370 18- to 55-year-old or 56- to 65-year-old patients with eGFR of 25 to 65 or 25 to 44 mL/min per 1.73 m^2, respectively, showed a reduction in the rate of eGFR decline (from 3.61 to 2.34 mL/min/1.73 m^2).[49] Reversible elevations in the alanine aminotransferase of more than three times the upper limit of normal occurred in 5.6% in the tolvaptan group and 1.2% in the placebo group. No patients had severe hepatocellular toxicity, likely because of more frequent monitoring and earlier discontinuation of tolvaptan. An analysis of 97 patients continuously treated with tolvaptan at a single center for 4.6 (range, 1.1–11.2) years showed that the effect on the rate of eGFR decline was sustained and cumulative over time.[50]

Tolvaptan is approved for the treatment of rapidly progressive ADPKD in the United States, Japan, Canada, the European Union, Switzerland, Norway, South Korea, and Australia. Criteria of rapid progression vary widely among countries, using a combination of age, baseline GFR, GFR slope, baseline TKV, and TKV rate of growth. Height-adjusted TKV (HtTKV) adjusted by age (image classification) is a practical and validated method to identify risk of rapid progression (Class 1C–1E) at early stages of the disease when the GFR is still normal.[51] Because of the potential hepatocellular toxicity, the Food and Drug Administration (FDA) in the United States requires a risk evaluation and mitigation strategy (REMS) program, including liver function testing before initiation and at specific intervals (after 2 and 4 weeks, then monthly for 18 months, and every 3 months thereafter) after initiation of treatment. A clinical trial of lixivaptan, a vasopressin V2 receptor antagonist predicted by a quantitative systems toxicology mathematical model to have a lower risk of hepatotoxicity compared with tolvaptan, is ongoing.

Somatostatin Analogs

Somatostatin acting on somatostatin receptors inhibits cAMP accumulation not only in the kidney but also in the liver. Somatostatin has a half-life of approximately 3 minutes, so more stable synthetic peptides (octreotide, lanreotide, pasireotide) have been developed for clinical use, which vary in stability and receptor affinity. In preclinical studies, these drugs reduced cAMP levels and proliferation of cholangiocytes in vitro, expansion of liver cysts in three-dimensional collagen culture, and development of kidney and liver cysts and fibrosis in animal models orthologous to ARPKD and ADPKD. Three initial small RCTs of octreotide or lanreotide[52–54,55–57] showed similar results. Kidney growth was halted during the first year of treatment and then resumed, possibly at a lower rate than without treatment. Liver volume decreased by 4% to 6% during the first year of treatment, and this reduction was sustained during the second year. Similar results were obtained in a larger RCT of patients (A Long-Acting Somatostatin on Disease Progression in Nephropathy Due to Autosomal Dominant Polycystic Kidney Disease [ALADIN]), in which a trend toward stabilization of GFR was observed after the first year.[58] The results of three additional RCTs have been recently reported. The Developing Interventions to Halt Progression of Autosomal Dominant Polycystic Kidney Disease-1 (DIPAK-1) trial, an open-label, 2.5-year RCT of lanreotide-LAR, 120 mg intramuscularly every 28 days, in 309 patients with eGFR 30 to 60 mL/min/1.73 m^2, confirmed a significant reduction in liver and kidney cyst growth, but no attenuation of eGFR decline.[59] ALADIN-2, a double-blind, placebo-controlled 3-year RCT of octreotide-LAR, 40 mg intramuscularly every 28 days, in 100 patients with eGFR between 15 and 40 mL/min/1.73 m^2 showed a significant effect on kidney growth and no effect on the rate of eGFR decline but a significant reduction in the rate of progression to ESKD, particularly in the patients with most advanced disease.[60] A double-blind, 1-year RCT of pasireotide (60 mg subcutaneously every 28 days) in 48 patients aged older than 18 years, with eGFR greater than 30 mL/min/1.73 m^2 and liver volume greater than 4000 mL, showed a reduction in liver volume and total kidney growth rates but no effect on eGFR.[61]

Octreotide and lanreotide are generally well tolerated. Self-resolving abdominal cramps and loose stools are common in the first few days after the injections. Other adverse effects include injection site granuloma and pain, cholelithiasis, steatorrhea, weight loss, and, rarely, hair loss. In DIPAK-1, an increased frequency of liver cyst infection in patients with a past history of a similar episode was observed. A high incidence of diabetes and hyperglycemia was observed in patients treated with pasireotide.

Mammalian Target of Rapamycin Inhibitors

The mammalian target of rapamycin (mTOR) is activated in animal models of PKD. Patients with the contiguous *PKD1/TSC2* gene syndrome have more severe PKD than those with ADPKD alone. This observation suggests a convergence of signaling pathways downstream from PC1 and the TSC proteins tuberin and hamartin that control the activity of mTOR. Studies in rodent models of PKD showed that the mTOR inhibitors sirolimus and everolimus significantly prevent cyst expansion and protect kidney function. However, two large RCTs using everolimus and sirolimus for 18 to 24 months have shown no benefit.[62,63]

Other Investigational Therapies

Pravastatin, an HMG-CoA reductase inhibitor, slowed the rate of kidney growth in a small RCT in children and young adults with ADPKD.[64] A phase II, multicenter, double-blind RCT of the Src inhibitor bosutinib reduced the rate of kidney growth, with a trend to worsen GFR (ClinicalTrials.gov NCT01233869). Clinical trials of the glycosylceramide synthase inhibitor venglustat, Nrf2 activator bardoxolone, vasopressin V2 receptor antagonist lixivaptan, multikinase inhibitor KD019, metformin, pioglitazone, nicotinamide, and triptolide are ongoing (see Fig. 46.2).

TRANSPLANTATION

Transplantation is the treatment of choice for ESKD in patients with ADPKD. There is no difference in patient or graft survival between patients with ADPKD and other ESKD populations. Living donor transplants also have graft survival no different from that of non-ADPKD populations. However, living related transplantation has only recently been widely practiced in the ADPKD population. In 1999, 30% of kidney transplants for patients with ADPKD were from living donors in the United States, compared with 12% in 1990.

Complications after transplantation are no greater in the ADPKD population than in the general population, and specific complications directly related to ADPKD are rare. Cyst infection is not increased after transplantation, and there is no significant increase in the incidence of symptomatic mitral valve prolapse or hepatic cyst infection. One study showed an increased rate of diverticulosis and bowel perforation in ADPKD. Whether ADPKD increases the risk for development of new-onset diabetes mellitus after transplantation is controversial.

Although practiced routinely in the past, pretransplantation nephrectomy has fallen out of favor. By 1 and 3 years after kidney transplantation, kidney volumes decrease by 37.7% and 40.6%, whereas liver volumes increase by 8.6% and 21.4%, respectively.[65] Indications for nephrectomy include a history of infected cysts, frequent bleeding, severe hypertension, and massive kidney enlargement with extension into the pelvis. There is no evidence of an increased risk for development of kidney cell carcinoma in native ADPKD kidneys after transplantation. When nephrectomy is indicated, hand-assisted laparoscopic nephrectomy is associated with less intraoperative blood loss, less postoperative pain, and faster recovery compared with open nephrectomy and is increasingly being used.

SELF-ASSESSMENT QUESTIONS

1. Age of ESKD onset in the patient with ADPKD depends on:
   - **A.** mutated gene (*PKD1* vs. *PKD2*).
   - **B.** type of mutation.
   - **C.** modifier genes.
   - **D.** environmental factors.
   - **E.** all of the above.
2. Which one of the following statements about ADPKD and intracranial aneurysm is *true?*
   - **A.** All ADPKD patients should be evaluated for intracranial aneurysms.
   - **B.** Most intracranial aneurysms rupture.
   - **C.** The risk for rupture of an intracranial aneurysm depends on its size and location.
   - **D.** Magnetic resonance angiography to screen for intracranial aneurysms is contraindicated in advanced CKD because it requires the administration of gadolinium.
   - **E.** None of the above.
3. Which one of the following is the most common risk factor for nephrolithiasis in ADPKD?
   - **A.** Low urine citrate
   - **B.** Hypercalciuria
   - **C.** Hyperuricosuria
   - **D.** Hyperoxaluria
   - **E.** Renal tubular acidosis
4. Which of the following statements about ADPKD and hypertension is *true?*
   - **A.** ACE inhibitors have been shown to be superior to β-blockers to treat hypertension and protect kidney function in patients with ADPKD.
   - **B.** Rigorous BP control has been shown to be superior to standard BP control in prospective studies to protect kidney function in patients with ADPKD and CKD stage 3.
   - **C.** Both A and B are true.
   - **D.** Both A and B are false.

Other Cystic Kidney Diseases

Lisa M. Guay-Woodford

Numerous disorders share kidney cysts as a common feature (Box 47.1).[1] These disorders may be inherited or acquired; their manifestations may be confined to the kidney or expressed systemically. They may present at a wide range of ages, from the perinatal period to old age (Fig. 47.1). The kidney cysts may be single or multiple, and the associated kidney morbidity may range from clinical insignificance to progressive parenchymal destruction with resultant kidney insufficiency.

The clinical context often helps distinguish these kidney cystic disorders from one another. Echogenic, enlarged kidneys in a neonate or infant should raise suspicion about autosomal recessive polycystic kidney disease (ARPKD), autosomal dominant polycystic kidney disease (ADPKD, see Chapter 46), tuberous sclerosis complex (TSC), or one of the many congenital syndromes associated with kidney cystic disease. Reduced kidney function in an adolescent suggests ARPKD or nephronophthisis (NPHP) as possible etiologies. The finding of a solitary cyst in a 5-year-old may indicate a calyceal diverticulum, whereas this finding in a 50-year-old is most compatible with a simple kidney cyst. Kidney stones occur in ADPKD and medullary sponge kidneys (MSKs). For those disorders with systemic manifestations, such as ADPKD, TSC, and von Hippel-Lindau (VHL) disease, the associated extrarenal features may provide other important differential diagnostic clues.

For an increasing number of the single-gene disorders, genetic testing is available in expert laboratories around the world. Genetic testing resources are listed at the National Institutes of Health (NIH) Genetic Testing Registry (http://www.ncbi.nlm.nih.gov/gtr).

AUTOSOMAL RECESSIVE POLYCYSTIC KIDNEY DISEASE

Definition

ARPKD is a severe, typically early-onset form of cystic disease that primarily involves the kidneys and biliary tract. Affected patients have a spectrum of clinical phenotypes that correlate in part with the age at presentation.

Etiology and Pathogenesis

Genetic Basis

All typical forms of ARPKD are caused by mutations in a single gene, *PKHD1,* that encodes multiple alternatively spliced isoforms predicted to form both membrane-bound and secreted proteins. The largest protein product of *PKHD1,* the fibrocystin/polyductin complex (FPC), contains one membrane-spanning domain and an intracellular C-terminal tail. FPC localizes, at least in part, to the primary cilium and the centrosome in kidney epithelial cells. The basic defects observed in ARPKD suggest that FPC mediates the terminal differentiation of the collecting duct and biliary tract. However, the exact function of the numerous isoforms has not been defined, and the widely varying clinical spectrum of ARPKD may depend in part on the nature and number of splice variants that are disrupted by specific *PKHD1* mutations.[2]

Although ARPKD is generally considered to be a genetically homogeneous disease, recent reports describe a few patients with atypical forms of ARPKD that result from mutations in either the *DZIP1L* gene or *CYS1,* the human orthologue of the gene disrupted in the *cpk* mouse, the most widely studied experimental model of ARPKD.[3,4] These children presented with hypertension and large, cystic kidneys; some progressed to end-stage kidney disease (ESKD). Distinguishing features of the disease phenotype in these children include more moderate kidney disease and the absence of clinically apparent liver disease.

Pathogenesis

ARPKD typically begins in utero, and the kidney cystic lesion appears to be superimposed on a normal developmental sequence. The tubular abnormality involves nonobstructive, fusiform, and/or saccular dilation of the kidney collecting ducts. In the liver, defective remodeling of the ductal plate in utero results in persistence of primitive bile duct configurations and the evolution of progressive portal tract fibrosis.[5] The remainder of the liver parenchyma develops normally. The defect in ductal plate remodeling is accompanied by abnormalities in the branching of the portal vein. The resulting histopathologic pattern is referred to as congenital hepatic fibrosis.

ARPKD is one of several kidney cystic diseases that are associated with congenital hepatic fibrosis, prompting these disorders to be described as hepatorenal fibrocystic diseases.[6] The primary cilium appears to play a central role in the pathogenesis of ARPKD and other hepatorenal fibrocystic diseases, so the broader term "ciliopathies" is used for these disorders, in which dysfunction of the cilia-centrosome complex appears to underpin the development of a wide array of phenotypes, including kidney cystic disease.[5]

Epidemiology

The estimated incidence of ARPKD is 1 per 20,000 live births. It occurs more frequently in Whites than in other ethnic populations. A recent U.S.-based study using electronic health record (EHR) data calculated an annualized incidence of 1 in 26,485 live births.[7]

Clinical Manifestations

The clinical spectrum of ARPKD is variable. Most cases are identified either in utero or at birth. The most severely affected fetuses have enlarged echogenic kidneys and oligohydramnios because of poor fetal urine output. These fetuses develop the Potter phenotype, with pulmonary hypoplasia, a characteristic facies, and deformities of the spine and limbs. Pulmonary hypoplasia continues to pose a severe clinical challenge and often dictates postnatal survival.[8] A recent EHR-based analysis estimated perinatal mortality to be about 21%.[7] Kidney

function, although frequently compromised, is rarely a cause of neonatal death.

For those who survive the first month of life, the reported mean 5-year patient survival rate is 85% to 90%. Morbidity and mortality result from severe systemic hypertension, reduced kidney function, and portal hypertension because of portal tract hyperplasia and fibrosis.[9] Hypertension usually develops in the first few months and ultimately affects 70% to 80% of patients. ARPKD patients have defects in both urinary-diluting capacity and concentrating capacity. Newborns can have hyponatremia, presumably resulting from defects in free water excretion. Although net acid excretion may be reduced, metabolic acidosis is not a significant clinical feature. Retrospective studies have noted an increased incidence of pyuria on urinalysis and culture-confirmed urinary tract infections (UTI).[2]

In the first 6 months of life, ARPKD infants may have a transient improvement in glomerular filtration rate (GFR) because of kidney maturation. Subsequently, a progressive but variable decline in GFR occurs, with patients presenting in the first month of life progressing more rapidly to ESKD than those presenting at more than 1 month of age.[10,11] With advances in effective therapy for ESKD, prolonged survival is common and for many patients, the hepatic complications become the predominant clinical issue.

On average, those infants with serum creatinine values greater than 2.2 mg/dL (200 µmol/L) progress to ESKD within 5 years, but this is highly variable. In longitudinal studies, the probability of freedom from ESKD is approximately 85% at 1 year, approximately 70% at 10 years, approximately 65% at 15 years, and approximately 40% at 20 years.[12]

In children who present later in childhood or in adolescence, portal hypertension is frequently the predominant clinical abnormality, with hepatosplenomegaly and bleeding esophageal or gastric varices, as well as hypersplenism with consequent thrombocytopenia, anemia, and leukopenia. Hepatocellular function is usually preserved. Ascending suppurative cholangitis is a serious complication and can cause fulminant hepatic failure.[13,14]

Other associated features include growth retardation, although the mechanism is not yet defined, and, very rarely, vascular aneurysms (intracranial and extracranial).[15,16]

BOX 47.1 Kidney Cystic Disorders

Disorders

Nongenetic

Developmental

Medullary sponge kidney (MSK)[a]

Kidney cystic dysplasia

- Multicystic dysplasia
- Cystic dysplasia associated with lower urinary tract obstruction
- Diffuse cystic dysplasia: syndromal and nonsyndromal

Acquired

Simple cysts

Solitary multilocular cysts

Hypokalemic cystic disease

Acquired cystic disease (in advanced kidney failure)

Genetic[b]

Autosomal Dominant

Autosomal dominant polycystic kidney disease

Autosomal dominant tubulointerstitial kidney disease

Tuberous sclerosis complex

von Hippel-Lindau syndrome

Autosomal Recessive

Autosomal recessive polycystic kidney disease

Nephronophthisis and nephronophthisis-like disorders (Meckel-Gruber syndrome, Joubert syndrome, Bardet-Biedl syndrome)

X-Linked

Oro-facio-digital syndrome type I

[a]MSK is generally considered to be a sporadic disorder, but recent studies provide evidence for familial clustering, involving autosomal dominant inheritance with reduced disease penetrance and variability in disease expression.

[b]Mendelian Inheritance in Man (http://www.ncbi.nlm.nih.gov/entrez/query.fcgi?db=OMIM)

Pathology

Kidney

The kidney involvement is invariably bilateral and largely symmetric. The histopathology varies depending on the age of presentation and the extent of cystic involvement (Fig. 47.2AB).

In the affected neonate, the kidneys can be 10 times normal size but retain the typical kidney contour. Dilated, fusiform collecting ducts

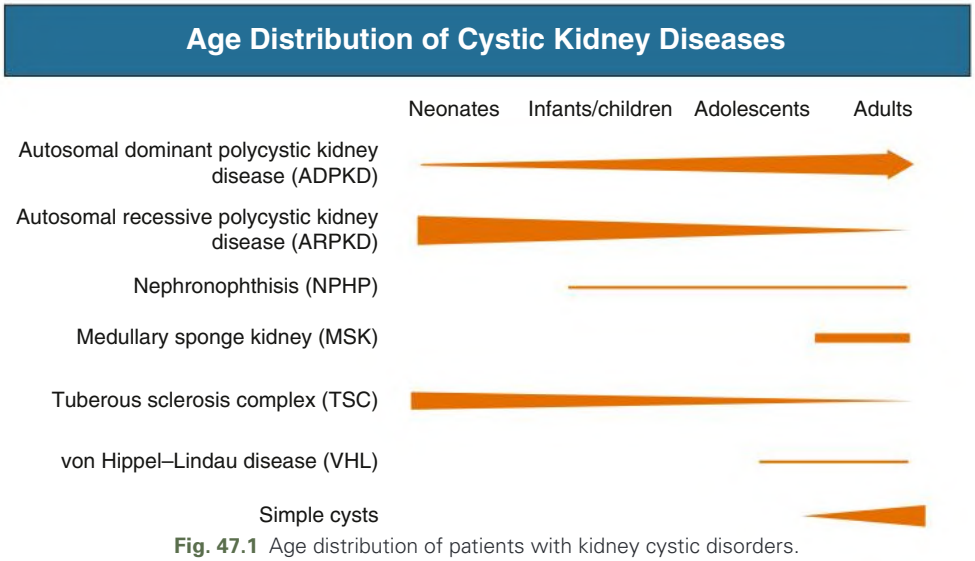

Fig. 47.1 Age distribution of patients with kidney cystic disorders.

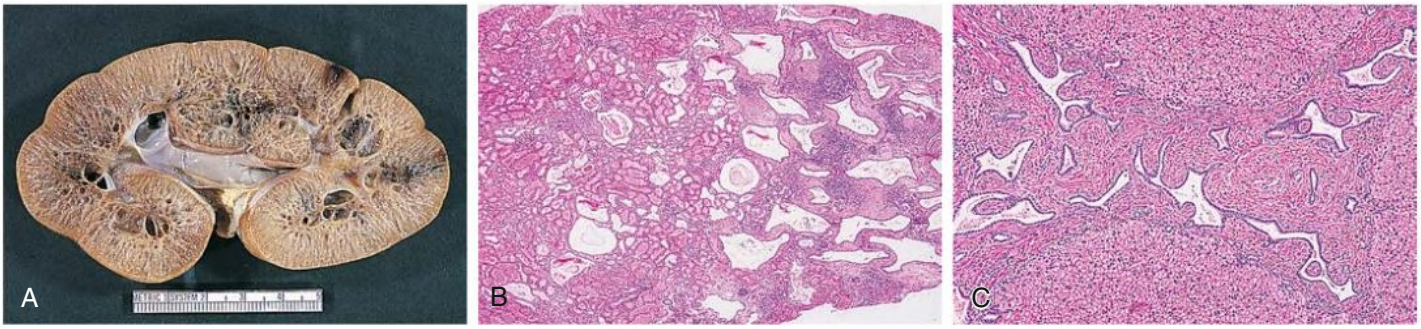

Fig. 47.2 Pathologic Features of Autosomal Recessive Polycystic Kidney Disease. (A) Cut section of autosomal recessive polycystic kidney disease (ARPKD) kidney from a 1-year-old child shows discrete medullary cysts and dilated collecting ducts. (B) Light microscopy shows later-onset ARPKD kidney with prominent medullary ductal ectasia (H&E stain; magnification ×10). (C) Light microscopy of congenital hepatic fibrosis shows extensive fibrosis of the portal area with ectatic, tortuous bile ducts and hypoplasia of the portal vein (H&E stain; ×40).

extend radially through the cortex. On histopathologic sections, the dilated medullary collecting ducts are often cut tangentially or transversely, resulting in a more spheroid appearance. Up to 90% of the collecting ducts are involved. Associated interstitial fibrosis is minimal in neonates and infants but increases with progressive disease.

In patients diagnosed later in childhood, the kidney size and extent of cystic involvement tend to be more limited. Cysts can expand to as large as 2 cm in diameter and may become more spherical. Progressive interstitial fibrosis is probably responsible for secondary tubular obstruction. In older children, medullary ductal ectasia is the predominant finding.

Cysts are lined with a single layer of nondescript cuboidal epithelium. The glomeruli and nephron segments proximal to the collecting ducts are initially structurally normal but are often crowded between ectatic collecting ducts or displaced into subcapsular wedges. The presence of cartilage or other dysplastic elements indicates a diagnosis other than ARPKD, such as cystic dysplasia.

Liver

The liver lesion in ARPKD is characterized by ductal plate malformation. The liver can be either normal in size or somewhat enlarged. Bile ducts are dilated (biliary ectasia) and marked cystic dilation of the entire intrahepatic biliary system (Caroli syndrome) is well described.[13] In neonatal ARPKD, the bile ducts are increased in number, tortuous in configuration, and often located around the periphery of the portal tract. In older children, the biliary ectasia is accompanied by increasing portal tract fibrosis and hypoplasia of the small portal vein branches (see Fig. 47.2C). The hepatic parenchyma may be intersected by delicate fibrous septa that link the portal tracts, but the hepatocytes themselves are seldom affected.

Diagnosis

Imaging

A number of other hepatorenal fibrocystic diseases can resemble or "phenocopy" ARPKD (Table 47.1).[6] Although most of these disorders are characterized by large, echogenic kidneys in the fetus and neonate, these can usually be distinguished by ultrasound. ARPKD kidneys in utero are hyperechogenic and display *decreased* corticomedullary differentiation because of the hyperechogenic medulla (Fig. 47.3A). With high-resolution ultrasound, the radial array of dilated collecting ducts may be imaged. In comparison, ADPKD kidneys in utero tend to be moderately enlarged with a hyperechogenic cortex and relatively hypoechogenic medulla causing *increased* corticomedullary differentiation.

Kidney size typically peaks at 1 to 2 years of age, then gradually declines relative to the child's body size and stabilizes by 4 to 5 years. With age, there is increased medullary echogenicity with scattered small cysts, measuring less than 2 cm in diameter. These cysts and progressive fibrosis can alter the usual kidney contour, causing ARPKD in some older children to be mistaken for ADPKD. Magnetic resonance imaging (MRI) or contrast-enhanced computed tomography (CT) scanning can be useful in delineating the kidney architecture (see Fig. 47.3B). Bilateral pelvicaliectasis and kidney calcifications have been reported in 25% and 50% of ARPKD patients, respectively. In adults with medullary ectasia alone, the cystic lesion may be confused with MSK.

The liver may be either normal in size or enlarged. It is usually less echogenic than the kidneys. Prominent intrahepatic bile duct dilation suggests associated Caroli syndrome. With age, the portal fibrosis tends to progress and in older children, ultrasound typically shows hepatosplenomegaly and a patchy increase in hepatic echogenicity.[13,14]

Genetic Testing

With the identification of *PKHD1* as the principal disease gene, genetic testing is available as a clinical diagnostic tool. The mutation detection rate is 80% to 87%. Current diagnostic approaches include gene-specific analysis and multigene testing panels using next-generation sequencing technologies.[17] Genetic testing is primarily applied in the context of prenatal testing and preimplantation genetic diagnosis.

Patients with two truncating mutations typically have a severe phenotype leading to perinatal or neonatal mortality, whereas missense mutations are typically associated with neonatal survival.[17,18] The European ARegPKD Consortium recently reported that the position of *PKHD1* variants is important in determining the phenotype. Patients with two missense variants affecting FPC amino acids 709 to 1837 or a missense variant in this region combined with a null variant *less frequently* develop ESKD. Patients with missense variants affecting FPC amino acids 1838 to 2624 have less severe liver disease, whereas variants affecting amino acids 2625 to 4074 are associated with poorer hepatic outcome.[19] These findings may facilitate genetic counseling, but caution is warranted because about 20% of ARPKD siblings have discordant clinical phenotypes, perhaps because of the modulating effect of genetic and environmental factors.[17]

Treatment

The survival of neonates with ARPKD has improved significantly in the last two decades because of advances in mechanical ventilation and

TABLE 47.1 Features of Kidney Cystic Disease in Children

Clinical Characteristics	ARPKD	NPHP	Meckel-Gruber[a]	GCKD[b]	ADPKD	TSC

Genetic testing[e]	Yes	Most	Most	Yes	Yes	Yes

[a]Meckel-Gruber syndrome is a severe, often lethal, autosomal recessive disorder characterized by bilateral kidney cystic dysplasia, biliary ductal dysgenesis, bilateral postaxial polydactyly, and variable CNS malformations. The triad of kidney cystic disease, occipital encephalocele, and polydactyly is most common. Genes disrupted in Meckel-Gruber syndrome have also been identified in NPHP and Joubert patients, suggesting a phenotypic spectrum.
[b]GCKD can occur as the infantile manifestation of ADPKD. Familial hypoplastic GCKD, because of mutations in *HNF1B,* the gene encoding hepatocyte nuclear factor (HNF1β), can be associated with MODY5.
[c]A contiguous germline deletion of both the *PKD1* and *TSC2* genes (the PKDTS contiguous gene syndrome) occurs in a small group of patients with features of TSC, as well as massive kidney cystic disease reminiscent of ADPKD, severe hypertension, and a progressive decline in kidney function with the onset of ESKD in the second or third decade of life.
[d]Joubert syndrome is a genetically heterogeneous, autosomal recessive disorder characterized by developmental defects in the cerebellum (cerebellar vermis aplasia) and the eye (coloboma), as well as retinitis pigmentosa, congenital hypotonia, and either ocular motor apraxia or irregularities in breathing patterns during the neonatal period. The disease can be associated with NPHP, and mutations in several *NPHP* genes have been described in Joubert patients.
[e]Genetic testing listed on the NIH Genetic Testing Registry (http://www.ncbi.nlm.nih.gov/gtr).

other supportive measures. Aggressive interventions such as unilateral or bilateral nephrectomies and continuous hemofiltration have been advocated in neonatal management, but prospective, controlled studies have yet to be performed.[9]

For children who survive the perinatal period, blood pressure (BP) control is a major clinical issue. Angiotensin converting enzyme (ACE) inhibitors, angiotensin receptor blockers (ARBs), adrenergic antagonists, and loop diuretics are effective antihypertensive agents. The management of ARPKD children with declining GFR should follow the standard guidelines established for chronic kidney disease (CKD) in children.[9]

Given the relative urinary concentrating defect, children with ARPKD should be monitored for dehydration during intercurrent illnesses associated with fever, tachypnea, nausea, vomiting, or diarrhea. In those infants with severe polyuria, thiazide diuretics may be used to decrease distal nephron solute and water delivery. Acid-base balance should be closely monitored and supplemental bicarbonate therapy initiated as needed.

Close monitoring for portal hypertension is warranted in all patients with ARPKD. There is no correlation between the severity of the kidney and liver disease.[14] Recent studies suggest that the platelet count combined with serial abdominal ultrasound (assessing liver and splenic size) and Doppler flow studies provide good surrogate markers for the portal hypertension severity.[14] Medical management may include sclerotherapy or variceal banding.[13] Surgical approaches such as portocaval or splenorenal shunting may be indicated in some patients. Although hypersplenism is fairly common, splenectomy is seldom warranted. Unexplained fever with or without elevated

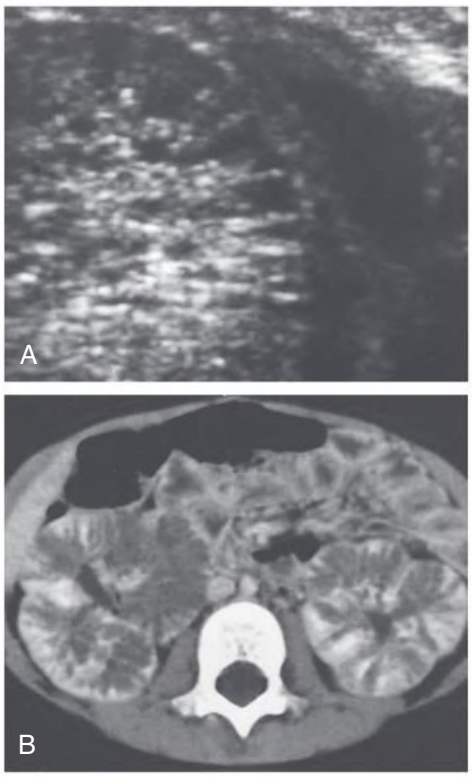

Fig. 47.3 Radiologic Findings Associated With Autosomal Recessive Polycystic Kidney Disease. (A) Autosomal recessive polycystic kidney disease (ARPKD) in a neonate. High-resolution ultrasound reveals radially arrayed dilated collecting ducts. (B) ARPKD in a symptomatic 4-year-old girl. Contrast-enhanced computed tomography shows striated nephrogram and prolonged corticomedullary differentiation.

transaminase levels suggests bacterial cholangitis and requires meticulous evaluation to make the diagnosis and guide aggressive antibiotic therapy.

Effective management of systemic and portal hypertension, coupled with successful kidney replacement therapy (KRT), has allowed long-term patient survival. Therefore, the prognosis in ARPKD, particularly for those children who survive the first month of life, is far less bleak than popularly thought and aggressive medical therapy is warranted.

Although current treatment of ARPKD is entirely supportive, preclinical studies suggest future benefit from new, targeted therapies.[2]

Transplantation

A prolonged period of dialysis in childhood has been associated with both cognitive and educational impairment.[20] Therefore, kidney transplantation is the treatment of choice for ESKD in ARPKD patients. ARPKD is a recessive disorder, and therefore either parent may be a suitable kidney donor. However, the identification of subtle kidney and liver abnormalities on ultrasound in ARPKD parents[21] mandates more extensive posttransplant follow-up. Native nephrectomies may be warranted in patients with massively enlarged kidneys to allow allograft placement.

In some patients, combined kidney-liver transplantation may be appropriate.[22] Indications include the combination of kidney failure and either recurrent cholangitis or significant complications of portal hypertension (e.g., recurrent variceal bleeding, refractory ascites, and the hepatopulmonary syndrome). In addition, liver transplantation may be a consideration for patients with a single episode of cholangitis in the context of Caroli syndrome.[13]

NEPHRONOPHTHISIS: AUTOSOMAL DOMINANT TUBULOINTERSTITIAL KIDNEY DISEASE

Definitions

NPHP and autosomal dominant tubulointerstitial kidney disease (ADTKD; formerly known as medullary cystic kidney disease [MCKD]) share a triad of histopathologic features: tubular basement membrane irregularities, tubular atrophy with cyst formation, and interstitial cell infiltration with fibrosis. These histopathologically similar disorders differ in their mode of transmission, age of onset, and genetic defects. NPHP is an autosomal recessive disorder that manifests in childhood, whereas ADTKD occurs in adults. NPHP is more common than ADTKD and has been reported as an isolated kidney disease and also in association with systemic manifestations, including retinitis pigmentosa, congenital hepatic fibrosis, oculomotor apraxia, and skeletal anomalies.

Nephronophthisis

NPHP is an autosomal recessive tubulointerstitial nephropathy and one of the most frequent inherited causes of ESKD in children and adolescents.[23] The term *nephronophthisis* derives from the Greek, meaning "progressive loss of nephrons."

Genetic Basis

Multiple disease-causing genes have been identified. Defects in *NPHP1* account for 20% of NPHP with large, homozygous deletions detected in 80% of affected family members and in 65% of sporadic cases. Mutations in each of the remaining NPHP genes cause 1% to 4% of NPHP-related disease, meaning that almost two-thirds of cases remain genetically unsolved.[24–26]

Clinical disease expression appears to be exacerbated by oligogenic inheritance, in which patients carry two mutations in a single *NPHP* gene as well as a single-copy mutation in an additional *NPHP* gene. In addition, multiple allelism, or distinct mutations in a single gene, appears to explain the continuum of multiorgan phenotypic abnormalities observed in NPHP-related disorders, which include Meckel-Gruber syndrome, Joubert syndrome, and Bardet-Biedl syndrome.[25,27]

Most of the protein products of the NPHP-associated genes are expressed in the cilia-centrosome complex[5]; NPHP is considered a ciliopathy.[25]

Clinical Manifestations

Kidney disease. Three distinct forms of NPHP (infantile, juvenile, and adolescent) were initially described, based on the age of onset of ESKD. In the infantile form, ESKD occurs before 5 years of age, whereas in juvenile NPHP (the most common form), ESKD occurs at a mean age of 13 years. However, recent studies have demonstrated that there is no clear genotype-phenotype correlation for this spectrum of presentations, and these disorders should be referred to with the single designation of NPHP.

Decreased urinary concentrating capacity is invariable in NPHP and usually precedes the decline in GFR, with typical onset between 4 and 6 years of age. Polyuria, polydipsia, and secondary enuresis are common. Salt wasting develops in most patients with kidney impairment, and sodium supplementation is often required until the onset of ESKD. One-third of patients become anemic before GFR is overtly reduced, perhaps because of impaired regulation of erythropoietin production by peritubular fibroblasts. Growth retardation (out of proportion to the degree of GFR reduction) is common.

Slowly progressive decline in GFR is typical of NPHP, with progression to ESKD at a median age of 13 years. Although symptoms can begin after the age of 2 years, they may progress insidiously, so that

15% of affected patients present with ESKD. There is no specific treatment. The disease is not known to recur in kidney allografts. Unlike patients with PKD or MSK, those with NPHP rarely develop flank pain, hematuria, hypertension, UTI, or kidney calculi.

Children with the relatively rare infantile NPHP variant develop symptoms in the first few months of life and rapidly progress to ESKD, usually before the age of 2 years, but invariably by 5 years of age. Severe hypertension is common in this disorder.[28]

Associated extrarenal abnormalities. Extrarenal abnormalities have been described in approximately 15% to 20% of patients with NPHP,[23] the most frequent of which is retinal dystrophy because of tapetoretinal degeneration (Senior-Loken syndrome). Severely affected patients present with coarse nystagmus, early blindness, and a flat electroretinogram (Leber amaurosis), whereas those with moderate retinal dystrophy typically have mild visual impairment and retinitis pigmentosa. Other extrarenal anomalies include oculomotor apraxia (Cogan syndrome), cerebellar vermis aplasia (Joubert syndrome), and cone-shaped epiphyses of the bones. Congenital hepatic fibrosis occurs on occasion in patients with NPHP, but the associated bile duct proliferation is mild and qualitatively different from that observed in ARPKD.

Pathology

In classic NPHP, the kidneys are moderately contracted with parenchymal atrophy causing a loss of corticomedullary demarcation. Histopathologic findings include tubular atrophy with thickened tubular basement membrane, diffuse and severe interstitial fibrosis, and cysts of variable size distributed in an irregular pattern at the corticomedullary junction and in the outer medulla. However, up to 25% of NPHP kidneys have no grossly visible cysts.

In the typical NPHP kidney lesion, clusters of atrophic tubules alternate either with groups of viable tubules showing dilation or marked compensatory hypertrophy. Multilayered thickening of tubular basement membranes is a prominent histopathologic feature (Fig. 47.4). This pattern is not unique, but the abrupt transition from one type of tubular profile to another suggests NPHP. Moderate interstitial fibrosis, usually without a significant inflammatory cell infiltrate, is interspersed among the atrophic tubules. Spherical, thin-walled cysts lined with a simple cuboidal epithelium may be evident at the corticomedullary junction, in the medulla, and even in the papillae. Microdissection studies indicate that these cysts arise from the loop of Henle, distal convoluted tubules, and collecting ducts. Glomeruli may be normal, although some may be completely sclerosed; others show periglomerular fibrosis, and still others have dilation of Bowman's space, suggestive of glomerulocystic kidney disease.[29]

In comparison, infantile NPHP has features of both classic NPHP (such as tubular cell atrophy, interstitial fibrosis, and tubular cysts) and PKD, including enlarged kidneys and widespread cystic involvement.

Diagnosis

In a child with NPHP and reduced GFR, ultrasound typically reveals normal-sized or small kidneys with increased echogenicity and loss of corticomedullary differentiation. On occasion, cysts can be detected at the corticomedullary junction or in the medulla. Thin-section CT scanning may be more sensitive than ultrasound in detecting these cysts.

The pathologic findings in NPHP are not unique; hence in the early stages of the disease, neither imaging nor histopathology can confirm the clinical diagnosis. Molecular testing can be useful; current strategies using multigene panels and next-generation sequencing technologies allow high-throughput mutation detection for known *NPHP* genes, but to date defects in these genes only explain disease in only up to 40% of patients with NPHP-related disorders.[24,25,27]

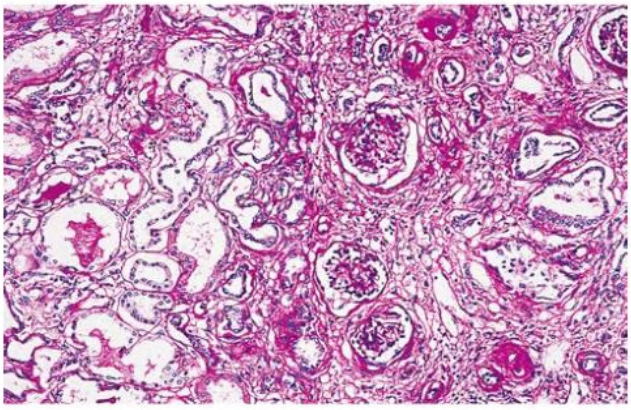

Fig. 47.4 Kidney Pathology in Nephronophthisis. Light microscopy shows tubulointerstitial nephropathy. Atrophic tubules with irregularly thickened basement membranes are surrounded by interstitial fibrosis. Dilated tubules are evident at the corticomedullary junction. (H&E stain; ×40.)

A recent Dutch study of more than 5500 patients with adult-onset ESKD found that 0.5% of the cohort were homozygous for *NPHP1* deletions.[30] A subsequent study in 18 adult patients with kidney biopsies consistent with NPHP found disease-causing mutations in seven patients (39%) involving the *NPHP1, NPHP3, NPHP4,* or *CEP164* genes.[31] These data extend the phenotypic spectrum of NPHP into adulthood and reinforce the utility of genetic testing for patients with ESKD of undetermined etiology.

Treatment

Current treatment of NPHP is supportive but preclinical studies suggest that targeted therapies may be beneficial. For example, treatment with a vasopressin receptor 2 antagonist remarkably attenuated kidney cystic disease progression in a mouse model of *NPHP*-related disease.[32] Others have proposed that therapeutic strategies should target the kidney fibrosis rather than cystic disease in NPHP and note that low-dose paclitaxel has shown promising results in rodent models of kidney fibrosis.[33]

Autosomal Dominant Tubulointerstitial Kidney Disease

The term *autosomal dominant tubulointerstitial kidney diseases* (ADTKD) has recently been proposed for the set of disorders previously described as MCKD, *UMOD*-related kidney disease, familial juvenile hyperuricemic nephropathy (HNFJ1; MIM 162000), and familial glomerulocystic disease with hyperuricemia (MIM 609886).[34] ADTKD is less common than NPHP and the kidney pathologic findings are indistinguishable, although the progressive tubulointerstitial fibrosis resulting in ESKD is slower in ADTKD. Some patients have phenotypically unaffected parents but an affected second- or third-degree relative, suggesting that disease is poorly recognized in affected family members and/or there is variable penetrance.

ADTKD typically manifests in adults, with familial kidney disease characterized by bland urinalysis (i.e., little or no proteinuria or hematuria) and slowly progressive loss of GFR. There may be hyperuricemia or gout. Ultrasound shows normal or small kidneys, sometimes with medullary cysts.

Disease-causing mutations in four genes, *MUC1, UMOD, REN,* and *HNF1B,* are responsible for most cases, with mutations in *SEC61A1* reported in a handful of families.[34] Hyperuricemia is a key feature of disease related to mutations in the *UMOD* and *REN* genes.

Uremia typically occurs after 60 years of age in ADTKD-*MUC1* (MCKD1, MIM 174000). In ADTKD-*UMOD* (MCKD2, MIM 603860) and ADTKD-*REN,* progression to ESKD occurs between the fourth and seventh decades of life. However, disease progression within families can be highly variable, with rare individuals reaching ESKD in their teens, whereas other individuals in the same family may not develop kidney failure until past age 80 years.[35]

MEDULLARY SPONGE KIDNEY

Definition

MSK is characterized by dilated medullary and papillary collecting ducts that give the kidney medulla a spongy appearance. It is associated with nephrocalcinosis, recurrent calcium nephrolithiasis, abnormalities in renal tubular acidification and urinary concentration, bone mineralization defects, and an increased risk for UTI.[36]

Etiology and Pathogenesis

Histopathologic observations of embryonal tissue in the affected papillae, coexistence of kidney tubular defects, and evidence of defects in the genes encoding the RET proto-oncogene and the glial cell line-derived neurotrophic factor (GDNF)[37] suggest that MSK results from a developmental defect in the ureteric bud-metanephric mesenchyme interaction. In addition, MSK occurs more frequently in individuals with other developmental anomalies and/or tumors (e.g., congenital hemihypertrophy, Beckwith-Wiedemann syndrome, congenital anomalies of the kidney and urinary tract [CAKUT] syndrome, and Wilms tumor).[38]

MSK is usually a sporadic disorder, but familial clustering with autosomal dominant inheritance[39] and evidence for genetic alteration in the RET-GDNF axis suggest a genetic basis for MSK in at least a subset of patients.

Epidemiology

In the general population, the frequency of MSK may be underestimated because some affected individuals remain asymptomatic. Up to 20% of patients with nephrolithiasis have at least a mild degree of MSK, but excretory urography in *unselected* patients indicates a disease frequency of approximately 1 in 5000 individuals.

Clinical Manifestations

MSK is asymptomatic unless complicated by nephrolithiasis, hematuria, or infection. Symptoms typically begin between the fourth and fifth decade of life, but adolescent presentations have been reported. Stones or granular debris in patients with MSK are composed of either pure apatite (calcium phosphate) or a mixture of apatite and calcium oxalate. Several factors appear to contribute to stone formation, including urinary stasis within the ectatic ducts, hypercalciuria, and hypocitraturia. Hyperparathyroidism also has been reported.

Hematuria is unrelated to either coexisting stones or infection and may be recurrent. The bleeding is usually asymptomatic unless gross hematuria causes clot-related colic. UTI may occur in association with nephrolithiasis or as an independent event. In patients with stones, infections are more likely to occur in females than in males.

Decreased urinary concentrating ability and impaired urinary acidification are common clinical features. In most patients, the acidification defect is not associated with overt systemic acidosis, but bone mineralization defects are well described.[38]

Pathology

The pathologic changes are confined to the medullary and intrapapillary collecting ducts. Multiple spherical or oval cysts measuring 1 to 8 mm may be detected in one or more papillae. These cysts may be isolated or may communicate with the collecting system. The cysts are frequently bilateral and often contain spherical concretions composed of apatite. The affected pyramids and associated calyces are usually enlarged, and nephromegaly can result when many pyramids are involved. The kidney cortex, medullary rays, calyces, and pelvis appear normal, unless complications (e.g., pyelonephritis or urinary tract obstruction) are superimposed.

Diagnosis

Abdominal plain radiographs often reveal radio-opaque concretions in the medulla (Fig. 47.5B). Historically, the diagnosis was established

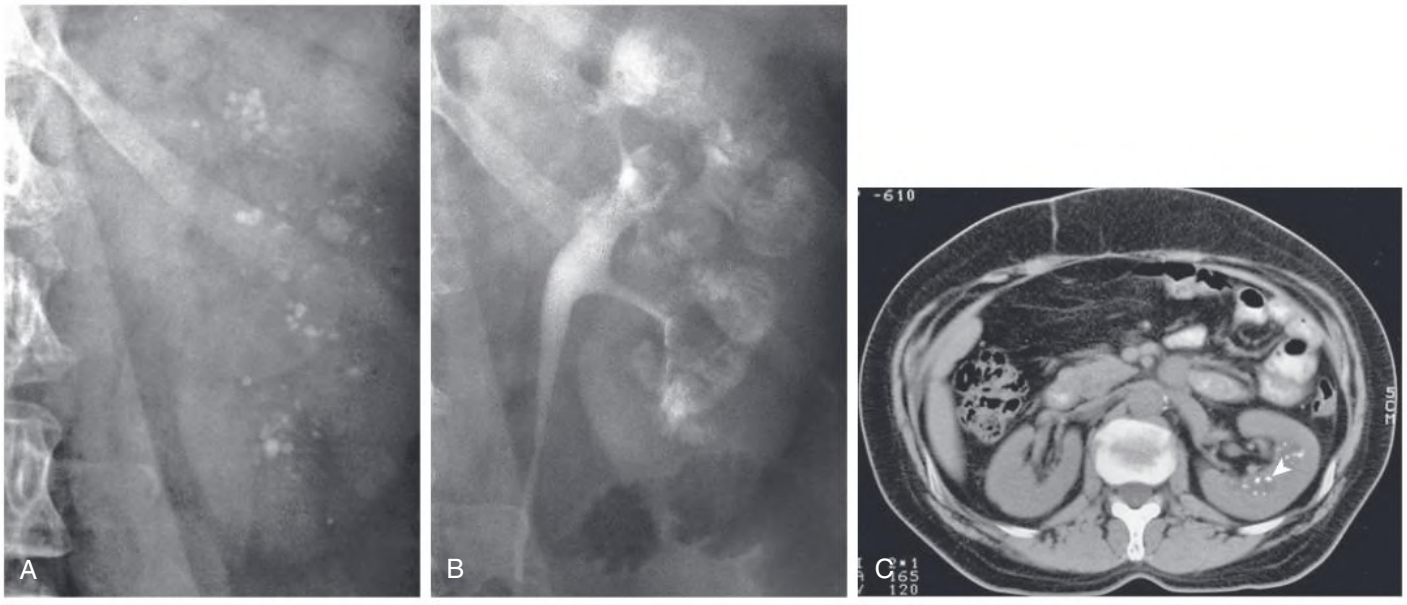

Fig. 47.5 Radiologic Findings Associated With Medullary Sponge Kidney. (A) Preliminary radiograph shows medullary nephrolithiasis. (B) Initial radiograph from excretory urography shows clusters of rounded densities in the papillae among discrete linear opacities (paintbrush appearance). (C) Nonenhanced computed tomography reveals densely echogenic foci in the medulla *(arrowhead).*

by excretory urography (see Fig. 47.5B). Retention of contrast media by the ectatic collecting ducts appears either as spherical cysts or, more commonly, as diffuse linear striations. The latter imparts a characteristic blush-like pattern to the papillae, the so-called bouquet of flowers or paintbrush appearance. Medullary nephrocalcinosis is a common but not invariant finding. Urography has been almost completely replaced by nonenhanced CT, which may help distinguish MSK from papillary necrosis or even ADPKD (see Fig. 47.5C).

Treatment

Asymptomatic patients with MSK require no therapy. Hematuria in the absence of stones or infection requires no intervention. If the tubular ectasia is unilateral and segmental, partial nephrectomy may alleviate recurrent nephrolithiasis and UTI. However, for the majority of patients who have bilateral disease, medical management is sufficient.

Hypercalciuria and hypocitraturia are the predominant factors contributing to MSK-related nephrolithiasis. The mainstays of treatment are a well-balanced diet consisting of fruits and vegetables, potassium citrate, and high fluid intake.[40] Patients with persistent hypercalciuria and/or recurrent stone formers may benefit from thiazide diuretics. If thiazides are poorly tolerated or contraindicated, inorganic phosphate therapy may be useful. To avoid struvite stone formation, oral phosphates should *not* be used in patients with previous UTIs caused by urease-producing organisms. Patients who recurrently form and pass stones may require lithotripsy or surgical intervention (see Chapter 60).

UTIs should be treated with standard antibiotic regimens and for some patients, prolonged therapy may be warranted. Urease-producing organisms, such as coagulase-negative *Staphylococcus,* are particularly problematic as urinary pathogens in MSK. Positive urine cultures, even with relatively insignificant colony counts, should be vigorously pursued.

With proper management of the clinical complications, the long-term prognosis is excellent. Progression to kidney impairment is unusual.

TUBEROUS SCLEROSIS COMPLEX

Definition

TSC is an autosomal dominant, tumor-suppressor gene syndrome in which benign focal malformations, called hamartomas, develop in multiple organ systems, including the kidneys, brain, heart, lungs, and skin.

Etiology and Pathogenesis

TSC results from inactivating mutations in one of two genes, *TSC1* on chromosome 9q32-q34 and *TSC2* on chromosome 16p13, adjacent to the *PKD1* gene. Large deletions involving both *PKD1* and *TSC2* result in the infantile severe polycystic kidney disease with tuberous sclerosis (PKDTS) contiguous gene deletion syndrome.

The focal development of hamartomas and the variability of disease expression even within families suggest that *TSC1* and *TSC2* function as tumor suppressor genes. The tumor suppressor gene paradigm proposes that two successive mutations are necessary to inactivate a target gene and cause tumor formation. The first mutation, inherited and therefore present in all cells, is necessary but not sufficient to produce tumors. A second mutation occurs after fertilization and is required to induce tumor transformation. The inactivating germ-line mutations identified in *TSC1* and *TSC2,* as well as the loss of heterozygosity detected in *TSC2*-associated and *TSC1*-associated hamartomas, support the hypothesis that both *TSC1* and *TSC2* function as tumor suppressor genes.

The *TSC2* gene product, tuberin, interacts with hamartin, the product of the *TSC1* gene. The hamartin/tuberin (*TSC1/TSC2*) complex functions in multiple cellular pathways, primarily by inhibiting the kinase activity of the mammalian target of rapamycin (mTOR), which functions in a protein complex (mTORC1) to integrate nutrient uptake, cell-cycle progression, cell growth, and protein translation[41] (Fig. 47.6). The *PKD1* gene product, polycystin-1, plays a key role in regulating mTORC1 activity by complexing with tuberin and mTOR, thereby inhibiting the mTOR pathway.[42] In a normal adult kidney, mTOR is inactive. With loss of function of either polycystin-1 or tuberin, mTOR activity is upregulated, contributing to dysregulated cell growth and cystogenesis. In addition, hamartin appears to function via TORC1-independent pathways to regulate the structural integrity of the primary cilium, suggesting that ciliary dysfunction is an additional mechanism in TSC pathogenesis.[43]

Epidemiology

TSC affects 1 in 6800 to 15,000 individuals,[44] with approximately 2 million people affected with TSC worldwide.[41] The disease penetrance is quite variable. About 70% of TSC patients are sporadic cases with no family history and the disease apparently results from new mutational events. Mutations in *TSC2* are detectable in approximately 70% of all patients with TSC, whereas *TSC1* mutations can be detected in about 20% of patients. In a substantial fraction of the remaining 10% of patients, the genetic defect may involve genetic mosaicism, whereby a mutational event in either *TSC2* or *TSC1* occurs after the one-cell stage of embryonic development.[41]

Clinicopathologic Manifestations

The clinical features of *TSC1*- and *TSC2*-linked disease are similar, although *TSC2*-linked disease tends to be more severe. The most common clinical manifestations include seizures, cognitive disability and/or autism, skin lesions, interstitial lung disease, and tumors in the brain, retina, kidney, and heart. In affected individuals over 5 years of age, the most common skin lesions are facial angiofibromas (Fig. 47.7), hypomelanotic macules, and ungual fibromas.

Kidney involvement occurs frequently in TSC, with kidney lesions that include angiomyolipomas (AMLs; 85%), cysts (30%–47%), and renal cell carcinoma (RCC; 2%–3%).[45–47] Other kidney neoplasms, interstitial fibrosis with focal segmental glomerulosclerosis (FSGS), glomerular microhamartomas, and peripelvic and perikidney lymphangiomatous cysts also have been reported. Kidney involvement in TSC often progresses insidiously but can result in considerable morbidity, including retroperitoneal hemorrhage, reduced GFR (~1%), and death. Kidney complications are the most frequent cause of death in TSC.[41]

Kidney Angiomyolipomas

Angiomyolipomas (AMLs) are benign kidney hamartomas composed of abnormal, thick-walled vessels and varying amounts of smooth muscle-like cells and adipose tissue (Fig. 47.8AB). These are the most common kidney lesion in TSC patients, detected in approximately 20% of children with TSC before 2 years of age and evident in approximately 67% of patients by age 10 years.[41] Whereas solitary AMLs are found in the general population, TSC-associated AMLs are multiple and bilateral, rarely occurring before 5 years of age, but increasing in frequency and size with age. They can become locally invasive, extending into the perirenal fat or, more rarely, the collecting system, renal vein, and even the inferior vena cava and right atrium.

Clinical manifestations occur secondary to hemorrhage (intratumoral or retroperitoneal) or mass effects (abdominal or flank masses and tenderness, hypertension, reduced GFR). Females tend to have

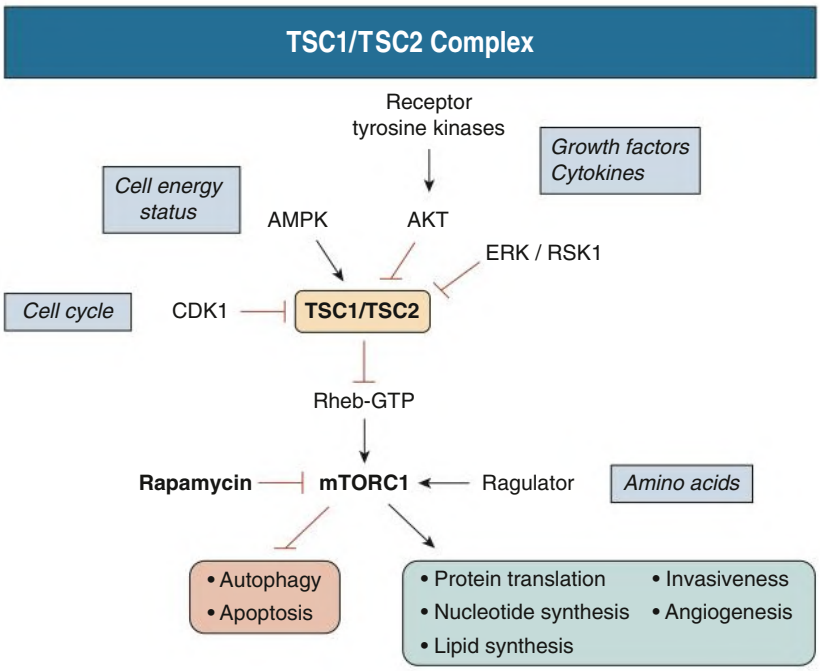

Fig. 47.6 The *TSC1/TSC2* complex regulates mTORC1 signaling by integrating extracellular and intracellular signals that promote metabolic homeostasis. Hamartin *(TSC1)* and tuberin *(TSC2)* integrate signals from extracellular cytokines and growth factors (via AKT and ERK/RSK1), the intracellular energy status (via AMPK), and the cell cycle (via CDK1) to direct signaling pathways that regulate cellular proliferation, differentiation, and migration. Tuberin contains a guanosine triphosphatase (GTPase)-activating protein domain in its carboxy terminus, and when it forms a complex with hamartin, the small GTPase Rheb is converted from its active GTP-bound state to an inactive guanosine diphosphate–bound state. Rheb is an activator of the mTORC1 kinase, which regulates a number of processes linked to protein synthesis and cell growth. mTORC1 is activated physiologically in response to growth factor signaling, which causes phosphorylation of tuberin, dissociation of the hamartin/tuberin complex, and increased levels of Rheb-GTP. Inactivation of the hamartin/tuberin complex through mutations in *TSC1* or *TSC2* leads to inappropriate activation of mTORC1. *AMPK,* Adenosine monophosphate–activated protein kinase; *CDK1,* cyclin-dependent kinase 1; *ERK,* extracellular signal–regulated kinase; *RSK,* ribosomal protein S6 kinase α3. (Modified from Lam HC, Siroky BJ, Henske EP. Renal disease in tuberous sclerosis complex: Pathogenesis and therapy. *Nat Rev Nephrol.* 2018;14[11]:704–716.)

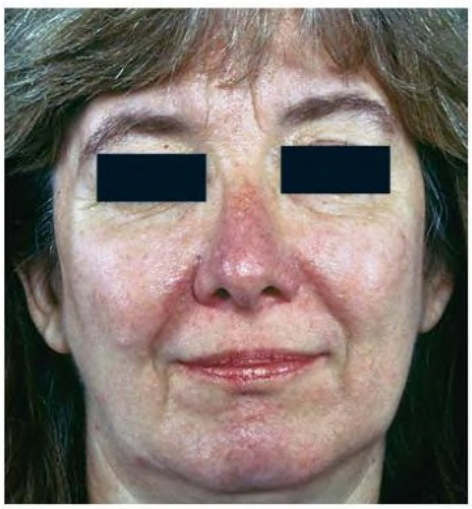

Fig. 47.7 Facial Angiofibromas in Tuberous Sclerosis Complex. The angiofibromas are small red bumps that give a facial rash in a butterfly distribution and on the chin.

more numerous and larger AML than males. Pregnancy appears to increase the risk for rupture and hemorrhage.[47]

Kidney Cystic Disease

Kidney cysts occur less frequently than AML and are evident in 35% to 50% of patients with TSC. However, like AML, kidney cysts tend to increase in size and number over time. The concurrence of cysts and AML is easily detected by CT and strongly suggests TSC.

The cysts in TSC can develop in any nephron segment. When limited in number and size, TSC-related cysts are predominantly cortical. In some cases, glomerular cysts predominate.[29] The cystic lining epithelia appear to be unique to TSC, with large and acidophilic epithelia containing large hyperchromatic nuclei with occasional mitotic figures (see Fig. 47.8C). Associated papillary hyperplasia and adenomas are common.

A small subset of affected infants can present with massive kidney cystic disease, severe hypertension, and a progressive decline in kidney function with the onset of ESKD in the second or third decade of life. The majority of these patients have a contiguous germ-line deletion involving both the *PKD1* and *TSC2* genes, the PKDTS contiguous gene

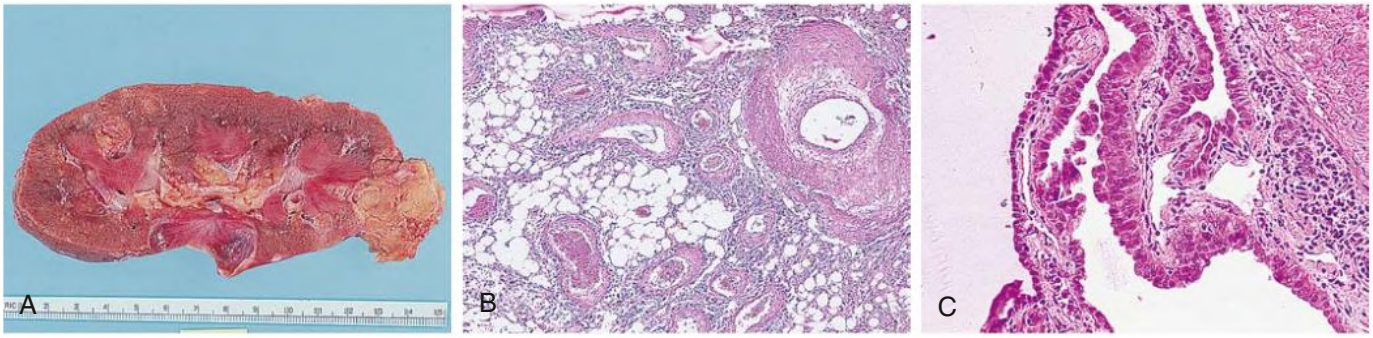

Fig. 47.8 Kidney Pathology in Tuberous Sclerosis Complex (TSC). (A) Cut section shows multiple kidney angiomyolipomas. (B) Light microscopy shows angiomyolipoma containing adipose tissue and spindle smooth muscle–like cells interspersed between abnormal vessels with thickened walls (H&E stain; ×16). (C) Light microscopy shows TSC cysts lined with distinctive epithelia consisting of large, acidophilic cells with hyperchromatic nuclei (H&E stain; ×65).

syndrome.[48] Early detection, strict BP control, initiation of mTOR1 inhibitor therapy to limit the growth of AML, and surveillance for TSC-associated renal cell carcinoma (RCC) may improve the overall prognosis.[49]

Kidney Neoplasms

Benign epithelial tumors, such as papillary adenomas and oncocytomas, are common in TSC patients and can be multifocal. Malignant transformation is rare, with 2% to 4% lifetime risk of developing RCC.[41] TSC-associated RCCs have a unique constellation of clinic-pathologic features, including female predominance, younger age at diagnosis, association with AML, multiplicity, and slow progression.[50] Three distinct histopathologic patterns predominate, with papillary RCC being most common, followed by hybrid oncocytic/chromophobe tumor and RCC with granular eosinophilic morphology. Although TSC-associated RCCs tend to have an indolent clinical course, the prognosis compared with sporadic RCC in the general population is unknown.

Diagnosis

TSC is a pleiotropic disease in which the size, number, and location of the lesions can be variable, even among affected individuals within the same family. Major and minor criteria have been developed to guide clinical diagnosis (Box 47.2). Two major features, or one major and two minor ones, are required to make the diagnosis of TSC. Imaging is the mainstay for diagnosis of TSC-associated kidney lesions. The presence of small cysts and fat-containing AMLs is strongly suggestive of TSC.

Kidney imaging is advised for monitoring disease progression in patients with TSC.[47] Ultrasound has historically been the preferred modality; it has high sensitivity in detecting the fat-rich AMLs and kidney cysts but is relatively insensitive for detecting fat-poor lesions. Current recommendations are to perform abdominal CT (Fig. 47.9) or MRI every 1 to 3 years for life to assess AML progression and kidney cystic disease.[51] On occasion, the distinction between an AML and RCC cannot be reliably established by imaging and biopsy is indicated.

TSC-associated kidney cysts can radiologically mimic simple cysts and, when numerous, ADPKD. In the absence of AML, TSC-related kidney cystic disease is suggested by the limited number of cysts compared with ADPKD and the absence of associated hepatic cysts. Although 10% of patients with TSC have hepatic AML, hepatic cysts are rare.

Gene-based diagnosis is currently available for *TSC1*- and *TSC2*-related disease and to detect large-scale deletions associated with the PKDTS contiguous gene syndrome.

BOX 47.2 Clinical Diagnostic Criteria for Tuberous Sclerosis Complex[a]

Major

Facial angiofibromas or forehead plaque
Nontraumatic ungual or periungual fibroma
Hypomelanotic macules (>3)
Shagreen patch (connective tissue nevus)
Multiple retinal nodular hamartomas
Cortical tuber(s)
Subependymal nodule
Subependymal giant cell astrocytoma
Cardiac rhabdomyoma(s) (≥1)
Lymphangioleiomyomatosis
Kidney angiomyolipoma

Minor

Multiple, random dental pits
Hamartomatous gastrointestinal or rectal polyps
Bone cysts
White matter radial migration lines
Gingival fibromas
Non-kidney hamartoma
Retinal achromic patch
"Confetti" skin lesions
Multiple kidney cysts

[a]Two major features or one major feature with two minor features indicate definite TSC; one major feature and one minor feature indicate probable TSC; and one major feature or two minor features indicates possible TSC.

Treatment

Kidney Angiomyolipomas

Kidney AMLs are generally benign and require no treatment. Larger AMLs frequently develop microaneurysms and macroaneurysms and are associated with a risk of serious hemorrhage, particularly in actively growing AML more than 3 cm in diameter or those less than 5 mm in diameter with aneurysms.[41,47] Large AMLs require preemptive treatment either with nephron-sparing surgery or embolization.[52] In addition to size and complications such as pain or hemorrhage, the inability to exclude an associated RCC should prompt intervention.

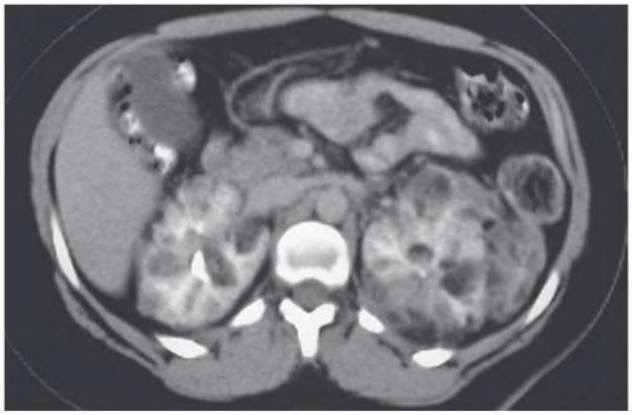

Fig. 47.9 Contrast-enhanced computed tomography showing bilateral angiomyolipomas associated with tuberous sclerosis complex.

When an associated malignancy cannot be excluded, nephron-sparing surgery, such as enucleation or partial nephrectomy, is preferred.

Defective mTORC1 signaling is a central feature of TSC. Recent international TSC guidelines recommend mammalian target of rapamycin (mTOR1) inhibitors (rapalogs) as the first-line therapy for the treatment of asymptomatic, growing angiomyolipomas more than 3 cm in diameter.[47] Sirolimus and everolimus are effective in reducing AML volume and/or postembolization response rates, with an acceptable safety profile,[41] although they have a range of adverse events which must be borne in mind (see Chapter 106).[53]

The increased frequency and size of the AMLs in females and the reports of hemorrhagic complications during pregnancy suggest that female sex hormones may accelerate AML growth. Therefore, it is prudent to caution females with multiple AMLs about the potential risks of pregnancy and estrogen administration.

Kidney Cystic Disease

The mainstay of treatment of TSC-associated kidney cystic disease is strict BP control. Benefit from mTORC1 inhibitors has been suggested by small studies but not definitively demonstrated.[41]

Kidney Carcinoma

TSC-associated RCC should be suspected in enlarging, fat-poor lesions or when intratumoral calcifications are present and should be confirmed by biopsy. Because TSC-associated RCCs are often slow growing and frequently bilateral, nephron-sparing surgery is the treatment of choice.

Kidney Replacement Therapy

CKD, although rare in tuberous sclerosis, can occur by several different mechanisms, including AML-related parenchymal destruction, progressive kidney cystic disease, interstitial fibrosis, and FSGS. On a large French study, TSC-associated ESKD had a prevalence of 1 per 100 patients with TSC and was more frequent in females (63%), with a mean age diagnosis of 29 years.[54]

A follow-up French national KRT registry study evaluated 99 patients with TSC, who progressed to ESKD primarily because of nephrectomy or repeated AML embolization. The age at initiation of KRT was 48.4 years. Fifty-four patients underwent kidney transplantation after an average of 23 months on dialysis. None of the patients had been treated with an mTORC1 inhibitor before dialysis, leaving open the possibility that reducing the size of AML with mTORC1 inhibitors may lower the number of patients with TSC requiring KRT.[55]

VON HIPPEL-LINDAU DISEASE

Definition

VHL disease is a dominantly transmitted, multisystem cancer predisposition syndrome associated with tumors of the eyes, cerebellum, spinal cord, adrenal glands, pancreas, and epididymis, as well as kidney and pancreatic cysts.[56]

Etiology and Pathogenesis

VHL disease is a tumor suppressor disorder, with disease resulting from a germ-line mutation and a subsequent somatic mutation in the *VHL* gene. In approximately 80% of patients, VHL is familial, whereas disease in about 20% of cases results from de novo mutations. Moreover, *VHL* mutations have been identified in sporadic RCC, implying that *VHL* plays an important role in the pathogenesis of RCC.[56,57]

The VHL protein (pVHL) is a central driver in a finely tuned rheostat system that regulates the response to low oxygen levels.[57] In the normal physiologic state, pVHL functions as part of a multiprotein E3 ubiquitin ligase complex that directs a number of proteins, most notably the alpha subunits of the transcription factor, hypoxia-inducible factor (HIF-α), for destruction via the ubiquination pathway. In cells that lack pVHL, HIF-α subunits are stabilized and bind to HIF-β. The heterodimer then translocates to the nucleus, leading to overexpression of HIF-target genes, which encode proteins that regulate glucose uptake, metabolism, extracellular pH, erythropoiesis, angiogenesis (vascular endothelial growth factor [VEGF] and platelet-derived growth factor B [PDGFB]), and mitogenesis (transforming growth factor β [TGF-β]). This transcriptional dysregulation promotes the pathologic growth and survival of endothelial cells, pericytes and stromal cells and, ultimately, their malignant transformation.[56,57]

Clinical Manifestations

VHL disease has an incidence of 1 in 36,000 live births and has been observed in all ethnic groups. Biallelic *VHL* inactivation leads to increased risk for central nervous system (CNS) and retinal hemangioblastomas, RCC, pheochromocytomas, pancreatic islet cell tumors, endolymphatic sac tumors, and papillary cystadenomas of the broad ligament (females) and epididymis (males). In addition, cystic changes can occur in the kidney and pancreas.[56]

VHL-associated disease clusters in two complexes (Table 47.2). In the initial stratification, patients with VHL disease can be subclassified based on a low risk (type 1) or high risk (type 2) of developing pheochromocytoma. Type 1 disease is characterized by large deletions or truncations of the *VHL* gene, which cause complete inactivation of the gene and result in high levels of HIF activity. Type 2 disease primarily involves missense mutations and is associated with partial activity of pVHL. Type 2 patients can be further subdivided into three subtypes: type 2A, which has a low incidence of kidney lesions; type 2B, which is associated with a high risk for RCC; and type 2C, which is associated only with pheochromocytoma and no other malignancies.[56]

In patients with VHL disease, the lifetime cumulative RCC risk approaches 70%.[58] RCCs are typically multiple and bilateral. Although RCC may manifest with hematuria or back pain, more often detection occurs as an incidental finding on unrelated imaging studies or during a screening protocol. The mean age of symptomatic presentation is 35 to 40 years, although patients have been diagnosed in adolescence. In VHL disease, males and females are equally affected with RCC, in contrast to the male predominance in sporadic RCC. VHL disease-associated RCC metastasizes to the lymph nodes, liver, lungs, and bones and accounts for about 50% of VHL-disease related deaths.

In addition to RCC kidney manifestations of VHL, multiple bilateral kidney cysts are found in 50% to 70% of patients.[56] Kidney cysts arise from tubular cells that have undergone somatic loss of the wild-type allele.

Historically, deterioration in GFR among patients VHL was thought to be unusual. However, a recent international consortium study of 96 patients with VHL and nonmetastatic RCC found that 16% of patients pretreatment and 25% of patients posttreatment (e.g., partial nephrectomy or tissue ablation) had CKD.[59]

Pathology

VHL disease-associated RCCs are mostly of the clear-cell type and usually bilateral and multifocal in distribution. Detailed microscopic examination of VHL disease associated kidney cystic lesions often reveals small foci of carcinoma. VHL disease-associated RCCs tend to have low-grade histology and a better 10-year survival than sporadic RCC. More advanced RCCs can metastasize, and metastatic disease is a major cause of death in patients with VHL.

TABLE 47.2 Classification of von Hippel-Lindau Subtypes

Subtype	Tumor Manifestations
Type 1	hemangioblastoma (CNS, retina), kidney cell carcinoma, pancreatic cysts low risk for pheochromocytoma
Type 2A	hemangioblastoma (CNS, retina), pheochromocytoma, low risk for kidney cell carcinoma
Type 2B	hemangioblastoma (CNS, retina), kidney cell carcinoma, pheochromocytoma, pancreatic cysts
Type 2C	predominantly pheochromocytoma very limited risk of hemangioblastoma and kidney cell carcinoma

CNS, Central nervous system.

Diagnosis

The minimum clinical criteria for the diagnosis of VHL disease in an at-risk individual include the presence of a single retinal or cerebellar hemangioblastoma, or RCC, or pheochromocytoma. Up to 50% of affected individuals with familial VHL disease may manifest only one feature of the syndrome. In presumed sporadic cases (20% of patients), the clinical diagnosis requires two tumors (such as two hemangioblastomas, or a hemangioblastoma and a characteristic visceral tumor).

Molecular analysis of the *VHL* gene is indicated in patients with known or suspected VHL or in at-risk children from VHL families, given that unsuspected, untreated tumors can cause significant morbidity. Presymptomatic genotyping can be useful in determining the phenotypic classification of VHL and used to direct monitoring for a specific subset of tumors. In addition, genotyping can be useful in distinguishing whether a pheochromocytoma has occurred in the context of a VHL type 2 mutation or multiple endocrine neoplasia (MEN) type 2 or is nonsyndromic.[60]

In patients with type 2 VHL disease, annual assessment of BP, measurement of urinary catecholamine metabolites, and abdominal ultrasound imaging should be initiated at the age of 2 years. Abdominal MRI and iodine-131 metaiodobenzyl-guanidine (MIBG) scans are indicated if abnormalities are detected. By age 16 years, all patients with VHL disease should have annual MRI scans of the abdomen. Ultrasound is a useful alternative imaging modality in pregnant persons. Annual assessment should be lifelong. Early detection of kidney disease and a multidisciplinary approach to follow-up can substantially improve survival.

Differential Diagnosis

The differential diagnosis of VHL disease–associated kidney lesions includes several conditions, most notably ADPKD and TSC (Table 47.3). As with VHL, ADPKD affects both sexes with a similar mean

TABLE 47.3 Clinical Characteristics of Kidney Cystic Disease in Adults

	Simple Cysts	ADPKD	MSK	VHL	TSC	Acquired Cystic Disease
Age at clinical onset	>30 y	30–40 y	20–40 y	30–40 y	10–30 y	Chronic kidney disease
Cysts	Single/multiple	Multiple	Multiple	Few, bilateral	Multiple	Multiple
Cyst infection	Uncommon	Common	Common	Uncommon	Uncommon	Uncommon
Tumors	No	Rare	No	RCC, often bilateral	AML/RCC	Common

age at presentation. However, in VHL disease, kidney involvement is characterized by a few bilateral cysts, RCC, normal kidney size, normal BP, and usually normal GFR. Kidney cyst infection, a frequent finding in ADPKD, is uncommon in VHL disease, and RCC is an infrequent complication of ADPKD. Cysts in the liver are frequent in ADPKD and rare in VHL disease. Pancreatic cysts are rare in ADPKD but can be numerous and scattered through the pancreas in VHL disease (Fig. 47.10A). The CNS in ADPKD is affected by arterial aneurysms, whereas hemangioblastomas are the predominant CNS manifestation in VHL disease (see Fig. 47.10B).

TSC should be considered in the differential diagnosis of multiple kidney tumors. In both TSC and VHL disease, multiple kidney cysts occur. However, the TSC-associated kidney tumor is usually an AML, and extrarenal lesions readily distinguish VHL disease and TSC.

Treatment

Nephron-sparing surgery continues to be the mainstay of treatment for localized RCC in patients with VHL disease.[56] Repeated surgical intervention may be required as tumors continue to develop. Percutaneous and laparoscopic radiofrequency ablation therapy is effective in treating smaller tumors (<3 cm) with low complication rates, but frequent posttreatment monitoring is required.[56] The role of adjuvant therapy with drugs that inhibit the pVHL-HIF-VEGF pathway, such as the multiple tyrosine kinase inhibitors (TKI; e.g., sunitinib, sorafenib, and pazopanib) and monoclonal antibody VEGF inhibitor (e.g., bevacizumab), remains controversial.[58]

Bilateral nephrectomy and kidney transplantation may be an acceptable alternative to repeated nephron-sparing surgery in patients with VHL disease–associated RCC. It remains to be determined whether posttransplant immunosuppression enhances the growth of the retinal and CNS hemangioblastomas and other lesions found in patients with VHL disease.

For RCCs that have locally advanced or metastasized, systemic approaches with immunotherapy (checkpoint inhibitors) and molecularly targeted agents (VEGF receptor TKIs, monoclonal antibody VEGF inhibitors, and mTOR inhibitors), as well as radiation therapy, all may have a role depending on the extent of disease, sites of involvement, and patient-specific factors.[58]

SIMPLE CYSTS

Introduction and Definition

Simple kidney cysts are the most commonly acquired cystic lesion and occur twice as frequently in males as in females. Simple cysts are usually unilateral and may be either solitary or multiple. They occur rarely in children but become increasingly common with age.[61] In a seminal ultrasound study, unilateral cysts were detected in 1.7% of patients aged 30 to 49 years, 11% of patients aged 50 to 70 years, and 22% to 30% of patients older than 70 years.[62] This age-related increase in cyst incidence has been corroborated by MRI studies.

Etiology and Pathogenesis

Simple kidney cysts likely originate from the distal convoluted tubule or collecting ducts and may arise from kidney tubular diverticula, but the pathogenic mechanisms are unknown. Focal tubular obstruction and kidney parenchymal ischemia have both been suggested as etiologic processes. Less likely is the possibility that simple cysts arise from calyceal diverticuli because simple cysts are often found in the kidney cortex and their frequency increases with age.

Age, smoking, reduced GFR, and hypertension[63] have been implicated as risk factors for simple cysts. However, these associations may be coincidental, given that the studies were largely retrospective, the cohorts had variable reasons for diagnostic referral, and the observations were not optimally controlled for patient age.[64]

Clinical Manifestations

Simple cysts are typically asymptomatic. However, increasing evidence supports a relationship between simple kidney cysts and hypertension,[63] which may be associated with increased renalase levels.[65] In addition, red blood cell abnormalities (elevated red blood cell mass, hematocrit, and hemoglobin) are well described in patients with simple kidney cysts.[66] Patients can also present with hematuria, flank pain, evidence of infection, or obstruction of the collecting system. Clinical symptoms are more common with neoplasms than simple cysts and should therefore prompt evaluation for cyst-associated malignancy.[64]

Pathology

Whether unilateral or bilateral, simple cysts are usually spherical and unilocular. They may be solitary or multiple. On average, simple cysts measure 0.5 to 1.0 cm in diameter, but 3 to 4 cm cysts are not uncommon. Simple cysts can occur in the cortex, where they can protrude from the cortical surface (exophytic cysts), the corticomedullary junction, or in the medulla. By definition, they do not communicate with the kidney pelvis. The cyst walls are typically thin and transparent, lined with a single layer of flattened epithelium. Cyst fluid is essentially an ultrafiltrate of plasma. In the wake of infection, cyst walls can become thickened, fibrotic, and even calcified.

Diagnosis

Simple cysts are most often detected as incidental findings during abdominal imaging studies. On occasion, they are discovered during radiologic evaluation of palpable abdominal masses, pyelonephritis, or hematuria after abdominal trauma.

The critical clinical challenge is to distinguish single or multiple simple cysts from cysts associated with ADPKD, other cystic diseases, or RCC. This distinction can usually be made on the basis of patient age, family history, and imaging (see Table 47.3).

The ultrasound features of simple cysts include smooth walls, lack of septae, and no intracystic debris. If the ultrasound pattern is indeterminate, CT scanning should be performed. Benign cysts have homogeneous attenuation, no contrast enhancement, thin and smooth cyst walls, and no associated calcifications, unless prior infection has occurred.

A classification system for kidney cysts based on their appearance and enhancement on CT, described by Israel and Bosniak, is widely used and informs management (see Table 63.5).[67]

Treatment

Simple cysts associated with pain or renin-dependent hypertension can be managed with percutaneous aspiration under radiologic guidance and instillation of a sclerosing agent into the cyst cavity.[68] Laparoscopic or retroperitoneoscopic cyst unroofing (marsupialization) may be more appropriate for large cysts containing volumes in excess of 100 mL. Cyst infection with *Enterobacteriaceae, Staphylococci,* and *Proteus* has been reported and operative or percutaneous drainage is often required in addition to antibiotic treatment.

SOLITARY MULTILOCULAR CYSTS

Solitary multilocular cysts are generally benign neoplasms that arise from the metanephric blastema. These solitary cysts also have been designated multilocular cystic nephroma, benign cystic nephroma, and papillary cystadenoma. By definition, the cystic structures are unilateral, solitary, and multilocular. The cystic locules do not communicate with each other or with the kidney pelvis. These locules are lined with a simple epithelium and the interlocular septa do not contain differentiated kidney epithelia structures.

There is a spectrum of multilocular cysts; at one end is cystic nephroma (CN) and at the other end is cystic partially differentiated nephroblastoma (CPDN), in which the septa contain foci of blastemal cells. It is not clear whether a multilocular cyst represents a congenital abnormality in nephrogenesis, a hamartoma, a partially or completely differentiated Wilms tumor, or a benign variant of Wilms tumor.

There is a bimodal age distribution[69]; approximately half the cases occur in children younger than 4 years and half the cases are detected in adults. The childhood cases (mostly CPDN) are usually found in males, whereas multilocular cysts presenting in adulthood (mostly CN) occur more commonly in females. An abdominal or flank mass is the most common clinical feature because these cysts are typically quite large and often replace an entire pole. Associated hematuria, calculi, urinary tract obstruction, and infection occur in rare instances. Diagnosis can be made either by ultrasound or CT (Fig. 47.11).

Fig. 47.11 Solitary Multilocular Cyst. Contrast-enhanced computed tomography shows a solitary, septated, and well-circumscribed kidney cystic lesion in the right kidney.

Almost all multilocular cysts are Bosniak class III (see Table 63.5), complex kidney cysts suspicious for malignancy.[67] CPDN in children may contain blastema and incompletely differentiated metanephric tissue but usually has a benign course. In adults, associated foci of kidney cell carcinoma or sarcoma must be excluded. For both diagnostic accuracy and treatment, partial nephron sparing surgery is usually required. The typical prognosis of solitary multilocular cysts is excellent.

KIDNEY LYMPHANGIOMATOSIS

Kidney lymphangiomatosis is a rare, generally benign disorder characterized by developmental malformation of kidney lymphatic channels. Synonyms include kidney lymphangioma, peripelvic lymphangiectasia, or kidney hygroma.[70]

The cystic phenotype is widely variable and the underlying pathogenesis is unclear. Dilation may involve a single lymphatic channel or multiple channels. The lymphangiectasis may be unilateral or bilateral, may be limited to the hilar region, or may extend into the kidney parenchyma to the corticomedullary junction. On occasion, kidney lymphangiomatosis may be very extensive and simulate either ADPKD or ARPKD.[71,72] The distinguishing features include cyst lining by lymphatic endothelium and cyst fluid–containing lymphatic constituents such as albumin and lipid.

The characteristic ultrasound or CT findings include multiple, bilateral small peripelvic cysts that splay the renal hilum, as well as capsular cysts in the perirenal space, both separated by thin septations. Kidney lymphangiomas are most often asymptomatic and require no treatment. However, the condition may be exacerbated by pregnancy, resulting in large perinephric lymph collections and ascites that can require percutaneous drainage.

GLOMERULOCYSTIC KIDNEY DISEASE

Glomerular cysts occur in three different clinical contexts: (1) isolated glomerulocystic kidney disease (GCKD); (2) glomerulocystic kidneys associated with heritable malformation syndromes, such as TSC, Meckel syndrome, autosomal dominant tubulointerstitial kidney disease (ADTKD), oro-facio-digital syndrome type I; trisomies 9,

13 and 18; short-rib polydactyly syndromes; and Zellweger cerebrohepatorenal syndrome; and (3) glomerular cystic changes in dysplastic kidneys.[29]

Isolated GCKD can occur as a sporadic condition, a familial disorder, or as the infantile manifestation of ADPKD. Pathologically, the kidney architecture is normal, with no dysplastic elements in the cortex and no evidence of urinary tract obstruction. Cystic dilation predominantly involves Bowman's space and the initial proximal tubule. GCKD is defined as a twofold to threefold dilation of Bowman's space compared with the normal glomerular dimension. Glomerular cysts can be distributed from the subcapsular zone to the inner cortex. The typical ultrasound pattern in GCKD involves increased echogenicity of the kidney cortex with minute cysts, smaller than those evident in ADPKD. T2-weighted MRI typically reveals numerous, uniformly small, cortical cysts.[73] Young infants with either familial or sporadic forms of GCKD may also have kidney medullary dysplasia and biliary dysgenesis.[29]

Heritable GCKD is usually transmitted as an autosomal dominant trait, often occurring as the infantile expression of ADPKD. In these infants, the kidneys are bilaterally enlarged and diffusely cystic. In non–ADPKD-associated GCKD families, the kidneys are typically normal in size, although on occasion, enlarged kidneys are observed. Finally, several sporadic cases of nonsyndromal GCKD have been described, suggesting either new spontaneous mutations or a recessively transmitted disorder.[29]

Familial hypoplastic GCKD (MIM 137920) appears to be a distinct form of GCKD that results from mutations in *HNF1B,* the gene encoding hepatocyte nuclear factor 1β.[74] The kidneys are smaller than normal and often associated with medullocalyceal abnormalities. Tubular abnormalities include hyperuricemia with or without gout, hypokalemia, hypomagnesemia, and polyuria.[75] This multisystem disease is pleiotropic among affected family members with variable associations of hypoplastic GCKD, gynecologic abnormalities, and maturity-onset diabetes of the young, type V (MODY5).

ACQUIRED CYSTIC DISEASE

Hypokalemic Cystic Disease

Kidney cysts are often seen in association with chronic hypokalemia secondary to primary hyperaldosteronism or other kidney potassium-wasting disorders. Nearly 50% of patients with idiopathic adrenal hyperplasia and 60% of patients with adrenal tumors are reported to have kidney medullary cysts, which typically regress after adrenalectomy. Medullary cysts have been reported in children with type I RTA, and patients with mutations involving subunits of the H^+-ATPase can also have radiologic findings of medullary sponge kidney. Whether these abnormalities and/or the severity of nephrocalcinosis alter the progression of CKD in these patients is not known.[76]

Hilar Cysts

Hilar cysts are spherical accumulations of clear, fat droplet-containing fluid within the kidney sinus. These cystic structures are not lined by epithelia. They are most commonly seen in debilitated patients and may represent atrophy of the kidney sinus fat.

Perinephric Pseudocysts

Perinephric pseudocysts are also unlined cavities. They typically occur under the kidney capsule or in the perirenal fascia as a result of urine extravasation from traumatic or spontaneous rupture of a kidney cyst or as the posterior extension of a pancreatic pseudocyst. Surgical intervention is indicated for associated urinary tract obstruction. Otherwise, treatment is directed to the underlying cause.

Acquired Cystic Disease in Kidney Failure

Acquired cystic disease is a significant complication of prolonged kidney failure (see Table 47.3), occurring as the result of progressive structural end-stage kidney remodeling and may be associated with kidney cell carcinoma. Acquired kidney cystic disease is discussed further in Chapter 92.

SELF-ASSESSMENT QUESTIONS

1. Extrarenal complications of ARPKD can include which of the following?
   - **A** Congenital hepatic fibrosis
   - **B.** Caroli syndrome
   - **C.** Growth retardation
   - **D.** Intracranial aneurysms
   - **E.** All of the above
2. Which kidney cystic disease is distinguished by small, contracted kidneys?
   - **A.** ARPKD
   - **B.** NPHP
   - **C.** MSK
   - **D.** von Hippel–Lindau disease
   - **E.** None of the above
3. Which phenotypic feature most accurately distinguishes tuberous sclerosis complex from von Hippel–Lindau disease?
   - **A.** Systemic hypertension
   - **B.** Kidney cysts
   - **C.** Kidney angiomyolipomas
   - **D.** Kidney cell carcinoma
   - **E.** Liver cysts
4. Gene-based testing is a clinically informative tool for which of the following disorders?
   - **A.** ARPKD
   - **B.** NPHP
   - **C.** MSK
   - **D.** von Hippel–Lindau disease
   - **E.** All of the above
5. Medullary sponge kidney is a single-gene disorder in a subset of patients.
   - **A.** True
   - **B.** False

Alport Syndrome and Other Familial Glomerular Syndromes

Michelle N. Rheault, Clifford E. Kashtan

ALPORT SYNDROME

Definition

Alport syndrome (AS) is an inherited disorder of basement membranes caused by mutations affecting specific proteins of the type IV (basement membrane) collagen family. The major features of AS are hematuria, progressive nephritis with proteinuria and declining kidney function, sensorineural deafness, and ocular abnormalities. Although AS is a rare disease, affecting approximately 1 in 50,000 people, it is the second most common monogenic kidney disorder, after polycystic kidney disease. AS is seen in patients of all ethnicities and nationalities and accounts for approximately 0.5% of adults and 1.7% of children with end-stage kidney disease (ESKD) in the United States.[1]

Etiology and Pathogenesis

Type IV Collagen

Type IV collagen is a major constituent of basement membranes. The type IV collagen family of proteins involves six isomeric chains, designated α1(IV) to α6(IV). Each of these chains has a major collagenous domain of about 1400 residues containing the repetitive triplet sequence glycine (Gly)–X–Y, in which X and Y represent a variety of other amino acids; a C-terminal noncollagenous (NC1) domain of about 230 residues; and a noncollagenous N-terminal sequence of 15 to 20 residues.

Each type IV collagen molecule is a heterotrimer composed of three α chains. Formation of these heterotrimers is initiated by C-terminal NC1 domain interactions, accompanied by folding of the collagenous domains into triple helices. There are at least three types of type IV collagen heterotrimer: $\alpha1(IV)_2$–α2(IV), α3(IV)–α4(IV)–α5(IV), and $\alpha5(IV)_2$–α6(IV). Type IV collagen triple helices form open, nonfibrillar networks that associate with laminin assemblies through interactions mediated by nidogen to form basement membranes.

The six type IV collagen genes are arranged in pairs on three chromosomes (Fig. 48.1). The 5′ ends of each gene pair are adjacent to each other, separated by sequences of varying length that contain motifs involved in transcriptional regulation.

In basement membranes there is a ubiquitous network involving the α1(IV) and α2(IV) chains; and other networks, restricted in distribution, composed of α3(IV), α4(IV), and α5(IV) chains, or α5(IV) and α6(IV) chains. Glomerular basement membrane (GBM) contains separate α1–α2(IV) and α3–α4–α5(IV) networks, whereas epidermal basement membranes (EBMs) contain separate networks of α1–α2(IV) chains and α5–α6(IV) chains. The α3α4α5(IV) network is also expressed in Bowman's capsule and distal tubule in the kidney, alveolar basement membranes, and basement membranes of the testis, eye, and ear.[2] A network of α1, α2, α5, and α6(IV) chains has been described in smooth muscle basement membranes.[2] These various networks likely have different physical and functional characteristics and interact differently with other matrix components and adjacent cells. α1–α2(IV) chains are also found in mesangial matrix.

Genetics

There are three forms of AS: an X-linked form resulting from mutations at the *COL4A5* locus, primarily affecting the α5(IV) chain; an autosomal recessive form arising from mutations at the *COL4A3* locus or the *COL4A4* locus, affecting the α3(IV) and α4(IV) chains, respectively; and an autosomal dominant form from heterozygous mutations in *COL4A3* or *COL4A4* (Table 48.1). Approximately 80% of AS was previously thought to be inherited in an X-linked manner, with 15% autosomal recessive and 5% autosomal dominant inheritance patterns observed. With the advent of next-generation sequencing (NGS), it is clear that autosomal dominant AS (ADAS) is more common than previously recognized, accounting for approximately 20% to 30% of affected families.[3]

X-linked Alport syndrome. X-linked AS (XLAS) is the predominant form of the disease. Hundreds of *COL4A5* variants have been described, mostly missense mutations, splice-site mutations, and deletions of fewer than 10 base pairs. A common missense mutation involves replacement of a glycine residue in the collagenous domain of the α5(IV) chain by another amino acid. Such mutations are thought to interfere with the normal folding of the α5(IV) chain into triple helices with other α(IV) chains.

In untreated males with *COL4A5* mutations, the risk of progression to ESKD is 50% by age 30 years, 80% by 40 years, and nearly 100% by 60 years, and most experience deafness.[4] Genotype has a strong correlation with kidney disease progression in males with XLAS. In males with truncating variants (large deletions, nonsense mutations, truncating splicing variants, or a small mutation changing the mRNA reading frame), the risk for developing ESKD before age 30 years is 90%. Nontruncating splice-site mutations and missense mutations have a less severe renal phenotype with 70% and 50% reaching ESKD by age 30 years, respectively.[4,5] Females with XLAS have a wide variability in disease severity, and there is no genotype-phenotype correlation.[6] The severity of disease in a female heterozygous for a *COL4A5* mutation probably depends primarily on the relative activities of the mutant and normal X chromosomes in renal, cochlear, and ocular tissues because of random X-inactivation.[7]

Autosomal recessive Alport syndrome. Autosomal recessive AS (ARAS) arises from mutations affecting both alleles of *COL4A3* or *COL4A4*.[8] ARAS should be suspected when an individual with typical clinicopathologic features of the disease lacks a family history, especially when a young female has severe disease, such as deafness, nephrotic syndrome, or impaired kidney function. However, sporadic cases of AS may represent de novo mutations at the *COL4A5* locus or a germline *COL4A5* mutation in the proband's mother. Most patients with ARAS develop ESKD and deafness before age 30 years, regardless of sex.[8]

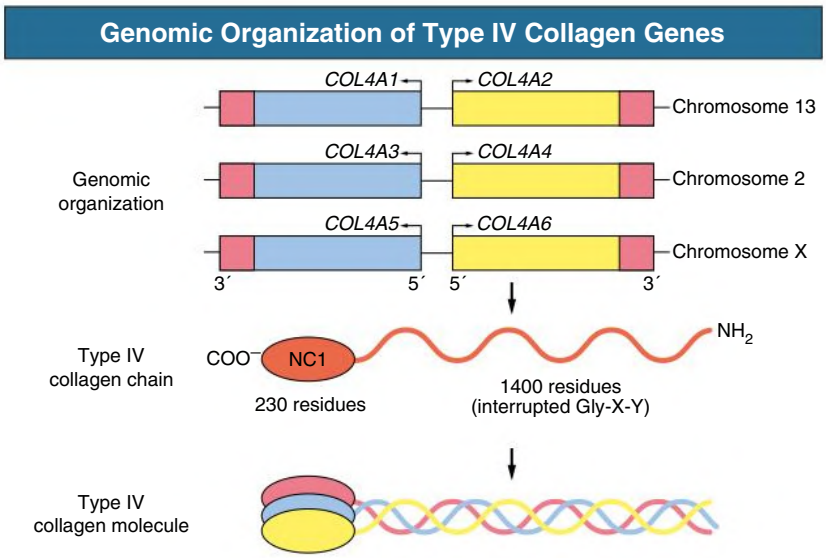

Fig. 48.1 Genomic Organization of Type IV Collagen Genes. Each type IV collagen chain is synthesized from one of the pairs of type IV collagen genes. Each type IV collagen molecule is a heterotrimer of three type IV collagen chains (See also Fig. 48.4).

TABLE 48.1 Molecular Genetics of Alport Syndrome

Inheritance	Affected Locus	Gene Product
X-linked Alport syndrome (XLAS)	*COL4A5*	α5(IV)
X-linked + leiomyomatosis	*COL4A5* + *COL4A6*	α5(IV) + α6(IV)
Autosomal-recessive Alport syndrome (ARAS)	*COL4A3* *COL4A4*	α3(IV) α4(IV)
Autosomal-dominant Alport syndrome (ADAS)	*COL4A3* *COL4A4*	α3(IV) α4(IV)

Autosomal dominant Alport syndrome. Heterozygous mutations in *COL4A3* or *COL4A4* are associated with a spectrum of phenotypes, including isolated microhematuria, chronic kidney disease (CKD) with proteinuria, and ESKD. We prefer to classify all individuals with heterozygous variants in *COL4A3* or *COL4A4* as having ADAS, including those with hematuria and attenuated GBMs.[9] Patients with progressive ADAS tend to have a slower course to ESKD than those with XLAS or ARAS.[10,11]

COL4A3 and *COL4A4* heterozygous variants may also manifest as focal segmental glomerulosclerosis (FSGS) with or without classic AS GBM findings of thinning or thickening with lamellation. This association has been reported frequently since the initial report in 2007.[12–14] Type IV collagen mutations are among the most common genetic mutations identified in up to 31% of adults with familial FSGS[14] and up to 10% of a cohort of predominantly sporadic FSGS.[15]

Type IV Collagen in Alport Basement Membranes

The GBMs and tubular basement membranes of males with XLAS usually fail to express the α3(IV), α4(IV), and α5(IV) chains but do express the α1(IV) and α2(IV) chains (Fig. 48.2). Females with XLAS frequently exhibit mosaic expression of the α3(IV), α4(IV), and α5(IV) chains in GBM, whereas expression of the α1(IV) and α2(IV) chains is preserved. Most males with XLAS show no EBM expression of α5(IV), whereas female heterozygotes frequently display mosaicism (Fig. 48.3). Lens capsules of some males with XLAS do not express the α3(IV), α4(IV), or α5(IV) chains, whereas expression of these chains appears normal in other patients.

In most patients with ARAS, GBM shows no expression of the α3(IV), α4(IV), or α5(IV) chains, but α5(IV) and α6(IV) are expressed in Bowman's capsule, distal thin basement membrane (TBM), and EBM (Fig. 48.4). Therefore, XLAS and ARAS may be differentiated by immunohistochemical analysis. Basement membrane expression of type IV collagen α chains appears to be normal in patients with ADAS.

These observations indicate that a mutation affecting one of the chains involved in the α3–α4–α5(IV) network can prevent GBM expression not only of that chain but also of the other two chains as well; evidence suggests that this reflects posttranslational events. Some mutant chains are unable to participate in the formation of trimers; as a result, the normal chains that are prevented from forming trimers undergo degradation. Other mutations may allow formation of abnormal trimers that are degraded before deposition in basement membranes can occur (Fig. 48.5).

Ultrastructural studies of human AS cochleae suggest that the hearing deficit may be attributable to a defect in adherence of the organ of Corti to the basilar membrane.[16] The lens capsules of AS patients with anterior lenticonus exhibit thinning and dehiscence by electron microscopy (EM) indicative of mechanical failure.[17]

Clinical Manifestations

Kidney Involvement

Hematuria is the cardinal finding of AS. Affected males have persistent microhematuria. Many also have episodic macrohematuria during upper respiratory tract infections, usually during the first two decades of life. Hematuria has been discovered in the first year of life in affected males, in whom it is probably present from birth. Males who are free of hematuria during the first 10 years of life are unlikely to be affected.

More than 90% of females with XLAS have persistent or intermittent microhematuria, but about 5% of obligate heterozygotes never manifest hematuria.[6] Hematuria is persistent in both males and females with ARAS. About 50% of individuals with heterozygous variants in *COL4A3* or *COL4A4* mutations have hematuria.

Proteinuria is usually absent early in life but develops eventually in all males with XLAS and in males and females with ARAS. Proteinuria increases progressively with age and may result in nephrotic syndrome.

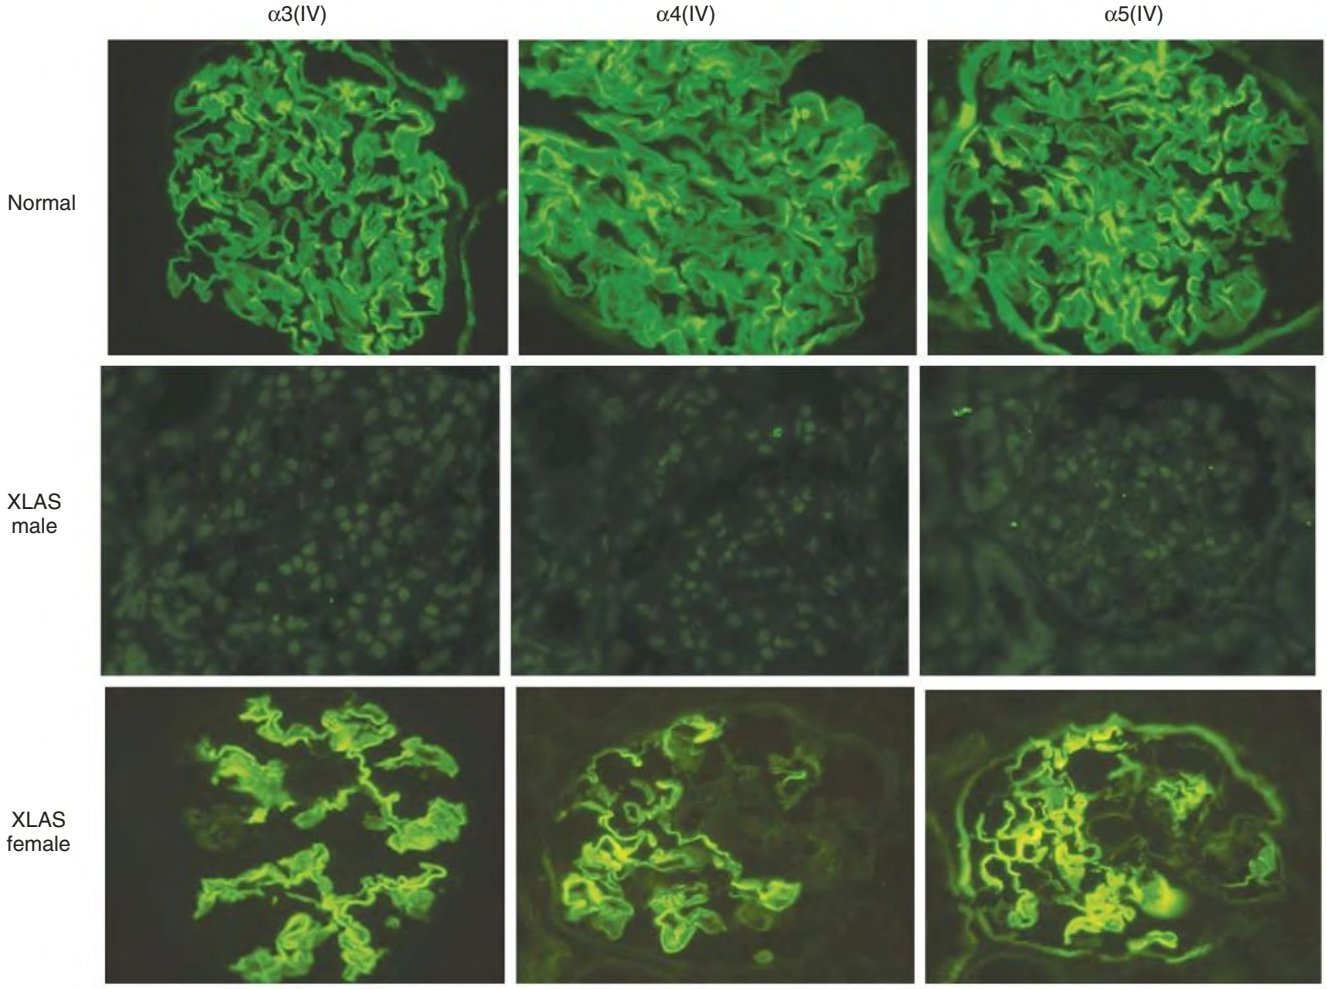

Fig. 48.2 Immunohistochemistry of Glomerular Basement Membrane (GBM) in X-Linked Alport Syndrome. In a normal individual *(top row),* GBM stains strongly for the α3(IV), α4(IV), and α5(IV) chains of type IV collagen. Staining of GBM of an affected male is negative for each of these chains *(middle row),* whereas an affected female shows mosaic immunoreactivity *(bottom row).*

Proteinuria develops eventually in at least 75% of heterozygous females[6] and in an uncertain percentage of individuals with heterozygous variants in *COL4A3* or *COL4A4*. Hypertension also increases in incidence and severity with age and is more likely in affected males than affected females with XLAS, but there are no sex differences in hypertension frequency in ARAS.

ESKD develops in all affected males with XLAS at a rate determined primarily by the nature of the underlying *COL4A5* mutation.[4] Thus, the rate of progression is fairly constant among affected males within a particular family, but there is significant interkindred variability. Significant intrakindred variability in the rate of progression to ESKD has been reported in some families with missense *COL4A5* mutations.

Progression to ESKD in females with XLAS was considered an unusual event until a 2003 European study of several hundred females with XLAS found that 12% developed ESKD before age 40 years (vs. 90% of males with XLAS), increasing to 30% by 60 years and 40% by 80 years.[6] A confirmatory European registry study showed a 15% prevalence of ESKD in heterozygous females.[18] The risk for ESKD is significantly increased in heterozygotes with proteinuria. The outcome of XLAS in females is presumed to depend on the relative activities of the normal and mutant X chromosomes, but other unknown factors also likely influence outcome.[7] Macrohematuria in childhood, nephrotic syndrome, and the finding of diffuse GBM thickening by EM are risk factors for CKD in affected females.[19] Sensorineural deafness and anterior lenticonus also suggest an unfavorable outcome in affected females. Both males and females with ARAS appear likely to progress to ESKD during the second or third decade of life.[8]

Cochlear Defects

Deafness is frequently but not universally associated with the Alport kidney lesion, occurring in about 90% of males and 25% to 30% of females with XLAS.[4,6] In some families with Alport nephropathy and apparently normal hearing, deafness may occur late and may be very slowly progressive.

Hearing loss in AS is never congenital and usually becomes apparent by late childhood to early adolescence in males with XLAS and in both males and females with ARAS. Hearing loss is present in 50% of males with XLAS by approximately age 15 years, 75% by 25 years, and 90% by 40 years.[4] Hearing loss is less common in females with XLAS, with 10% of XLAS affected by age 40 years and about 20% by 60 years.[6] Hearing loss is also common in ARAS with approximately 40% to 66% of individuals affected[8] but less common in ADAS with only 2% to 13% affected.[10,11] Hearing impairment in members of families with AS is always accompanied by evidence of kidney involvement. In its early stages, the hearing deficit is detectable only by audiometry, typically

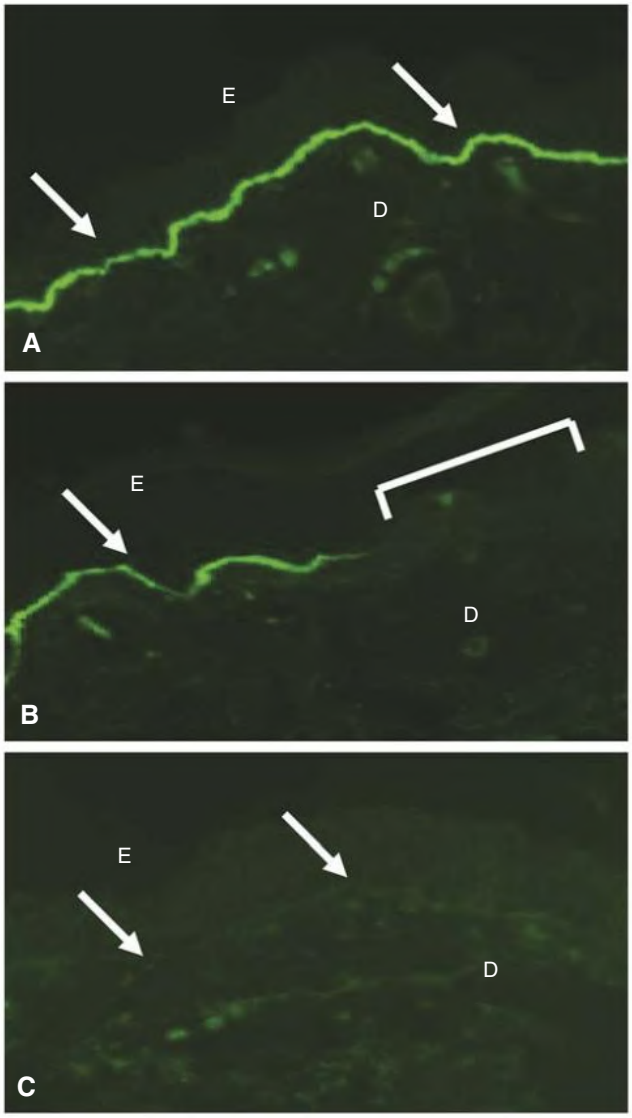

Fig. 48.3 Immunohistochemistry of Epidermal Basement Membrane (EBM) in X-Linked Alport Syndrome. (A) In a normal male, EBM shows strong staining for α5(IV) at the dermoepidermal junction *(arrows)* between dermis *(D)* and epidermis *(E)*. (B) In an affected female, EBM shows mosaic staining *(arrow);* the *white bracket* identifies a length of EBM negative for α5(IV). (C) In affected males, staining of EBM *(arrows)* for α5(IV) is absent.

with bilateral reduction in sensitivity to tones in the range of 2000 to 8000 Hz. In affected males, the deficit extends progressively to other frequencies, including those of conversational speech.

Ocular Defects

Ocular defects occur in 30% to 40% of males with XLAS and in about 15% of XLAS females.[4,6] *Anterior lenticonus,* a cone-shaped distortion of the anterior surface of the lens, is virtually pathognomonic of AS, occurs in about 15% of males with XLAS, and is almost entirely restricted to AS families with progression to ESKD before age 30 years and deafness.[4] Anterior lenticonus is absent at birth, usually appearing during the second to third decade of life after the onset of CKD and is bilateral in 75% of patients (Fig. 48.6A). The spectrum and frequencies of ocular lesions appear to be similar in XLAS and ARAS.[20] Ocular lesions are almost never observed in ADAS.[10,11]

Another common ocular manifestation of AS is a maculopathy, with whitish or yellowish flecks or granulations in a perimacular distribution. This is present in 50% to 60% of males with XLAS, in males and females with ARAS, and in approximately 15% of females with XLAS[20] (see Fig. 48.6B). In most individuals the maculopathy does not appear to be associated with any visual abnormalities, although giant macular holes causing visual impairment have been reported in some subjects.[20a]

Corneal endothelial vesicles (posterior polymorphous dystrophy) have been observed in AS and may indicate defects in the Descemet membrane, the basement membrane underlying the corneal endothelium. Recurrent corneal erosion in AS has been attributed to alterations of the corneal EBM.

Leiomyomatosis

The association of AS with leiomyomatosis of the esophagus and tracheobronchial tree has been reported in about 30 families. Affected females typically also have genital leiomyomas, with clitoral hypertrophy and variable involvement of the labia majora and uterus. Bilateral posterior subcapsular cataracts also occur frequently in affected individuals. Symptoms usually appear in late childhood and include dysphagia, postprandial vomiting, retrosternal or epigastric pain, recurrent bronchitis, dyspnea, cough, and stridor. This syndrome typically arises from a contiguous gene deletion on the X chromosome involving exon 1 of *COL4A5,* the common promoter region that regulates gene expression of *COL4A5* and *COL4A6,* and the first 2 exons of the adjacent *COL4A6* gene.[21] The genotype-phenotype relationship in this disorder is uncertain because deletions in this region may occur without associated leiomyomas and, conversely, some families with XLAS and leiomyomas do not have deletions involving the common promoter region and *COL4A6.*[22]

Hematologic Defects

An autosomal dominant syndrome of hereditary nephritis, deafness, and megathrombocytopenia called *Epstein syndrome* has been described in a small number of families. Families with Fechtner syndrome exhibit these features and leukocyte inclusions (May-Hegglin anomaly). Both Epstein and Fechtner syndrome arise from mutations in nonmuscle myosin heavy-chain IIA *(MYH9).*[23] Although in some patients the ultrastructural changes in GBM resemble those of AS, basement membranes of these patients do not have abnormal expression of type IV collagen α chains. Therefore, Epstein and Fechtner syndromes are best considered distinct forms of hereditary nephritis rather than variants of AS.

Arterial Abnormalities

Aneurysmal dilation of the thoracic and abdominal aorta and smaller arterial vessels has been described in a small number of males with AS.[24]

Kidney Pathology

There are no pathognomonic lesions on light microscopy (LM) or immunofluorescence (IF) in AS. In affected males, biopsies obtained before 5 years of age typically show no LM changes. Mesangial hypercellularity and matrix expansion are typically observed in older children and adolescents. Glomeruli of affected males eventually show FSGS, and interstitial fibrosis and tubular atrophy are often found in affected males older than 10 years.[25] LM findings in affected females correlate with proteinuria and kidney function; an affected female of any age who has isolated microhematuria is likely to have little or no abnormality by LM. Indirect IF of type IV collagen α-chain expression in renal or skin basement membranes can be diagnostic (see earlier discussion).

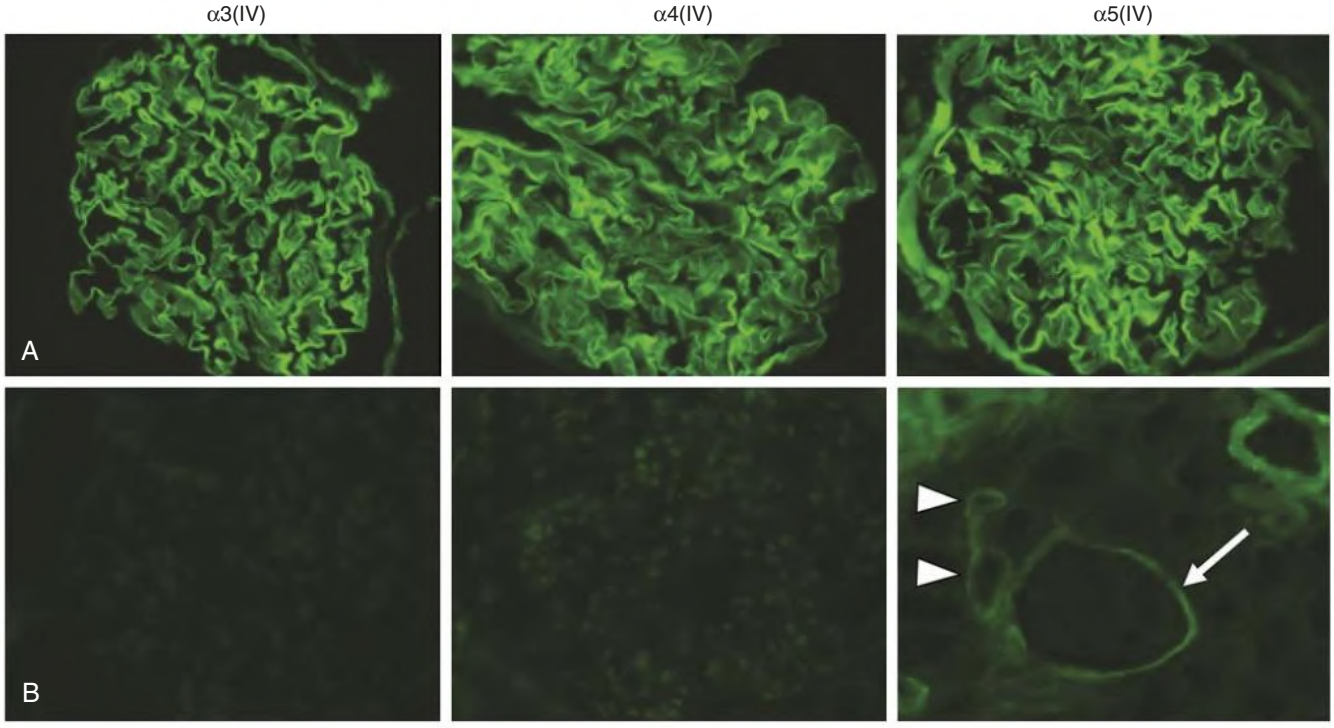

Fig. 48.4 Immunohistochemistry of Kidney in a Patient With Autosomal Recessive Alport Syndrome. (A) Normal glomerular basement membrane (GBM) and Bowman's capsule staining for α3(IV), α4(IV), and α5(IV). (B) Patient shows no GBM staining, but α5(IV) is present in Bowman's capsule *(arrow)* and distal tubular basement membranes *(arrowheads)*.

EM frequently reveals diagnostic abnormalities. In most patients with AS there is variable thickening, thinning, basket weaving, and lamellation of the GBM (Fig. 48.7). The thick segments measure up to 1200 nm in depth, usually have irregular outer and inner contours, and are found more frequently in males than in females. The lamina densa is transformed into a heterogeneous network of membranous strands, which enclose clear electron-lucent areas that may contain round granules of variable density measuring 20 to 90 nm in diameter. There are variable degrees of epithelial foot process fusion.

Not all Alport kindreds demonstrate these characteristic ultrastructural features. Thick, thin, normal, and nonspecifically altered GBMs have all been described. Affected young males, heterozygous females at any age, and, on occasion, affected adult males may have diffusely attenuated GBM measuring as little as 100 nm or less in thickness rather than the pathognomonic lesion. There are a number of families reported with features of hereditary FSGS with or without the classic AS basement membrane lesion associated with mutations in *COL4A3* or *COL4A4*.[13] These findings highlight the utility of detailed genetic evaluation to avoid misdiagnosis.

Diagnosis and Differential Diagnosis

Fig. 48.8 summarizes the evaluation of patients with hematuria and a positive family history. AS should be included in the initial differential diagnosis of patients with persistent microhematuria after excluding structural abnormalities of the kidneys or urinary tract (see Chapter 63). The presence on EM of diffuse thickening and multilamellation of the GBM predicts a progressive nephropathy, regardless of family history. However, in a patient with a negative family history, EM cannot differentiate de novo XLAS from ARAS. In some patients, the biopsy findings may be ambiguous, particularly in females and young patients of either sex. Furthermore, families with progressive nephritis and *COL4A5* mutations in association with GBM thinning have been described, indicating that the classic Alport GBM lesion is not present in all Alport kindreds.

If an undiagnosed patient has hematuria and multiple relatives with hematuria, who should undergo kidney biopsy? The natural history of the AS kidney lesion suggests that older, male individuals are more likely to exhibit diagnostic ultrastructural GBM abnormalities. In families with a firm diagnosis of AS established, evaluation of individuals with newly recognized hematuria can be limited to ultrasound of the kidneys and urinary tract to exclude coincidental tumor or structural anomalies of the urinary tract.

Absence of the α3, α4, and α5 chains of type IV collagen from GBM and distal TBM is unique to AS (Table 48.2). Expression of α5(IV) in the EBM detected by IF may be informative, but apparently normal expression of type IV collagen α chains in basement membranes does not exclude the diagnosis of AS. Although mosaic expression of α5(IV) is diagnostic of a heterozygous *COL4A5* variant, a normal result does not exclude heterozygosity.

A firm histologic diagnosis of AS cannot always be established, or it may not be possible to determine the mode of transmission, despite careful evaluation of the pedigree and application of the full range of histologic methods. In these situations, genetic analysis by NGS or whole exome sequencing (WES) provides information essential for determining prognosis and guiding genetic counseling. Genetic analysis for AS is widely available in commercial and research laboratories and ideally should be pursued in all patients with suspected or biopsy-confirmed AS to establish the genotype and facilitate cascade testing of at-risk family members.

Genetic analysis using conventional Sanger sequencing identifies 80% to 90% of males with *COL4A5* mutations. NGS and WES allow for simultaneous evaluation of *COL4A3, COL4A4,* and *COL4A5*.[26] Identification of a specific genotype can provide valuable prognostic information about the risks for kidney disease progression and

associated hearing loss and eye findings in an individual patient.[4] Once a new diagnosis of AS is made, all potentially affected family members including females should be screened for hematuria to identify those who may be at risk for progressive kidney disease, and targeted mutation analysis can be offered to at-risk individuals.[27]

Natural History

Microhematuria, the first and invariable kidney manifestation of AS, probably reflects GBM thinning with focal ruptures because of defective expression of the α3–α4–α5(IV) network. Proteinuria likely results from altered podocyte interactions with the abnormal GBM, and declining kidney function is attributable to profibrotic processes in glomeruli and in the tubulointerstitial compartment. What factors initiate and drive the progression of Alport nephropathy to ESKD, and how are these factors influenced by *COL4* genotype?

Reduction in the quantity of the α3–α4–α5(IV) network in GBM, as likely occurs in subjects with heterozygous variants in *COL4A3* or *COL4A4,* probably has consequences different from complete loss of this network, as occurs in most males with XLAS and most patients with ARAS. The normal transition from the $\alpha1(IV)_2$–$\alpha2(IV)_1$ network of nascent glomeruli to the α3(IV)– α4(IV)– α5(IV) network of mature glomeruli fails to occur in AS, and α1(IV) and α2(IV) chains accumulate in Alport glomeruli as the disease progresses.[28,29] Alport GBM also shows overexpression of other matrix proteins normally absent from GBM or present in scant quantities, including type V collagen, type VI collagen, laminin α2 chain, and fibronectin. These alterations in GBM composition are unique to AS.[28,30] Both glomerular endothelial cells and podocytes appear to contribute to the accumulation of these proteins in Alport GBM. Recently mesangial filopodial invasion of the GBM with deposition of ectopic laminin chains was proposed as another mechanism of matrix accumulation.[31] Alterations in glomerular extracellular matrix are accompanied by changes in glomerular cell behavior, including expression of transforming growth factor β1, integrins, and matrix metalloproteinases. Activation of fibrogenic pathways in the renal interstitium presumably represents a downstream consequence of glomerular disease.

Treatment

Current recommendations for delaying ESKD in patients with AS focus on the early introduction of renin-angiotensin-aldosterone system (RAAS) blockade to suppress urinary protein excretion.[27,32,33] The use of RAAS blockade is based on experimental and clinical evidence as well as practical considerations. Angiotensin-converting enzyme (ACE) inhibition lengthens survival in mice with ARAS, doubling survival when begun before the onset of proteinuria. ACE inhibition begun after the onset of proteinuria also improves survival in Alport mice, to a lesser degree. The effect of

ramipril on survival was superior to that of candesartan in a murine comparison study.

Uncontrolled clinical studies in AS have shown that RAAS blockade can reduce proteinuria. In a large multicenter, randomized, double-blind study comparing losartan with placebo or amlodipine in children with AS and proteinuria, there was a significant reduction in proteinuria with losartan over 12 weeks.[34] A 3-year extension of this study showed comparable efficacy of enalapril and losartan in reducing proteinuria.[35] A retrospective review of treated Chinese children with AS similarly showed a decline in proteinuria with ACE inhibition that was sustained over 5 years of follow-up.[36]

Retrospective data from the European Alport Registry indicates that ACE inhibitor therapy initiated while glomerular filtration rate (GFR) is still normal delays ESKD by years.[37] This also has been shown in pairs of affected brothers discordant for ACE inhibitor therapy with a delay in ESKD of a median of 13 years in the earlier treated brother.[37] The beneficial effect of ACE inhibition is observed in males with XLAS because of truncating and nontruncating variants in *COL4A5*.[5] ACE inhibitors can be used safely in children with CKD at doses that achieve suppression of urinary protein excretion.[38] RAAS blockers are relatively inexpensive and widely available, so in theory any individual in the world with AS should be able to receive treatment.

Consensus recommendations for the management of AS children include (1) early screening for hematuria in at-risk children, (2) regular determination of urinary protein excretion on diagnosis, and (3) initiation of RAAS blockade once overt proteinuria develops.[33] A recent update of these guidelines recommends consideration of treatment at the time of diagnosis in males with XLAS and males and females with ARAS, even if urine albumin levels are normal. A randomized controlled trial (RCT) examining the effect of RAAS blockade on the transitions from isolated hematuria to microalbuminuria to overt proteinuria showed that RAAS blockade delayed these transitions.[39] Prospective trials of add-on therapies such as bardoxolone methyl and anti-microRNA-21 are in progress.

Transplantation

Kidney transplantation is typically successful in patients with AS who reach ESKD with graft survival equivalent to that in patients with other diagnoses.[40] However, anti-GBM glomerulonephritis involving the kidney allograft is a rare but dramatic manifestation of AS, occurring in 2% to 3% of male patients with AS who undergo transplantation and typically presents in the first year (see Chapter 25).

Are females who are heterozygous for *COL4A5* mutations suitable kidney donors? Clearly, those with proteinuria, hypertension, or reduced GFR should not donate, nor should females with hearing

TABLE 48.2 Immunostaining for Type IV Collagen in Alport Syndrome

[a]In some Alport kindreds, staining of basement membranes for type IV collagen chains is entirely normal. Therefore, a normal result does not exclude a diagnosis of X-linked Alport syndrome.
[b]Some heterozygous females have normal basement membrane immunoreactivity for type IV collagen chains. Therefore, a normal result does not exclude the carrier state.

loss. A case series of heterozygous donors showed new-onset hypertension, proteinuria, and decline in GFR after kidney donation in most females.[41] Given the recent finding that 30% to 40% of heterozygous females may eventually develop ESKD, the risk that a heterozygous donor will ultimately develop significant reductions in GFR must be higher than for the usual kidney donor. However, a common clinical scenario is a mother choosing to donate to her son with AS, and the choices of the whole family should be considered.

HEREDITARY ANGIOPATHY WITH NEPHROPATHY, ANEURYSMS, AND CRAMPS (HANAC SYNDROME)

An autosomal dominant hereditary angiopathy associated with nephropathy, aneurysms, and muscle cramps (HANAC syndrome) is caused by missense mutations in the *COL4A1* gene that allow for expression of an abnormal α1(IV) chain.[42] Findings in affected individuals include microhematuria and macrohematuria, mild reduction in GFR, and kidney cysts. Retinal arteriolar tortuosity and retinal hemorrhage are common in affected individuals, as are intracranial aneurysms and leukoencephalopathy. Some affected individuals have elevated serum creatine kinase and muscle cramps.

Kidney biopsy in affected individuals with hematuria shows no abnormalities of GBM structure or type IV collagen expression. However, basement membranes of Bowman's capsules, tubules, and interstitial capillaries may exhibit irregular thickening, splitting into multiple layers and focal interruptions.

FABRY DISEASE (ANDERSON-FABRY DISEASE)

Definition

Fabry disease is caused by hereditary deficiency of the enzyme α-galactosidase A (α-Gal A), resulting in the intracellular accumulation of neutral glycosphingolipids with terminal α-linked galactosyl moieties (Fig. 48.9). Clinically, this leads to progressive CKD, pain crises, sweating abnormalities, vascular cutaneous lesions, and cardiac and eye abnormalities.

Etiology and Pathogenesis

More than 1000 mutations causing Fabry disease have been identified in *GLA*, the gene for α-Gal A, which is located on the X chromosome. Most of the described mutations are associated with the classic Fabry phenotype, in which there is less than 3% α-Gal A activity with multisystem involvement. Certain missense mutations with greater than 3% α-Gal A activity have been identified in patients with a mild phenotype limited to cardiac abnormalities. Prevalence of the classic form is up to 1 in 22,570 males by newborn screening studies and 1 in 1390 males for the males with milder phenotype.[43]

Glycosphingolipids are normal constituents of the plasma membrane, the membranes of intracellular organelles, and circulate in association with apolipoproteins. The neutral glycosphingolipids that accumulate in Fabry disease are identical to those found in normal tissue. All tissues except red blood cells accumulate globotriaosylceramide (Gb3), with the highest concentrations found in the diseased kidney.

Clinical Manifestations and Pathology

Fabry disease is a multisystem disorder, with prominent and potentially devastating involvement of the kidneys, heart, and peripheral and central nervous systems. As expected for an X-linked disorder, severe clinical manifestations occur in hemizygous males, whereas heterozygous females have a variable but typically less severe course. In affected males, the initial features of the disease are seen in childhood and early adolescence and consist of paresthesias and pain in the hands and feet with episodic pain crises. The course of the disease is variable but usually leads to ESKD in the third to sixth decade. There is risk of premature death because of myocardial or cerebral infarctions. Severe Fabry disease in a female reflects extensive inactivation of the X chromosome carrying the normal α-Gal A allele.[44]

Kidney Involvement

Although the earliest manifestation of kidney involvement is a urinary concentrating defect, the nephropathy of Fabry disease typically manifests as mild to moderate proteinuria, sometimes with microhematuria, beginning in the third decade, although proteinuria in childhood is reported. Nephrotic syndrome is unusual. Urinary oval fat bodies, with a Maltese cross configuration when viewed with a polarizing microscope, are a result of the large amounts of glycosphingolipid in the urine (see Chapter 4, Fig. 4.2B). Deterioration of GFR is gradual, with hypertension and ESKD developing by the fourth or fifth decade of life. Heterozygous females typically have mild kidney involvement but up to 10% may develop ESKD.

Glomerular visceral epithelial cells are enlarged and packed with small, clear vacuoles that represent glycosphingolipid material (Fig. 48.10). Vacuoles also may be seen in parietal epithelial cells and the epithelial cells of the distal convoluted tubule and loop of Henle, but only rarely in mesangial cells, glomerular endothelial cells, or proximal tubular epithelial cells. There is progressive segmental and global glomerulosclerosis. Vacuoles are also observed in endothelial cells and smooth muscle cells of arterioles and arteries.

On EM, there are abundant inclusions within lysosomes, particularly within visceral epithelial cells (Fig. 48.11). The inclusions (myelin figures) are typically round, involving concentric layers of dense material separated by clear spaces. The layers may be arranged in parallel (zebra bodies). Detachment of visceral epithelial cells from the underlying basement membrane may be observed. Inclusions are also observed in heterozygous females, although usually in smaller numbers than in affected males. Typical inclusions may be noted in excreted renal tubular cells.

The progression of Fabry nephropathy to ESKD probably reflects two parallel processes. Visceral epithelial cell dysfunction, which results in proteinuria, is followed by visceral epithelial cell detachment and necrosis, leading to capillary loop collapse and segmental sclerosis. Simultaneously, progressive impairment of arteriolar flow may develop as enlarging endothelial cells impinge on vascular lumina, resulting in ischemic glomerular damage.

Heart Defects

Glycosphingolipid accumulation in coronary artery endothelial cells and in the myocardium results in coronary artery narrowing, which may lead to angina, myocardial infarction, or congestive heart failure. Left ventricular hypertrophy (LVH) may be an early finding. Arrhythmias resulting from infiltration of the conduction system and valvular lesions also may occur. Certain missense mutations affecting α-Gal A may present as isolated LVH.

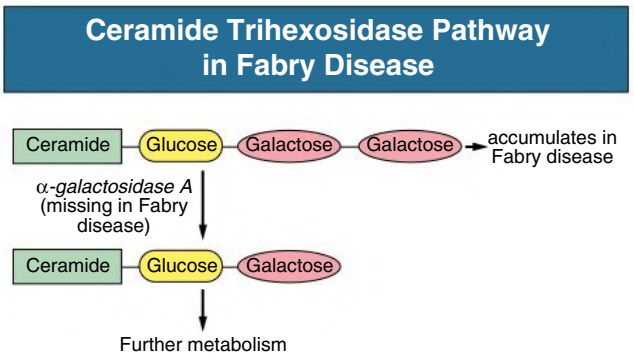

Fig. 48.9 Ceramide Trihexosidase Pathway in Fabry Disease. α-Galactosidase A deficiency leads to tissue accumulation of trihexosylceramide.

Nervous System

Autonomic dysfunction is a prominent feature of Fabry disease, typically manifested by hypohidrosis, acral paresthesias and pain, and altered intestinal motility. Cerebrovascular symptoms (secondary to narrowing of the vascular lumen from accumulation of glycosphingolipid in vascular endothelial cells) tend to appear during the fourth decade and include hemiparesis, vertigo, diplopia, dysarthria, nystagmus, nausea and vomiting, headache, ataxia, and memory loss. The vertebrobasilar circulation is preferentially involved. Symptoms are often recurrent. Life-threatening intracerebral hemorrhage and infarction are not unusual. Dementia arising from glycosphingolipid accumulation in small cerebral blood vessels also has been described.

Skin

Angiokeratomas usually appear during the second decade of life and can be the earliest presentation of Fabry disease, presenting as dark-red macules or papules of variable size (Fig. 48.12), originally known as *angiokeratoma corporis diffusum.* Typical locations include the lower trunk, buttocks, hips, genitalia, and upper thighs. The number of lesions varies from none up to 40 and increase in size and number.[45] On histologic examination, angiokeratomas consist of dilated small veins in the upper dermis, covered by hyperkeratotic epidermis. Telangiectasias may be noted, especially behind the ears.

Eyes

Characteristic corneal opacities are common in both males and females with Fabry disease, present in approximately 75% of affected males and females.[46] These lesions, termed *verticillata,* are identified by slit-lamp examination and are whorls of whitish discoloration that radiate from the center of the cornea. Cataracts (23% of males and 10% of females) and dilated conjunctival or retinal vessels may be observed.[46]

Lungs

Dyspnea and cough are common in males with Fabry disease, often with obstructive features on spirometry. This may be a consequence of fixed narrowing of the airways caused by glycosphingolipid accumulation.

Diagnosis

Diagnosis of affected males usually can be made clinically, with the additional information from slit-lamp eye examination to identify corneal opacities. The diagnosis should be confirmed by demonstrating decreased (<25%) or absent α-Gal A activity in serum, leukocytes, cultured skin fibroblasts, or tissue. Atypical variants may have enzyme activity up to 35% of normal. Heterozygous females may have very low (<25%) α-Gal A activity similar to that in males or may have more normal levels, making measurement of enzyme activity an insensitive way of diagnosing carriers. If enzyme levels are equivocal, alternative approaches to diagnosis include careful slit-lamp eye examination, measurement of urinary ceramide digalactoside and trihexoside, kidney biopsy, and genetic testing. Genetic testing for Fabry disease is widely available. Identification of carriers is particularly relevant when family members are being considered as living kidney donors.

Fabry disease should be considered in patients with unexplained ESKD, especially if LVH is present or there is a history of stroke or nondiabetic paresthesia. Fabry disease accounts for 0.1% to 0.2% of patients on hemodialysis and 0.9% of patients with hypertensive LVH.[47]

Treatment

The introduction of enzyme replacement therapy with recombinant human α-Gal A (agalsidase) has transformed the treatment of Fabry disease. RCTs showed that agalsidase administration for 5 to 6 months resulted in reduced plasma and urine Gb3; amelioration of neuropathic pain; enhanced quality of life; clearing of Gb3 deposits from kidney, heart, and skin; and improved cerebral blood flow.[48] Treatment of classic Fabry disease patients with agalsidase-β with baseline proteinuria of less than 1 g/day had stabilization of GFR over 5 years of follow-up. Addition of RAS blockade to enzyme replacement can result in sustained reductions in proteinuria. In patients with ESKD, agalsidase may be infused during hemodialysis because there is little clearance of the enzyme by hemodialysis. Agalsidase therapy has been recommended for all affected males and symptomatic carrier females, but the drug is prohibitively expensive in many parts of the world.[49-51]An alternative treatment approach based on chemical "chaperones" is under investigation; however, a recent study did not show a significant treatment effect.

Kidney transplantation is an effective treatment for advanced Fabry nephropathy but does not ameliorate the extrarenal manifestations. Transplanted kidneys from deceased donors or unaffected living donors may develop glycosphingolipid inclusions, but this usually is not clinically significant. Fabry heterozygotes should not become kidney donors. Coronary artery and cerebrovascular disease are the major causes of mortality in patients with Fabry disease who have undergone kidney transplantation. Kidney allograft recipients with Fabry disease are candidates for agalsidase treatment.

Fabry Disease in Childhood

Often it is not appreciated that the signs and symptoms of Fabry disease typically begin in childhood, particularly pain crises, acroparesthesias, angiokeratomas, and corneal opacities, and thus the diagnosis is frequently delayed until adulthood.[50] Accumulation of Gb3 in podocytes has been identified in children before onset of proteinuria; however, current recommendations do not support initiation of enzyme replacement therapy for asymptomatic children unless over age 16 years.[49] Symptomatic children with Fabry disease are potential candidates for agalsidase therapy.[50]

NAIL-PATELLA SYNDROME

Definition

Nail-patella syndrome (NPS) is an uncommon autosomal dominant condition characterized by hypoplasia or absence of the patellae, dystrophic nails, dysplasia of the elbows and iliac horns, and kidney disease.

Etiology and Pathogenesis

NPS is caused by mutations in the LIM homeodomain transcription factor *LMX1B,* including missense, splicing, insertion or deletion, and nonsense alterations. In vitro studies of the transcriptional

effects of mixing wild-type and mutant *LMX1B* suggest that NPS results from haploinsufficiency of *LMX1B,* rather than a dominant-negative effect. LMX1B is essential for the maintenance of differentiated podocytes in adult kidneys through effects on actin cytoskeletal organization.

Clinical Manifestations

Kidney Involvement

Clinically apparent kidney disease occurs in fewer than half of NPS patients. The nephropathy is usually benign, with an approximately 3% to 5% risk for progression to ESKD.[52,53] The clinical signs of NPS nephropathy appear in adolescence or young adulthood and typically include microhematuria and mild proteinuria, although some patients develop nephrotic syndrome and mild hypertension. The severity of these manifestations may differ substantially in related individuals.

Fig. 48.14 Nail-Patella Syndrome. *Arrowheads* denote iliac horns. ((Courtesy Dr. R. Vernier.))

Skeletal Defects

The patellae are absent or hypoplastic in more than 90% of patients with NPS, which may be associated with knee joint effusions and osteoarthritis (Fig. 48.13).[52,53] In about 80% of patients, osseous processes project posteriorly from the iliac wings (iliac horns), which is pathognomonic (Fig. 48.14). Anomalies of the elbows include aplasia, hypoplasia, and posterior processes at the distal end of the humeri.

Nails

Nail abnormalities occur in about 98% of patients and are typically bilateral and symmetric. Fingernails are affected more often than toenails. The nails may be absent or dystrophic with discoloration, koilonychia, longitudinal ridges, or triangular lunulae.[52]

Kidney pathology

LM findings in NPS are nonspecific and may demonstrate FSGS, mild mesangial hypercellularity, or no changes, in which case EM is required to make the diagnosis. EM shows multiple irregular lucencies of the GBM, giving it a moth-eaten appearance (Fig. 48.15). Such lucencies also may be observed in the mesangium. These lucent areas sometimes contain cross-banded collagen fibrils, which are more easily observed after staining with phosphotungstic acid (Fig. 48.16). The fibrils, which are type III collagen, tend to be arranged in clusters, and the surrounding GBM is often thickened. This may be observed without clinically evident kidney disease, but fibrils have not been found in extraglomerular basement membranes. Cross-banded fibrils of type III collagen have been seen in GBM of patients with glomerular disease who lack nail or skeletal abnormalities, sometimes as a familial condition with autosomal recessive inheritance (collagen III glomerulopathy; see Chapter 29). It is unclear whether there is a pathogenic relationship between collagen type III glomerulopathy and NPS.

Treatment

No specific therapy is available for the nephropathy of NPS. There has been no reported recurrence in transplanted kidneys. Because NPS is an autosomal dominant disorder, careful evaluation of potential living related kidney donors for features of NPS is essential.

SELF-ASSESSMENT QUESTIONS

1. A 15-year-old boy has AS. What statement about his parents is *most* likely to be *true?*
   - **A.** His father has AS.
   - **B.** His mother has AS.
   - **C.** Both parents are carriers of AS.
   - **D.** Neither parent has AS.
   - **E.** None of the above.
2. Which of the following ocular abnormalities have been described in patients with AS?
   - **A.** Anterior lenticonus
   - **B.** Recurrent corneal erosions
   - **C.** Perimacular flecks
   - **D.** Posterior polymorphous dystrophy
   - **E.** All of the above
3. Which one of the following statements about hearing loss in AS is true?
   - **A.** AS may be picked up by neonatal hearing screening.
   - **B.** In males with AS, hearing loss is usually undetectable by audiometry until adulthood.
   - **C.** Hearing loss in AS initially targets high frequencies above the range of conversational speech.
   - **D.** The hearing loss of AS is conductive.
   - **E.** Hearing loss in AS is typically unilateral.

Inherited Disorders of Sodium and Water Handling

Detlef Bockenhauer

INTRODUCTION

Glomerular filtration yields about 150 L of water and 21,000 mmol of sodium (Na) in a healthy individual in 24 hours, yet only minute fractions of these quantities are excreted eventually in the urine. The precise amount excreted is tightly regulated to maintain homeostasis. A large number of different tubular transporters are involved in this homoeostatic process and either directly or indirectly dependent on the electrochemical gradient generated by the Na^+,K^+-ATPase. In this way, Na reabsorption is central not only for volume but also for acid-base and electrolyte homeostasis. This molecular integration of homeostatic processes is reflected in the clinical picture: whereas disorders of water transport primarily cause a disturbance of serum Na concentration, disorders of Na transport generate clinical signs and symptoms related to blood pressure (BP), electrolytes, and acid-base disturbances, which help establish the diagnosis.

PHYSIOLOGY OF SODIUM AND WATER REABSORPTION

Sodium Transporters and the Corresponding Inherited Disorders

In all tubular epithelial cells, a basolateral energy-requiring Na^+,K^+-ATPase will ensure that intracellular Na is kept at low levels, whereas K is high. Coupled with apical K channels, which use the concentration gradient to establish a lumen-positive electrical potential, an electrochemical gradient for Na is created across the apical cell membrane, which drives Na uptake from the tubular lumen into the cell via dedicated transporters and channels.

Based on anatomic and molecular characteristics, the tubule is typically divided in four functional segments: the proximal tubule (PT), the loop of Henle and for sodium handling specifically the thick ascending limb (TAL), the distal convoluted tubule (DCT), and the collecting duct (CD). Each of these segments has specific apical Na transporters or channels (Fig. 49.1). Transport across the basolateral membrane to complete Na reabsorption is facilitated by the Na^+,K^+-ATPase in all segments. Na transport in these segments is inhibited by specific diuretics, which can help understand inherited disorders of Na transport by comparing them to the effects of the corresponding diuretic.

In the PT, an apical Na-hydrogen (H) exchange protein (NHE3) facilitates most of the Na reabsorption. Because of this connection with H excretion (and thus acid-base homeostasis), this transport process is indirectly blocked by carbonic anhydrase inhibitors, such as acetazolamide. So far, no inherited disorder of isolated Na in the PT has been reported. Instead, impaired reabsorption in the PT typically occurs with a general proximal dysfunction, which underlies the renal Fanconi syndrome (Chapters 13 and 50).

In the TAL, the Na^+-K^+-$2Cl^-$ cotransporter (NKCC2) can be blocked by loop diuretics, such as furosemide and bumetanide. The corresponding inherited disorder is Bartter syndrome, where the function of this transporter is either directly or indirectly impaired. Thus, Bartter syndrome can be conceptualized as "inherited furosemide use."

In the DCT Na is reabsorbed by the Na-Cl cotransporter (NCCT), which is inhibited by thiazides. Disorders involving this transporter include Gitelman syndrome, caused by inherited loss-of-function of this transporter. Gitelman syndrome can therefore be conceptualized as "inherited thiazide use." The mirror image of Gitelman syndrome is pseudohypoaldosteronism type 2 (PHA2) or Gordon syndrome. The underlying genetic causes lead to an overactivity of NCCT.

In the CD, Na reabsorption is facilitated by the epithelial sodium channel (ENaC). Amiloride and triamterene specifically block ENaC. Several inherited disorders affect transport through this channel. Inherited loss-of-function of ENaC is called pseudohypoaldosteronism type 1 and is autosomal recessive, whereas gain-of-function underlies Liddle syndrome. Because ENaC is highly regulated by the mineralocorticoid receptor (MR), several other disorders affect ENaC function through dysregulation of the MR. These and other disorders are discussed in detail later and listed in Table 49.1.

Water Reabsorption

In the PT, water follows sodium chloride (NaCl) passively through aquaporins, the constitutively open water transport proteins in apical and basolateral tubular cell membranes. In this way Na transport is directly linked to unregulated water reabsorption. The TAL and the CD are the 2 segments critical for regulated water reabsorption. The TAL is water impermeable and thus also called the diluting segment, as salt transport via NKCC2 dilutes the tubular fluid. This also helps establish the interstitial concentration gradient, which drives water reabsorption in the arginine-vasopressin (AVP)-sensitive parts of the nephron, the late DCT and CD. In this way, sodium transport is also linked to regulated water reabsorption. Consequently, patients with Bartter syndrome have impaired urinary concentrating ability, which helps explain the polyuria associated with this disorder.

Final control over water reabsorption is exerted in the CD and regulated by AVP. In the absence of this hormone, the apical membrane of the epithelial cells in CD are water impermeable, resulting in water diuresis. Binding of AVP to the AVPR2 receptor in the CD initiates a signaling cascade that results in the insertion of the water channel aquaporin 2 (AQP2) into the apical membrane, allowing water to pass through the epithelial cell layer, following the interstitial concentration gradient, resulting in antidiuresis. Inherited disorders affecting the function of AVPR2 or AQP2 cause either nephrogenic diabetes insipidus (NDI) through loss-of-function or nephrogenic syndrome of inappropriate antidiuresis (NSIAD) through gain-of-function.

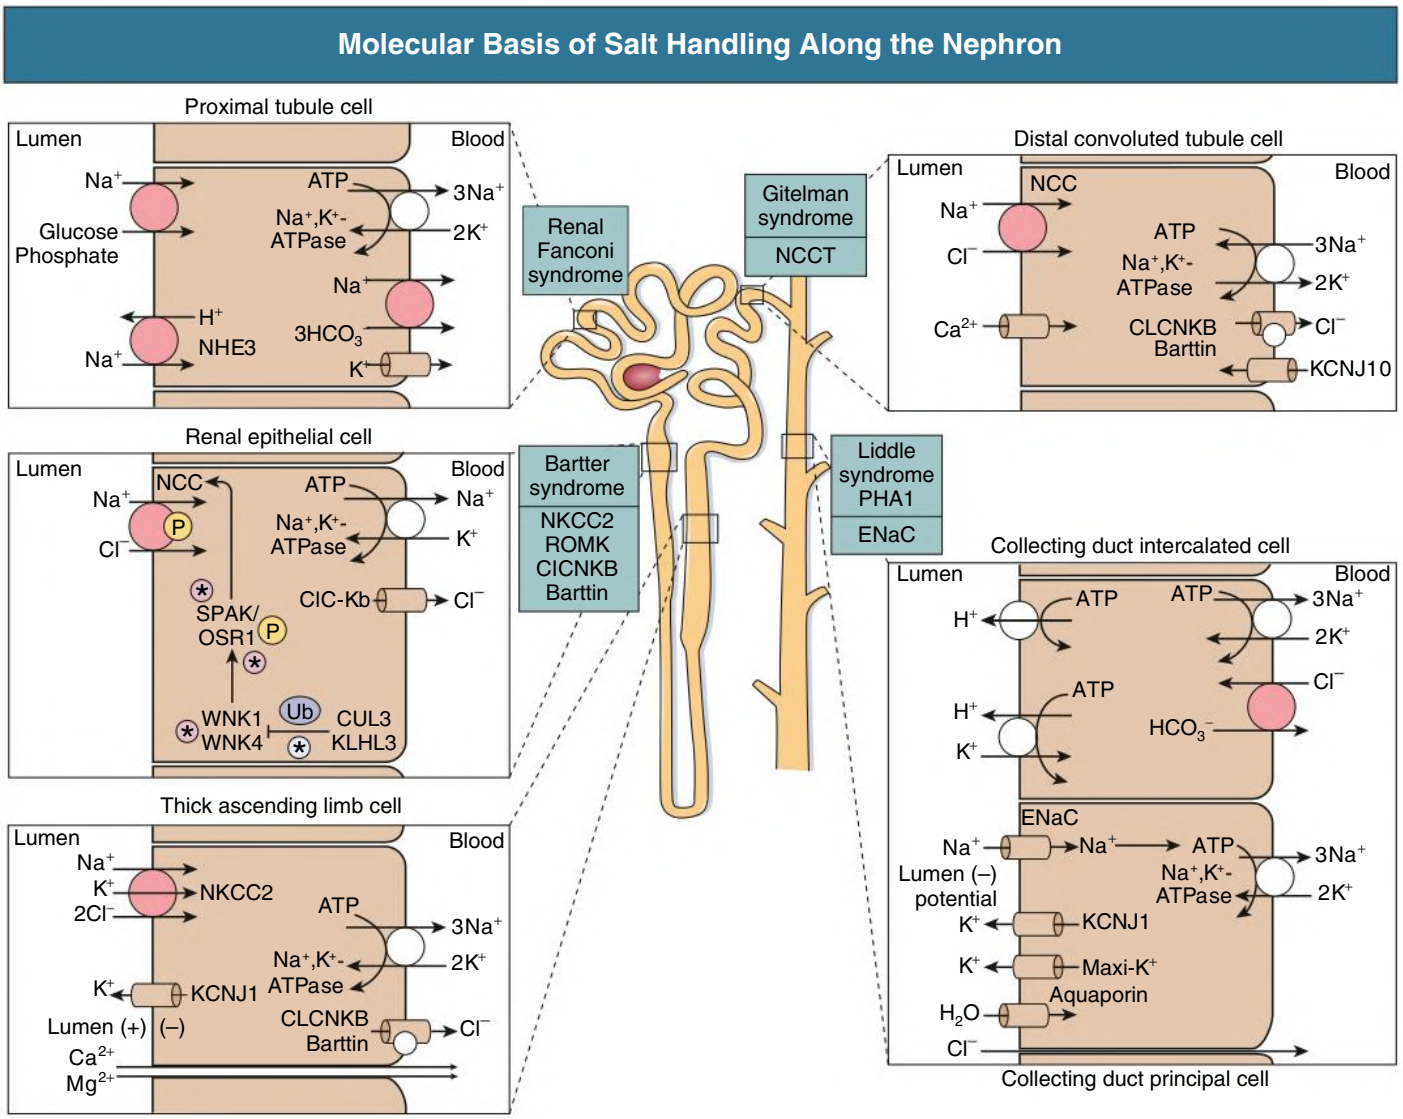

Fig. 49.1 Overview of the Molecular Basis of Salt Handling Along the Nephron in the Four Main Functional Subunits of the Tubule. Note that Na^+,K^+-ATPase is expressed on the basolateral aspect of the epithelial cells along the entire nephron, establishing the electrochemical gradient for Na reabsorption and providing an exit pathway for Na. In contrast, on the apical side, segment-specific transporters and channels provide the entry pathway for Na into the epithelial cells. *Salt transport in the proximal tubule:* The majority of filtered salt (roughly 70%–80%) is reabsorbed here through a variety of transporters. The electrochemical gradient for Na is used as driver for a number of transport processes, thereby linking Na reabsorption to acid-base and phosphate homeostasis, as well as glucose and other substrate transport. *Salt transport in the thick ascending limb (TAL) of the loop of Henle:* Approximately 10% to 20% of filtered Na is reabsorbed in this segment with the furosemide-sensitive Na^+-K^+-$2Cl^-$ (NKCC2, variants of which cause Bartter syndrome type 1) cotransporter providing entry into the epithelial cell. Apical K recycling through the KCNJ1 (ROMK) channel (the cause of Bartter syndrome type 2) ensures the efficient functioning of NKCC2 and helps establish a lumen-positive transepithelial voltage that drives paracellular cation reabsorption. Chloride exits the cell through basolateral Cl channels, predominantly CLCNKB (the cause of Bartter syndrome type 3). The β subunit (Barttin, cause of Bartter syndrome type 4) is crucial for normal functioning of CLCNKB. *Salt transport in the distal convoluted tubule (DCT):* Approximately 5% to 10% of filtered Na is reabsorbed in this segment via the thiazide-sensitive Na-Cl-cotransporter (NCCT, the cause of Gitelman syndrome) on the apical side. Note the presence of the same chloride channel (CLCNKB) on the basolateral side as in TAL. This explains why pathogenic variants in this channel cause Bartter syndrome type 3 (a disorder of TAL) but can phenocopy Gitelman syndrome (a disorder of DCT). *Salt transport in a principal cell of the collecting tubule:* Approximately 2% to 5% of filtered Na is reabsorbed in this segment via the amiloride-sensitive epithelial sodium Na channel (ENaC). Loss-of-function variants in this channel cause pseudohypoaldosteronism type 1 (PHA1), whereas gain-of-function causes Liddle syndrome. Na uptake is indirectly coupled to K (through ROMK) and proton secretion through the H^+-ATPase in the neighboring intercalated cell. Aldosterone activates the mineralocorticoid receptor, which increases the activity of ENaC and Na^+,K^+-ATPase, which increases Na reabsorption and K and proton secretion, resulting in hypokalemic alkalosis. Cortisol is also a ligand for the mineralocorticoid receptor but is normally removed by oxidation by 11β-hydroxysteroid dehydrogenase to cortisone. *ATP,* Adenosine triphosphate; *WNK,* with-no-lysine kinase. (From Hoenig MP, Zeidel ML. Homeostasis, the milieu interieur, and the wisdom of the nephron. *Clin J Am Soc Nephrol.* 2014;[9]:1272–1281.)

DISORDERS OF SODIUM HANDLING

Based on the clinical and biochemical phenotype, five main categories can be distinguished. Algorithms to help establish the individual diagnoses are shown in Figs. 49.2 and 49.3:

1. Hypokalemic acidosis with low-normal BP (renal Fanconi syndrome and distal renal tubular acidosis, discussed in Chapters 13 and 50)
2. Hypokalemic alkalosis and low-normal BP (Bartter syndrome, Gitelman syndrome, EAST syndrome)
3. Hypokalemic alkalosis and high BP (Liddle syndrome, apparent mineralocorticoid excess [AME], glucocorticoid-remediable hyperaldosteronism [GRA], adrenal 17α-hydroxylase deficiency, adrenal 11β-hydroxylase deficiency, Cushing disease)
4. Hyperkalemic acidosis and low-normal BP (pseudohypoaldosteronism type 1, adrenal 21-hydroxylase deficiency, adrenal aldosterone synthase deficiency)
5. Hyperkalemic acidosis and high BP (Gordon syndrome)

Some of the disorders are caused by mutated renal transport proteins (e.g., Gitelman syndrome) or associated regulatory proteins (e.g., Gordon syndrome). In others, the genetic defect resides in the adrenals, and the changes in adrenal mineralocorticoids and glucocorticoids create the renal phenotype. All the inherited disorders discussed here are rare, with estimated incidences typically around 1:100,000.

CONDITIONS WITH HYPOKALEMIA, METABOLIC ALKALOSIS, AND LOW-NORMAL BP

Bartter Syndrome

Bartter syndrome is a genetically heterogeneous disorder of salt reabsorption in the TAL.[1]

Pathogenesis

Currently, four causative genes have been associated with Bartter syndrome: *SLC12A1* (encoding NKCC2) for Bartter syndrome type 1; *KCNJ1* (encoding KCNJ1, also called ROMK) for type 2; *CLCKNB* (encoding CLCK-B), type 3; and *BSND* (encoding Barttin), type 4 (Table 49.1; see also Fig. 49.1). In addition, another disorder called familial hypocalcemic hypercalciuria, caused by activating mutations in *CaSR*, encoding the calcium-sensing receptor, can cause Bartter-like electrolyte abnormalities and is thus sometimes referred to as Bartter type 5.[2] Although all the genetic defects directly or indirectly impair salt reabsorption through NKCC2, there are differences between the various forms of Bartter syndrome that typically allow correct classification on clinical grounds (see Fig. 49.2). An important first discriminator is the urine calcium excretion. The TAL is an important segment for calcium reabsorption, which occurs passively through paracellular pathways, lined by claudins, which provide transport specificity.[3] The driving force for this is generated by the combined action of NKCC2

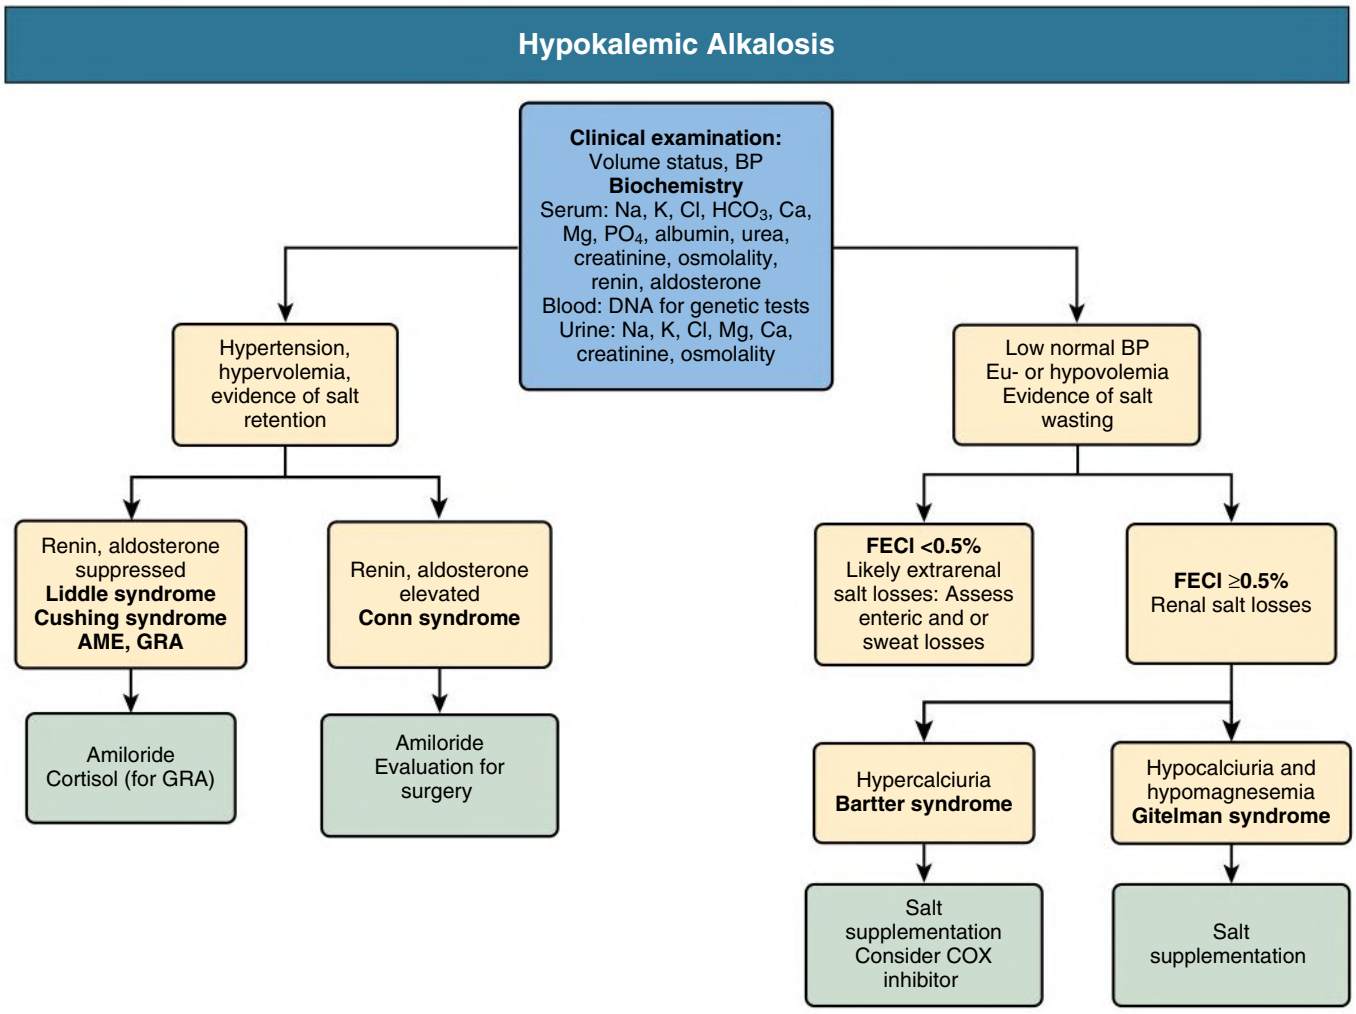

Fig. 49.2 Diagnostic and management algorithm for inherited conditions causing hypokalemic alkalosis. *AME,* Apparent mineralocorticoid excess; *BP,* blood pressure; *COX,* cyclooxygenase; *FECl,* fractional excretion of chloride; *GRA,* glucocorticoid-remediable aldosteronism.

and KCNJ1; transport via NKCC2 is electroneutral, whereas K is recycled back into the tubular lumen via KCNJ1, establishing a lumen positive transepithelial potential. Consequently, calcium reabsorption in the TAL is impaired in Bartter types 1 and 2, leading to hypercalciuria and nephrocalcinosis, whereas it is typically unaffected in types 3 and 4. CLCKNB is also expressed in the DCT, so symptoms of Bartter type 3 can overlap with Gitelman syndrome. Hypomagnesemia is thus a common feature. Finally, Barttin is critical also for inner ear function, so affected patients not only have Bartter syndrome but also sensorineural deafness.

The macula densa is part of the TAL, and it is in the macula densa that the first initial step of tubuloglomerular feedback (TGF) is localized: reduced Cl absorption in the macula densa initiates a signaling cascade that includes enhanced prostaglandin E2 (PGE2) production with consequent activation of renin and aldosterone.[4] Because Cl absorption is impaired in Bartter syndrome, these patients have impaired TGF with elevated levels of PGE2, renin, and aldosterone, and the latter mediates the characteristic hypokalemic metabolic alkalosis.[5] The dramatic upregulation of TGF is reflected in hypertrophy of the juxtaglomerular apparatus.[6]

Clinical Manifestations

Bartter syndrome from pathogenic variants in *SLC12A1, KCNJ1,* or *BSND* usually has earlier onset than that caused by variants in *CLCKNB.* Most manifest already during pregnancy, leading to the term *antenatal* Bartter syndrome.[7,8] In contrast, the later onset form is often called *classic* Bartter syndrome, as this is the phenotype originally described by Bartter and colleagues.[6]

The clinical features of antenatal Bartter syndrome include polyuria, hypokalemic metabolic alkalosis, and high urinary chloride excretion in a newborn with vomiting, failure to thrive, and a history of polyhydramnios and premature delivery. In pregnancies affected by polyhydramnios, a prenatal diagnosis of Bartter syndrome may be suggested by elevated protein concentrations in amniotic fluid, if genetic testing is not informative.[9] Bartter syndrome type 2 (BS2) can have a different phenotype in the first days of life, as KCNJ1 is not only involved in salt reabsorption in the TAL but also mediates K secretion in CD. Consequently, patients with BS2 often present initially with hyperkalemia and hyponatremia, leading to an erroneous diagnosis of pseudohypoaldosteronism type 1 (PHA1).[10] Over the first few days to weeks, serum K levels decrease, presumably due

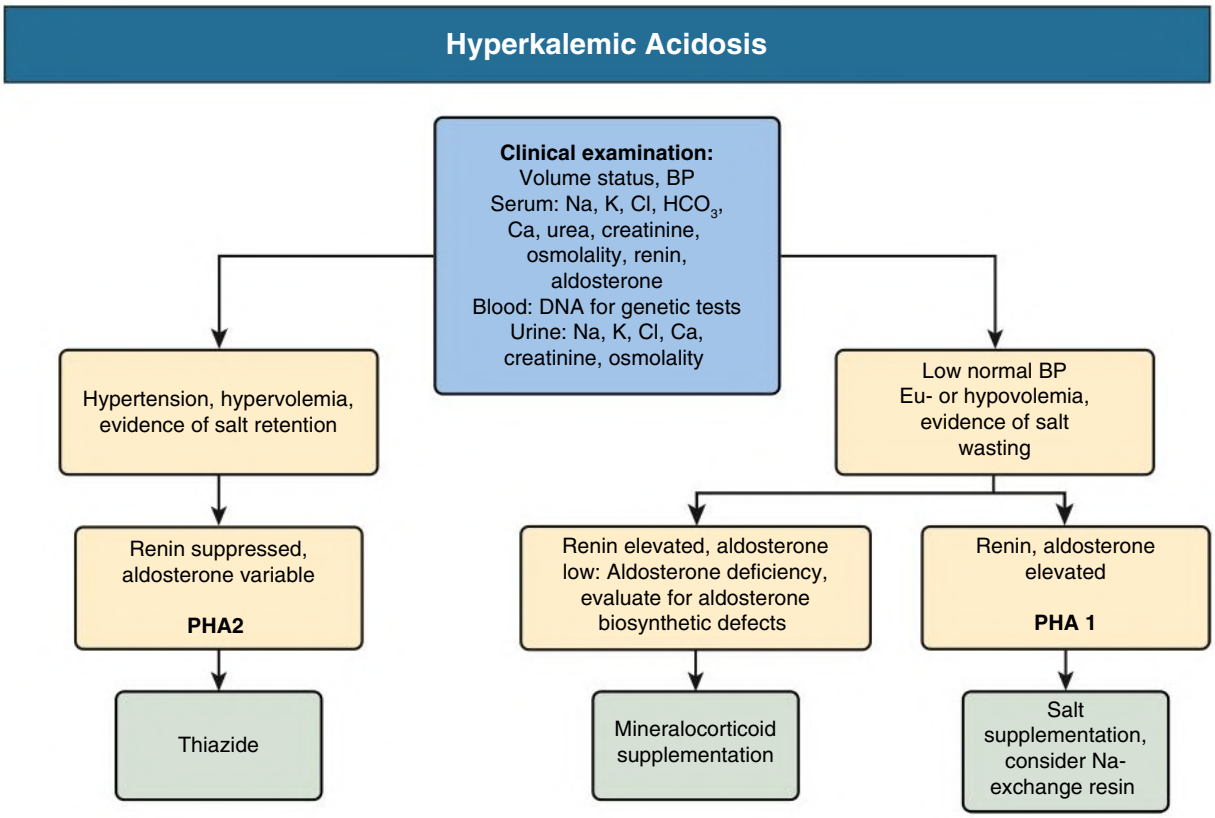

Fig. 49.3 Diagnostic and management algorithm for inherited conditions causing hyperkalemic acidosis. *BP,* Blood pressure; *PHA1,* pseudohypoaldosteronism type 1; *PHA2,* pseudohypoaldosteronism type 2.

to the expression of other K channels in CD that can compensate for the loss of KCNJ1 function.

Hypercalciuria and nephrocalcinosis are typical for BS1 and BS2, as the coupling of the electroneutral NKCC2 transporter with recycling of potassium into the tubular lumen through KCNJ1 is establishing the transepithelial voltage that drives Ca (and Mg) reabsorption through the paracellular pathway.[3]

Classic Bartter syndrome is typically associated with pathogenic variants in *CLCNKB* (Bartter syndrome type 3 or BS3). These patients present mostly in the first decade of life with vomiting, polyuria, recurrent episodes of dehydration, and hypokalemic metabolic alkalosis. Interestingly, electrolyte abnormalities are typically more severe than in antenatal Bartter syndrome.[7,8] Moreover, hypomagnesemia with renal Mg^{2+} wasting is common. Presumably, this is due to the expression of CLC-Kb in both TAL and DCT, thus affecting salt reabsorption in both these nephron segments. This may also explain the phenotypic overlap between Bartter and Gitelman syndrome, as some patients with BS3 can phenotypically mimic Gitelman syndrome.[11]

Bartter syndrome type 4 (BS4) is also characterized by sensorineural deafness. Clinically, it typically manifests as a more severe form of BS3, sometimes with extreme electrolyte abnormalities.[5] Presumably, in BS3, the closely related chloride channel CLC-Ka can compensate for the loss of CLC-Kb function in the inner ear and to some degree also in the kidney. However, both channels require Barttin as subunit, so that loss of function of Barttin is functionally equivalent to loss of both chloride channels.[12] Of note, BS4 patients typically experience progressive chronic kidney disease (CKD), although a milder phenotype has been reported, presumably to mutations with residual Barttin function.[13]

Diagnosis

The key features of Bartter syndrome are hypokalemic, hypochloremic alkalosis with evidence of renal Cl and K wasting and low or normal BP.

Differential Diagnosis

In syndromes of chronic severe hypokalemia with metabolic alkalosis, the differential diagnosis may be facilitated greatly by taking into consideration the associated BP and the urinary chloride concentration (Fig. 49.4).

Hypertension with hypokalemic alkalosis indicates a primary activation of salt reabsorption in the CD, such as from pathologic activation of the MR (e.g., hyperaldosteronism) or the sodium channel ENaC. If Bartter syndrome is associated with a normal or low-normal BP, however, extrarenal or renal Cl and Na losses are the cause. Extrarenal loss of sodium occurs in diarrhea, vomiting, or burns and is characterized by very low Cl concentrations in the urine with a fractional chloride excretion less than 0.5%.[14] Congenital chloride diarrhea can be misdiagnosed as BS, as the biochemical picture in the blood is identical, and the large and often clear-appearing stool volume is misinterpreted as urine, especially in female babies in diapers.[15] It is critical to demonstrate the renal loss of salt that is typical of Bartter and Gitelman syndrome, and diuretic use. Further analysis of Mg and urinary Ca excretion can then help distinguish between the various forms of Bartter and Gitelman syndrome (Table 49.2). Genotyping is recommended to confirm the final diagnosis.

Treatment

Neonates with Bartter syndrome typically have marked fluid and electrolyte disturbances that need to be corrected carefully. Salt

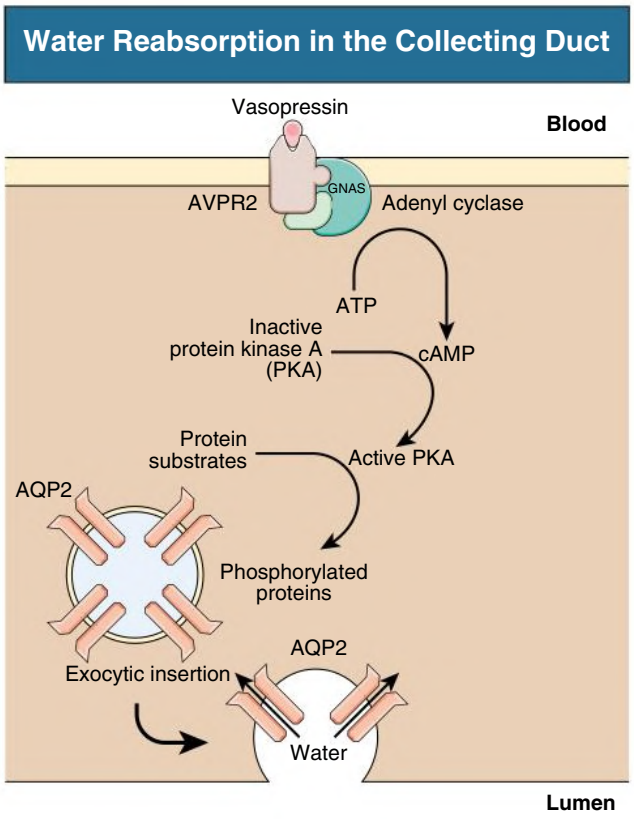

Fig. 49.4 Activation of the basolateral arginine-vasopressin type 2 receptor (AVPR2) initiates the signaling cascade that ultimately results in insertion of the water channel aquaporin 2 (AQP2) in the apical membrane, making it water permeable and thus allowing water reabsorption and urinary concentration. Genetic variants leading to loss-of-function of AVPR2 cause X-linked nephrogenic diabetes insipidus, whereas those with gain-of-function cause nephrogenic syndrome of inappropriate antidiuresis (NSIAD). Similarly, gain-of-function variants in the stimulatory G-protein alpha subunit also cause NSIAD. Loss-of-function variants in AQP2 are the cause of autosomal nephrogenic diabetes insipidus. *ATP,* Adenosine triphosphate; *cAMP,* 3′,5′-cyclic adenosine monophosphate; *GNAS,* genome-wide association studies; *PKA,* protein kinase A.

supplementation is often helpful; however, antenatal Bartter syndrome can be complicated by a secondary form of NDI, in which case a high solute intake can lead to hypernatremia.[16] Potassium chloride supplementation is commonly provided. Addition of spironolactone or amiloride may be useful in improving hypokalemia and alkalosis but worsens the salt wasting and thus increases the risk of hypovolemia and should only be provided with sufficient salt supplementation.[5] The same applies for angiotensin-converting enzyme (ACE) inhibitors, which are not recommended.[17]

A key problem in renal wasting disorders is that supplementation primarily results in increased urinary losses. After supplementation, plasma levels transiently rise, leading to an increased concentration in the glomerular filtrate with consequent loss in the urine and decreasing plasma levels. Monitoring the efficacy of supplementation thus depends strongly on the timing of the blood sample. Although cardiac arrhythmias and other severe complications have been reported with marked hypokalemia,[18] the dramatic swings in plasma concentration associated with high-dose supplementation may be more harmful than consistent levels below the normal range. Moreover, high-dose supplementation may cause gastrointestinal symptoms (e.g., ulcers, diarrhea) that can worsen the electrolyte profile. Thus, smaller but more frequent administration of electrolyte supplements may be better tolerated and safer.

A key component of treatment especially of antenatal BS is prostaglandin synthesis inhibition through cyclooxygenase inhibition by nonsteroidal antiinflammatory drugs (NSAIDs) such as indomethacin (1–3 mg/kg/24 h). Selective COX2 inhibitors may provide similar efficacy with less potential toxicity.[19] NSAIDs act by interfering with the pathologic tubuloglomerular feedback in BS and enhancing proximal sodium reabsorption.[5] Treatment results in reduction of polyuria and polydipsia, improved growth and activity, and better control of plasma electrolytes. Plasma levels of renin and aldosterone often decrease, sometimes into the normal range.

Outcomes

Dramatic complications such as intracranial hemorrhage and bronchopulmonary dysplasia are typically seen in patients with antenatal BS and are a consequence of extreme prematurity. As with most diseases, there is a spectrum of severity. The electrolyte and acid-base imbalance itself can be severe with complications such as arrhythmias, paralysis, rhabdomyolysis, and apnea, yet others may have few symptoms, and some patients are diagnosed incidentally later in life. Importantly, even patients with more severe electrolyte imbalance usually improve clinically with appropriate therapy. Progressive CKD can be a complication of prematurity but can also be seen in BS3 patients born at term and is common in BS4.

Gitelman Syndrome

Gitelman syndrome is an autosomal recessive condition characterized by hypokalemic hypochloremic metabolic alkalosis with hypocalciuria and hypomagnesemia. The prevalence of Gitelman syndrome is estimated at approximately 1:40,000 in White populations, making it arguably the most frequent inherited tubulopathy.[20]

Pathogenesis

The similarity between the features of Gitelman syndrome and those caused by thiazide administration originally suggested that the defect might be in the DCT, which was subsequently confirmed by genetic studies that linked the condition to inactivating mutations in *SLC12A3,* the gene encoding the thiazide-sensitive transporter NCCT (see Fig. 49.1 and Table 49.1).[21] Loss of NCCT function results in Na and Cl wasting from this segment, leading to hypovolemia with secondary activation of the renin-aldosterone system. As in Bartter syndrome, the resulting increase in CT Na reabsorption is counterbalanced by K and H excretion, causing hypokalemic alkalosis.

The hypocalciuria may be caused by enhanced proximal tubular calcium reabsorption, secondary to plasma volume contraction.[22] The renal magnesium wasting is caused by downregulation of the epithelial magnesium channel TRPM6 in DCTs.

Clinical Manifestations and Diagnosis

The severity of symptoms varies widely. More severely affected patients complain of a decreased quality of life with fatigue and muscle weakness, inability to work for extended periods, salt craving, and polyuria.[23] Cardiac disturbances, muscle cramps, and tetany are only exceptionally present. Chondrocalcinosis and sclerochoroidal calcifications can occur later in life.[20] Laboratory evaluation shows hypokalemic hypochloremic metabolic alkalosis with hypocalciuria and hypomagnesemia with elevated urinary Cl, K, and Mg excretion. BP will usually be in the low-normal range. The differential diagnosis includes Bartter syndrome, especially BS3, HNF1B-related disease, and EAST syndrome, as well as acquired disorders, such as thiazide abuse and Sjögren syndrome.[20] Genotyping should be performed to confirm the diagnosis.

TABLE 49.2 Distinguishing Features of Individual Bartter and Gitelman Syndromes

	BARTTER					
Feature/Syndrome	**Type 1**	**Type 2**	**Type 3[a]**	**Type 4**	**Type 5[b]**	**Gitelman**
Antenatal manifestations (polyhydramnios)	Common	Common	Variable	Common	Always	Absent
Age at presentation	Neonate	Neonate	Variable	Neonate	Neonate	Childhood/adolescence
Polyuria, polydipsia	Marked	Marked	Rare	Common	Marked	Rare
Neonatal hyperkalemia/acidosis	Absent	Common	Absent	Absent	Absent	Absent
Spontaneous resolution	Absent	Absent	Absent	Absent	Always	Absent
Urinary calcium excretion	Elevated	Elevated	Variable	Normal	Elevated	Low
Nephrocalcinosis	Common	Common	Rare	Rare	Rare	Absent
Hypomagnesemia	Rare	Rare	Common	Common	Rare	Common
Urine prostaglandins	Elevated	Elevated	Variable	Elevated	Elevated	Normal

[a]Note the intermediate phenotype of Bartter syndrome type 3, which can present with typical features of Bartter syndrome but also phenocopy Gitelman syndrome and even switch between these two phenotypes in an individual.
[b]As Bartter syndrome type 5 spontaneously resolves typically around the estimated date of delivery, features detailed here only are present during the active disease period.

Treatment

Gitelman syndrome is primarily a salt-wasting disorder, and treatment should therefore include a liberal salt intake, if not pharmacologic supplementation. K and Mg supplements are usually given to improve muscle weakness or cramps. However, dosing may be limited by diarrhea and abdominal discomfort, and values in the normal range are typically not achieved. In exceptional cases of severe symptoms, parenteral Mg has been infused. NSAID are usually not helpful. K-sparing diuretics may improve the biochemistry but compound the salt wasting and should thus be considered carefully.

The long-term prognosis is good for cardiac and renal function, as well as for general health, although some patients do complain about markedly impaired quality of life. There is no clear association between severity of the electrolyte imbalance and symptoms, which complicates adjustment of treatment.

CONDITIONS WITH HYPOKALEMIA, METABOLIC ALKALOSIS, AND HYPERTENSION

Conditions with hypokalemia, metabolic alkalosis, and hypertension are caused by primary activation of the MR or its downstream effector, the epithelial Na-channel ENaC (see Fig. 49.1).

Liddle Syndrome

Liddle syndrome is an autosomal dominant disorder caused by gain-of-function of ENaC.[24] Consequently, the enhanced Na reabsorption through ENaC is independent of MR activation. Renin and aldosterone levels are suppressed, and there is no response to MR blockers, such as spironolactone or eplerenone. However, triamterene and amiloride, which are blockers of ENaC, correct hypertension, renal K loss, and alkalosis.[25]

Pathogenesis

Liddle syndrome is caused by variants in genes encoding the β (*SCNN1B*) or γ (*SCNN1G*) subunit of ENaC. The majority of patients carry a variant that impairs retrieval of the channel from the membrane, leading to enhanced ENaC activity.[26] The variants result in truncations of the cytoplasmic C-terminal tail of the affected subunits. CD Na reabsorption depends on the channel density present in the apical cell membrane. Channel density is regulated by removal of ENaC from the cell membrane by ubiquitination and degradation. In Liddle syndrome, the mutated ENaC protein cannot be recognized by NEDD4, a ubiquitin ligase protein; thus, the channels remain in the cell membrane for prolonged periods. This action results in enhanced sodium reabsorption, hypertension, and hypokalemic alkalosis (see Fig. 49.1).

Clinical Manifestations and Diagnosis

Liddle syndrome is a rare disorder of hypertension that typically first presents in teenage children with hypokalemic metabolic alkalosis and low blood levels of renin and aldosterone. However, clinical manifestation as early as the newborn period has been described.

This condition is easily distinguished from primary hyperaldosteronism or renal artery stenosis by the finding of low renin and aldosterone levels. Other conditions with similar phenotype include AME and GRA (Table 49.3), as well as 11β-hydroxylase (steroid 11β-monooxygenase) or 17α-hydroxylase (steroid 17α-monooxygenase) deficiency and can be separated by urinary steroid profiles and genetic testing. An activating mutation of the MR with exacerbation of hypertension in pregnancy has also been reported and should be differentiated.[27]

Treatment

Therapy consists of ENaC blockade with triamterene or amiloride, which usually normalizes the BP and K levels. Because the pathogenetic disorder is not correctable with age, lifelong therapy is required. Patients who have developed end-stage kidney disease from uncontrolled hypertension do not experience recurrence of the disease after transplantation, as the graft does not contain the genetic alteration.

Apparent Mineralocorticoid Excess

Pathogenesis

AME is an autosomal recessive condition resulting from deficiency of the type II (renal and placental) isoform of the enzyme 11β-hydroxysteroid dehydrogenase. Clinical features of AME are similar to those of Liddle syndrome, but symptoms typically present earlier (in infancy) and more severely.

Normally, aldosterone is the principal ligand for the MR and in this way increases synthesis of various proteins, chiefly Na^+,K^+-ATPase on the basolateral surface and ENaC on the apical surface. These proteins facilitate the increased Na reabsorption and K secretion in the aldosterone-sensitive distal nephron (see Fig. 49.1). Interestingly, MR

TABLE 49.3 Features of Liddle Syndrome, Apparent Mineralocorticoid Excess (AME), and Glucocorticoid-Remediable Aldosteronism (GRA)

Feature/Syndrome	Liddle	AME	GRA
Inheritance	AD	AR	AD
Age at presentation	Childhood/adolescence	Neonate/infancy	Childhood/adolescence
Plasma aldosterone	Suppressed	Suppressed	Elevated
Plasma renin activity	Suppressed	Suppressed	Suppressed
Urinary mineralocorticoid metabolites	Normal	Elevated ratios of THF + allo-THF to THE; free cortisol to cortisone	Elevated cortisol C-18 oxidation products
Response of the Hypertension to:			
Glucocorticoids	No	Yes[a]	Yes
Amiloride	Yes	Yes	Yes
Spironolactone	No	Yes	Yes

These syndromes are all characterized by hypokalemia, metabolic alkalosis, and hypertension.
Response to amiloride is representative for all blockers of the epithelium sodium channel (e.g., triamterene), and response to spironolactone is representative for all blockers of the mineralocorticoid receptor (e.g., eplerenone).
[a]Glucocorticoids are not standard treatment of AME. However, exogenous administration of a glucocorticoid that does not activate the mineralocorticoid receptor (e.g., cortisone) but that suppresses endogenous cortisol production would ameliorate the hypertension.
AD, Autosomal dominant; *AR,* autosomal recessive; *THE,* tetrahydrocortisone; *THF,* tetrahydrocortisol.

is not specific for aldosterone, but can also bind cortisol, which circulates in blood at roughly 1000-fold higher concentration than aldosterone. To provide specificity for aldosterone, the MR is protected by the activity of the 11β-hydroxysteroid dehydrogenase type 2 (HSD11B2), which is highly expressed in the distal nephron and metabolizes cortisol to cortisone, which lacks MR binding ability.

Loss-of-function mutations in HSD11B2 thus cause AME by nonspecific activation of MR by cortisol.[28] Interestingly, carbenoxolone and glycyrrhizic acid (found in licorice compounds) are potent inhibitors of this enzyme and so can cause an acquired form of AME. HSD11B2 is also expressed in the placenta, likely explaining the intrauterine growth retardation typically seen in AME patients.

Clinical Manifestations and Diagnosis

AME is characterized by early onset of severe hypertension in childhood, hypokalemia, metabolic alkalosis with suppressed plasma levels of renin and aldosterone, and increased metabolites of cortisol in the urine. A history of low birth weight and subsequent failure to thrive is typical.[29] Untreated, stroke and other complications of severe hypertension are seen even during childhood. Milder clinical manifestations can be seen with mutations that retain some functionality of the enzyme. Polyuria due to a urinary concentrating defect is another typical feature and likely linked to the electrolyte abnormalities in blood and urine, as it improves after treatment of AME.[30]

Establishing the diagnosis of AME is critical for proper treatment and should be prompted by the electrolyte profile and early-onset hypertension with suppressed renin and aldosterone levels. A urinary steroid profile is diagnostic by showing elevated urinary levels of hydrogenated metabolites of cortisol (tetrahydrocortisol plus allotetrahydrocortisol) compared with cortisone (tetrahydrocortisone). The ratio of urinary-free cortisol to cortisone is also increased. Genetic testing confirms the diagnosis.

Treatment

Treatment with blockers of MR (e.g., spironolactone or eplerenone) or its main effector ENaC (e.g., amiloride or triamterene) provides specific treatment. However, as MR blockers are competitive antagonists and in AME compete against the 1000-fold higher cortisol concentrations (compared with aldosterone), large doses are needed, and ENaC blockers (or a combination of both) are likely to be more effective.

Glucocorticoid-Remediable Aldosteronism

GRA is an autosomal dominant condition. Patients present with typical features of primary hyperaldosteronism: hypertension, suppressed plasma renin activity, and hypokalemia. Unlike primary hyperaldosteronism (due to aldosterone-producing adrenal adenoma), hypersecretion of aldosterone in GRA can be reversed by the administration of corticosteroids. Affected individuals have early-onset hypertension. There is a high prevalence of hemorrhagic stroke, largely as a result of ruptured intracranial aneurysms.

Pathogenesis

Patients with GRA have adrenocorticotropic hormone (ACTH)-sensitive aldosterone production occurring in the zona fasciculata of the adrenal gland, which is usually responsible only for cortisol synthesis. Normally, aldosterone is synthesized in the zona glomerulosa. The two isoenzymes of 11β-hydroxylase involved in the biosynthesis of aldosterone and cortisol are steroid 11β-hydroxylase (CYP11B1) and aldosterone synthase (CYP11B2), respectively. The genes for these isoenzymes are located close to each other on the long arm of chromosome 8. Unequal meiotic crossovers may produce hybrid genes by fusion of the promoter end of *CYP11B1* with the coding sequence of *CYP11B2,* so that aldosterone synthase is inappropriately regulated by ACTH.[31]

Diagnosis

Patients with GRA are often misdiagnosed with primary hypertension. Hypertensive patients with early-onset hypertension, early cerebral hemorrhage (<40 years), hypokalemia before or after diuretic therapy, and refractoriness to standard antihypertensive medication are candidates for GRA testing, especially in the presence of a family history of hypertension or early death. Similar to other genetic forms of hypertension (Liddle syndrome, AME, Gordon syndrome), plasma renin activity is suppressed. Aldosterone levels are normal to high and do not change with posture but are suppressed by dexamethasone.

A urinary steroid profile will show the biochemical hallmark of GRA in the form of increased levels of the so-called hybrid steroids (18-hydroxycortisol and 18-oxocortisol).

Genetic testing confirms the diagnosis.

Treatment

Treatment with low-dose corticosteroid is effective in GRA patients, as it suppresses ACTH and thus the aberrant ACTH-mediated aldosterone production in the zona fasciculata. Typically, 0.125 to 0.25 mg of dexamethasone or 2.5 to 5 mg of prednisolone is administered at bedtime. Therapeutic goals are normotension and normalization of biochemical markers (urinary 18-oxosteroid, serum aldosterone). MR antagonists (spironolactone, eplerenone) and ENaC antagonists such as amiloride and triamterene are also useful treatments.

Adrenal Enzymatic Disorders

Inherited deficiency of 11β- or 17α-hydroxylase, as well as specific heterozygous variants in the ion channels KCNJ5 and CACNA1H, also cause mineralocorticoid excess with hypertension and hypokalemic metabolic alkalosis. These disorders are covered in endocrinological textbooks and thus will not be discussed here in detail. Hypertension is caused by excessive mineralocorticoid production. Again, a urinary steroid profile helps establish the diagnosis, which can be confirmed by genetic testing.

CONDITIONS WITH HYPONATREMIA, HYPERKALEMIA, METABOLIC ACIDOSIS, AND NORMAL BLOOD PRESSURE

Conditions with hyponatremia, hyperkalemia, metabolic acidosis, and low-normal BP have features of mineralocorticoid deficiency either because of a synthetic defect or because of end organ resistance.

Pseudohypoaldosteronism

Pseudohypoaldosteronism (PHA) is a state of renal tubular unresponsiveness to the action of aldosterone.

Type 1 PHA exists in an autosomal dominant (adPHA1) and an autosomal recessive form (arPHA1). The adPHA1 is due to loss-of-function variants in *NR3C2* encoding the MR.[32] In contrast, arPHA1 is due to loss-of-function variants in the genes encoding the α, β, or γ subunits of ENaC.[33]

Diagnosis

PHA1 presents typically in the first few days (arPHA1) to weeks (adPHA1) of life with weight loss, hypovolemia, and poor feeding. Biochemistries will reveal the typical electrolyte profile with mild to moderate hyponatremia, often severe (arPHA1) hyperkalemia and metabolic acidosis. Urine biochemistries reveal inappropriately high Na excretion and virtually absent K secretion. Occasionally, patients with BS2 can present similarly (see "Bartter Syndrome" section). PHA1 can be distinguished from aldosterone deficiency states, such as congenital adrenal hyperplasia, by the massively elevated aldosterone levels in blood. The diagnosis can be confirmed by genetic testing. An acquired form of PHA1 can be seen with urinary tract obstruction and/or pyelonephritis.

Clinical Features

The clinical manifestations are dominated by electrolyte abnormalities and hypovolemia, which untreated can lead to circulatory shock. ENaC is also expressed in the skin and lungs, where it mediates salt reabsorption. Consequently, arPHA1 patients have increased sweat Na concentration and can develop a miliary rash from blockage of the sweat glands. In addition, patients can have cystic fibrosis–like lung disease due to viscous high-salt–containing bronchial secretions.

Treatment

The initial emergency treatment focuses on volume resuscitation with 0.9% saline. Without treatment, PHA1, especially arPHA1, can be lethal. Maintenance treatment consists of NaCl and $NaHCO_3$ supplementation adjusted to maintain euvolemia, normonatremia, and acid-base homeostasis. In arPHA1, Na-exchange resins can help stabilize patients by providing a steady source of Na and an alternative means for K excretion. Patients with adPHA1 typically improve spontaneously over the first few months of life and maintain normal plasma electrolytes without supplementation, although they typically maintain increased renin-aldosterone levels.[34]

Aldosterone Biosynthetic Defects

Patients with defects in aldosterone biosynthesis show salt wasting with hyponatremia, hyperkalemia, hypovolemia, and elevated plasma renin activity yet obviously low or absent aldosterone levels. These conditions are not detailed here.

CONDITIONS WITH HYPERKALEMIA, METABOLIC ACIDOSIS, AND HYPERTENSION

Pseudohypoaldosteronism Type 2 (Gordon Syndrome)

The clinical mirror image of Gitelman syndrome, Gordon syndrome is an autosomal dominant condition characterized by hypertension, hyperkalemia, and mild hyperchloremic metabolic acidosis.

Pathogenesis

Initially, two genes were identified as responsible for PHA2 (Table 49.1).[35] These genes encode two members of the with-no-lysine kinase family (WNK1 and WNK4), both expressed in the convoluted tubule and the CDs. WNK4 acts as a negative regulator of thiazide-sensitive NCCT function, reducing cell surface expression of NCCT. WNK4 also downregulates KCNJ1 and epithelial chloride flux. Pathogenic variants in *WNK4* are typically missense and cause loss-of-function, so that WNK4 loses its ability to suppress NCCT and KCNJ1, leading to Na and K retention. WNK1 prevents WNK4 from interacting with NCCT. Pathogenic variants in *WNK1* are typically intronic deletions that increase WNK1 expression. Subsequently, two further genes were identified variants in which cause PHA2: *CUL3* and *KLHL3*.[36] The encoded proteins form a ubiquitin-ligase complex that regulates WNK1 and WNK4 abundance. Interestingly, in addition to the autosomal dominant inheritance typical for PH2, variants in *KLHL3* can also be recessive. Moreover, pathogenic variants in *CUL3* are frequently de novo, so that the absence of a family history does not exclude the diagnosis. An acquired form of PHA2 can be seen as a side effect of calcineurin inhibitors, especially tacrolimus, which affect WNK activity.[37]

Clinical Manifestations and Diagnosis

Hyperkalemia may be present from birth, but as in GRA, hypertension may not manifest until later in life. Patients show hyperchloremic metabolic acidosis; plasma renin and aldosterone are variable, but renin activity is usually suppressed. Patients with CUL3-related disease appear to be phenotypically more seriously affected with higher plasma K levels, more pronounced acidosis and hypertension and consequently younger age at diagnosis.[36] In addition, most patients with CUL3 disease have failure to thrive and growth impairment.

Treatment

As specific inhibitors of NCCT, thiazides are able to completely correct the clinical and biochemical features of PHA2, except for the extrarenal manifestations in CUL3-related disease. Establishing the diagnosis is thus critical for targeted and effective treatment.

Congenital Nephrogenic Diabetes Insipidus

Congenital NDI is a rare polyuric disorder characterized by the failure to concentrate urine despite elevated levels of vasopressin. Congenital NDI is caused by mutations in key proteins controlling water reabsorption in the CD. Acquired diabetes insipidus (DI) is much more common, and its diagnosis and management are discussed in Chapter 9.

Pathogenesis

More than 90% of patients have X-linked recessive NDI with pathogenic variants in *AVPR2,* the gene for the arginine-vasopressin type 2 receptor (AVPR2). Consequently, the majority of patients are male, although female carriers can have a urinary concentrating defect of variable severity, presumably due to nonrandom X inactivation.[38] AVPR2 is expressed predominantly in the kidney, where it mediates urinary concentration, but to some degree also in the vasculature, where it mediates vasodilation and release of von Willebrand factor.[39] Well over 250 pathogenic variants have been reported so far.[38] In fewer than 10% of the families, congenital NDI has an autosomal recessive inheritance with pathogenic variants in *AQP2,* the gene encoding the water channel AQP2, which constitutes the final effector protein in the vasopressin-initiated signaling cascade. A rare autosomal dominant form of NDI, due to dominant negative variants in *AQP2,* has also been reported. Some inherited diseases, such as Bartter syndrome and AME, can also be associated with so-called secondary inherited NDI.[16] The etiology of the AQP2 deficiency in these disorders is unclear but likely related to the blood and/or urinary electrolyte abnormalities, as both hypokalemia and hypercalciuria have been associated with decreased AQP2 expression.

Clinical Features

Manifestations of congenital NDI typically appear within the first weeks to months of life. NDI does not cause polyhydramnios, as the osmotic load is cleared by the placenta. Clinical features at presentation are typically polyuria and failure to thrive, as well as a history of vigorous sucking followed by vomiting.[38] Unrecognized and untreated, the baby can experience hypernatremic dehydration, with delayed development and mental impairment as possible consequences. Cranial computed tomography may occasionally show dystrophic calcification in the basal ganglia and the cerebral cortex in such untreated patients.

Attention-deficit/hyperactivity disorder and impaired school performance are commonly reported and may be secondary to preoccupation with drinking and voiding. An adult patient usually drinks and voids about 10 to 12 L per day. Urinary tract dilation can be seen, especially if there are voiding abnormalities.

Some variants in either *AVPR2* or *AQP2* may retain partial functionality of the protein, leading to a phenotype of partial NDI, where urinary concentration is possible but subnormal. Clinical symptoms are consequently milder, and the disease may remain undiagnosed throughout life.[40]

Diagnosis

The initial diagnosis of DI rests on the combination of an inappropriately dilute urine in the context of hypernatremic dehydration. Thus, simple blood and urine chemistries easily establish the diagnosis, yet it is often delayed. When these infants present with a history of vomiting, physicians may be mistakenly reassured by the large urine output, considered as inconsistent with severe dehydration rather than recognizing it as a warning sign in the context of clinical dehydration. Once the diagnosis of DI has been established, the nephrogenic form can then be proven by the absence of a response in urinary concentration after administration of desamino-8-D-arginine vasopressin (DDAVP), a vasopressin analog with high specificity for AVPR2. DDAVP can be administered orally, nasally, or by intramuscular or intravenous injection. The most critical complication of the DDAVP test is the development of acute hyponatremia in those patients who respond to the drug yet keep on drinking. The risk for this is low, as most patients will simply stop drinking with normalization of serum osmolality, but patients with habitual polydipsia and infants hungry for milk are at risk. Careful observation with a limit in the volume of fluid intake equal to the volume of urine produced during the test is key to avoidance of this complication. Intravenous injection has the advantage of the shortest observation period (2 hours) combined with certainty of administration (which is variable via the oral or nasal route) and the ability to distinguish between X-linked and autosomal NDI. As patients with autosomal NDI still express AVPR2, they will show the vascular effects in the form of a small drop in BP, an increase in heart rate, and release of von Willebrand factor, whereas these changes are absent in patients with AVPR2 mutations. Serum levels of DDAVP with other modes of administration are not sufficient to appreciate these changes. A well-established protocol uses 0.3 μg/kg DDAVP intravenously, the same dose as used by hematologists in mild forms of hemophilia or von Willebrand disease.[39] A normal renal response to DDAVP is an increase in urine osmolality to greater than 800 mOsm/kg, whereas patients with NDI show no response and urine osmolality remains less than 200 mOsm/kg. An intermediate response may represent partial NDI or simply a washout of the medullary concentration gradient. The latter can be confirmed by achieving a urine osmolality of greater than 800 mOsm/kg after repeated administration of DDAVP. As normal urinary concentrating ability only develops during the first year of life, an intermediate response may be normal in infants.

Differential Diagnosis

Patients with central DI or habitual polydipsia can be distinguished by a normal response to DDAVP. Patients with secondary inherited NDI typically have other electrolyte abnormalities, such as hypokalemia and hypercalciuria, in addition to other features typical for the primary diagnosis, such as polyhydramnios in Bartter syndrome and hypertension in AME. Onset of polyuria later in childhood or adulthood argues for acquired forms of NDI. Patients with partial NDI represent a diagnostic challenge. Further blood tests and a renal ultrasound can help exclude underlying structural or parenchymal renal disease, such as nephronophthisis or tubulointerstitial or cystic kidney disease. Genetic testing can help confirm the diagnosis.

Treatment

Management of NDI concentrates on reduction of polyuria, avoidance of episodes of dehydration, and provision of sufficient calories to allow normal physical growth and development. A key factor in the determination of overall urine output is the osmotic load, which mainly derives from protein and salt intake. The higher the osmotic load, the more water is required to excrete it. Involvement of the dietician thus is key, especially in infancy, to minimize osmotic load, yet ensuring that protein and caloric intake meets the recommended daily intake.

A goal of 15 mOsm/kg is typically achievable; consequently, a patient with an average urine osmolality of 100 mOsm/kg would need 150 mL/kg/day to excrete this load.

Thiazide diuretics, such as hydrochlorothiazide (1–2 mg/kg/12 h), when combined with reduction of salt intake, are effective in reducing urine output. Thiazides inhibit salt reabsorption in DCTs, which leads to mild volume depletion. Hypovolemia stimulates fluid reabsorption in PTs, thereby diminishing water delivery to CDs. Combination therapy with amiloride (0.1–0.2 mg/kg every 8–12 hours) helps control the potential hypokalemia from thiazide treatment and may enhance the antipolyuric effect.

Prostaglandin synthase inhibitors are typically the most effective drugs in reducing urine volume, at least during infancy, probably by enhancing proximal sodium reabsorption. Indomethacin (1–2 mg/kg/day) is used most often but may reduce glomerular filtration rate and cause gastrointestinal side effects. Selective COX2 inhibitors, such as celecoxib, thus may be preferable, but their efficacy in NDI is so far anecdotal.

Nephrogenic Syndrome of Inappropriate Antidiuresis

NSIAD represents the mirror image of NDI and is the inherited equivalent to the syndrome of inappropriate antidiuresis (SIADH).

Pathogenesis

NSIAD is due to gain-of-function variants in *AVPR2,* leading to constitutive activation of the urinary concentrating mechanism in the CD, irrespective of serum osmolality.[41] The inheritance is X-linked dominant, although males are typically more severely affected.[42] Specific variants in genome-wide association studies, encoding the stimulatory G-protein alpha subunit, have also been associated with NSIAD and are not always associated with additional endocrine abnormalities.[43,44]

Clinical Features, Diagnosis, and Treatment

NSIAD is characterized by an inappropriately concentrated urine (>100 mOsm/kg) in the context of hyponatremia and hypoosmolality. In contrast to SIADH, vasopressin levels are adequately suppressed. Genetic testing will confirm the diagnosis. Severely affected patients (typically males) may have recurrent episodes of severe symptomatic hyponatremia, whereas others may have no apparent symptoms. Avoidance of fluid intake, mediated by low serum osmolality, constitutes simple and intuitive treatment and may explain the absence of symptoms in some patients.[42] Fluid restriction is difficult in infancy, as fluid and caloric intake is coupled. Increasing the osmotic load (e.g., by urea supplementation) may help symptomatic patients. AVPR2 antagonists (aquaretics) are typically not helpful, as there is no vasopressin excess.

SELF-ASSESSMENT QUESTIONS

1. Which of the following conditions is characteristically associated with hypocalciuria?
   - **A.** Bartter syndrome
   - **B.** Liddle syndrome
   - **C.** Gitelman syndrome
   - **D.** Gordon syndrome
2. The treatment of Bartter syndrome may include which of the following?
   - **A.** Amiloride
   - **B.** Prostaglandin synthesis inhibitors
   - **C.** KCl supplementation
   - **D.** NaCl supplementation
3. Hypokalemic, hypochloremic metabolic alkalosis is a sign of:
   - **A.** aldosterone deficiency.
   - **B.** enhanced Na transport through the epithelial sodium channel in the collecting duct.
   - **C.** pseudohypoaldosteronism type 1.
   - **D.** pseudohypoaldosteronism type 2.
4. Which of the following is the best suited maintenance fluid solution in patients with nephrogenic diabetes insipidus needing intravenous fluids?
   - **A.** 0.9% saline
   - **B.** Hartman solution
   - **C.** 5% dextrose in water
   - **D.** 0.45% saline

Fanconi Syndrome and Other Proximal Tubule Disorders

Annabelle N. Chua, Reeti Kumar, John W. Foreman

The proximal tubule reabsorbs the majority of several key solutes, including glucose, amino acids, bicarbonate, and phosphate. This chapter describes a number of disorders, mainly heritable, that affect proximal tubule reabsorption. Chapters 11 and 13 discuss familial forms of hyperphosphaturia and renal tubular acidosis (RTA), respectively.

Most nonelectrolyte solutes are reabsorbed in the proximal tubule through specific transport proteins that cotransport them in conjunction with sodium (Fig. 50.1). The driving force for this solute transport is the electrochemical gradient for sodium entry maintained by the enzyme Na^+,K^+-ATPase. Most disorders of isolated solute reabsorption are related to defects in specific transport proteins, whereas disorders affecting multiple solutes, such as Fanconi syndrome, are probably secondary to defects in energy generation, Na^+,K^+-ATPase activity, or dysfunction of cellular organelles involved with membrane protein recycling.

FANCONI SYNDROME

Definition

In the 1930s, de Toni, Debré, and coworkers and Fanconi independently described several children with the combination of renal rickets, glycosuria, and hypophosphatemia. Fanconi syndrome now refers to global dysfunction of the proximal tubule leading to excessive urinary excretion of amino acids, glucose, phosphate, bicarbonate, uric acid, and other solutes handled by this nephron segment. These losses lead to the clinical problems of acidosis, dehydration, electrolyte imbalance, rickets, osteomalacia, and growth failure. Numerous inherited or acquired disorders are associated with Fanconi syndrome (Box 50.1).

Etiology and Pathogenesis

The sequence of events leading to Fanconi syndrome is incompletely defined and probably varies with each cause. Possible mechanisms include widespread abnormality of most or all of the proximal tubule carriers, such as a defect in sodium binding to the carrier or insertion of the carrier into the brush border membrane, "leaky" brush border membrane or tight junction, inhibited or abnormal Na^+,K^+-ATPase pump, or impaired mitochondrial energy generation (see Fig. 50.1). An abnormality in energy generation has been implicated in multiple disorders, including hereditary fructose intolerance, galactosemia, mitochondrial cytopathies, and heavy metal poisoning, as well as in several experimental models of Fanconi syndrome. Abnormal subcellular organelle function, such as the lysosome in cystinosis or the megalin-cubilin endocytic pathway in Dent disease, is also a cause of Fanconi syndrome (Fig. 50.2).

In adults, the most common causes of persistent Fanconi syndrome are an endogenous or exogenous toxin such as a heavy metal, a medication, or dysproteinemia. In children, the most common persistent cause is an inborn error of metabolism, such as cystinosis. Specific causes of Fanconi syndrome are discussed after a general description of the clinical manifestations and treatment of the syndrome.

Clinical Manifestations

Fanconi syndrome gives rise to a number of clinical abnormalities (Box 50.2).

Aminoaciduria

Aminoaciduria is a cardinal feature of Fanconi syndrome. Virtually every amino acid is found in excess in the urine, thus the term *generalized aminoaciduria.* However, there are no clinical consequences because the losses are trivial (0.5–1 g/day) in relation to dietary intake.

Glycosuria

Glycosuria in the absence of hyperglycemia is another of the cardinal features of Fanconi syndrome and results from impaired tubular reabsorption of glucose. It is often one of the first diagnostic clues (Fig. 50.3). As with aminoaciduria, glycosuria rarely causes symptoms such as weight loss or hypoglycemia.

Hypophosphatemia

Hypophosphatemia from impaired phosphate reabsorption is common in Fanconi syndrome. Tubular phosphate handling can be assessed by measuring the tubular reabsorption of phosphate (TRP), which is normally greater than 80%, by the following equation:

$$TRP = 1 - (U_p \times P_c / U_c \times P_p) \times 100\%$$

where U_p, P_p, U_c, and P_c are the urinary and serum phosphate and creatinine concentrations, respectively. Subtle changes in phosphate reabsorption can be assessed by measuring the maximum phosphate reabsorption in relation to the glomerular filtration rate (TmP/GFR) on fasting urine and blood samples, as shown in Fig. 11.15. Elevated parathyroid hormone (PTH) and low vitamin D levels also may play a role in the phosphaturia of Fanconi syndrome, although these hormonal abnormalities are not always present. A few patients have impaired conversion of 25-hydroxyvitamin D to 1,25-hydroxyvitamin D; metabolic acidosis, another feature of Fanconi syndrome, also may impair this conversion. Another mechanism for the hypophosphatemia is impairment of the megalin-dependent reabsorption and degradation of filtered PTH.[1] Unabsorbed PTH then binds to receptors in more distal portions of the proximal tubule, leading to increased endocytosis of apical phosphate transporters and increased phosphaturia. The hypophosphatemia, especially if accompanied by

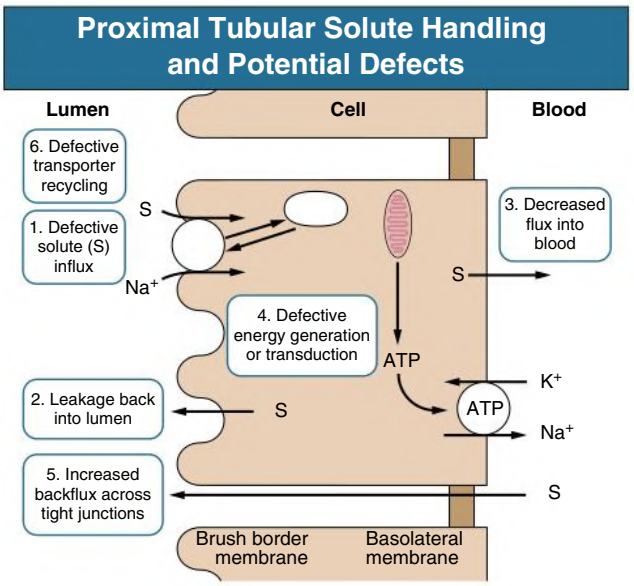

Fig. 50.1 Defects and Potential Defects in Proximal Tubular Solute Handling. Solute uptake by the brush border membrane from the lumen is coupled to Na^+ influx. The favorable electrochemical driving force for luminal Na^+ is maintained by the Na^+,K^+-ATPase pump. Transported solute is then either used by the cell or returned to the blood across the basolateral membrane. Fanconi syndrome could arise because of a defect in one of six areas as shown. *ATP,* Adenosine triphosphate.

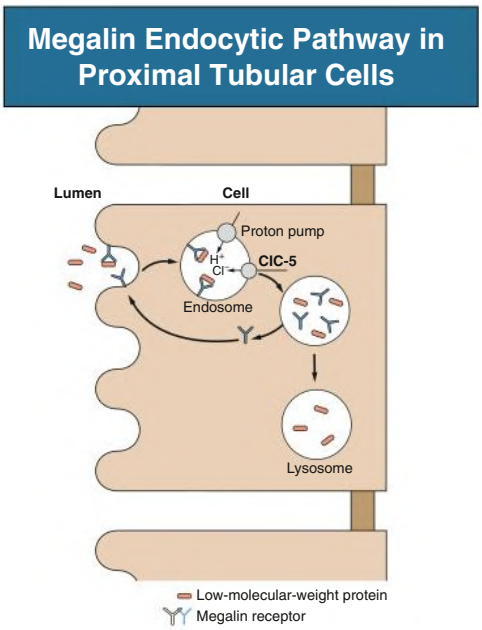

Fig. 50.2 Megalin-Cubilin Endocytic Pathway in Proximal Tubular Cells. Low-molecular-weight proteins in the luminal fluid bind to the megalin-cubilin complex and are endocytosed. The recycling of megalin and further catabolism of these proteins depend on acidification of the vesicle by a proton pump. The CIC-5 chloride channel provides an electrical shunt for efficient functioning of the proton pump. This endocytosis pathway plays a role in membrane transporter recycling, and disruption of this pathway interferes with absorption of other luminal solutes.

BOX 50.1 Causes of Fanconi Syndrome

Inherited

- Cystinosis
- Galactosemia
- Hereditary fructose intolerance
- Tyrosinemia
- Wilson disease
- Lowe syndrome
- Dent disease
- Glycogenosis
- Mitochondrial cytopathies
- Idiopathic

Acquired[a]

- Drugs: *cisplatin, ifosfamide, tenofovir, cidofovir, adefovir,* didanosine, gentamicin, azathioprine, valproic acid (sodium valproate), suramin, streptozocin (streptozotocin), ranitidine
- Dysproteinemias: multiple myeloma, Sjögren syndrome, light-chain proteinuria, amyloidosis
- Heavy metal poisoning: lead, cadmium
- Other poisonings: Chinese herbal medicine, glue sniffing
- Other: nephrotic syndrome, kidney transplantation, acute tubular necrosis

[a]Italics indicate more common causes.

BOX 50.2 Features of Fanconi Syndrome

Metabolic Abnormalities

- Glycosuria
- Hyperaminoaciduria
- Hypophosphatemia
- Acidosis
- Hypokalemia
- Hypouricemia
- Hypocarnitinemia

Clinical Features

- Rickets, osteomalacia
- Growth retardation
- Polyuria
- Dehydration
- Proteinuria

hyperparathyroidism and low 1,25-hydroxyvitamin D levels, often leads to significant bone disease, manifesting with pain, fractures, rickets, or growth failure.

Natriuresis and Kaliuresis

Natriuresis and kaliuresis are common in Fanconi syndrome and can give rise to significant and even life-threatening problems. The decreased proximal reabsorption of sodium leads to increased potassium excretion secondary to increased distal delivery of sodium and activation of the renin-aldosterone system from hypovolemia. In some cases, sodium and potassium losses are so great that hypokalemia and metabolic alkalosis result, simulating Bartter syndrome despite the lowered bicarbonate threshold.

Hyperchloremic Metabolic Acidosis

Hyperchloremic metabolic acidosis, another feature of Fanconi syndrome, is a result of impaired bicarbonate reabsorption by the proximal tubule (proximal or type 2 RTA; see Chapter 13). This impaired reabsorption can lead to the loss of more than 30% of the normal filtered load of bicarbonate. As the serum bicarbonate concentration ($[HCO_3^-]$) falls, the filtered load falls, and excretion drops such that the serum $[HCO_3^-]$ usually remains between 12 and 18 mmol/L. On occasion, there is an associated defect in distal acidification, usually

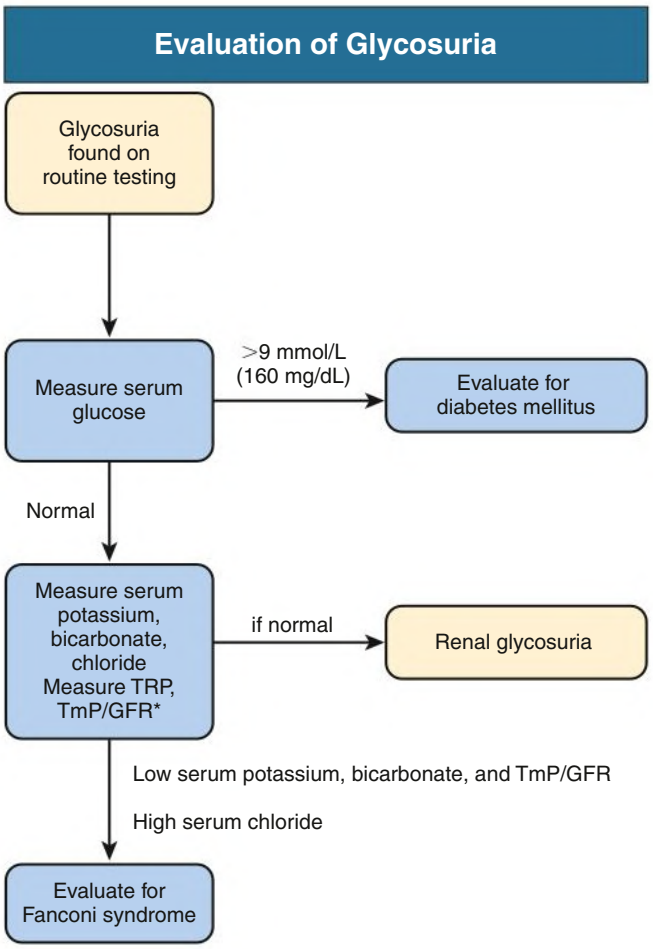

Fig. 50.3 Evaluation of Glycosuria. *GFR,* Glomerular filtration rate; *TmP,* tubular maximum reabsorptive capacity for phosphate; *TRP,* tubular reabsorption of phosphate.

in association with long-standing hypokalemia or nephrocalcinosis. Ammoniagenesis is usually normal or increased because of the hypokalemia and acidosis unless there is an associated impairment in glomerular filtration rate (GFR).

Polyuria and Polydipsia

Polyuria, polydipsia, and frequent bouts of severe dehydration are common symptoms in young patients with Fanconi syndrome. The polyuria is mainly related to the osmotic diuresis from the excessive urinary solute losses; but some patients have an associated concentrating defect, especially those with prolonged hypokalemia.

Growth Retardation

Growth retardation in children with Fanconi syndrome is multifactorial. Hypophosphatemia, disordered vitamin D metabolism, and acidosis contribute to growth failure, as do chronic hypokalemia and extracellular volume contraction. Glycosuria and aminoaciduria probably do not play a role. However, even with correction of all these metabolic abnormalities, most patients fail to grow, especially those with cystinosis.

Hypouricemia

Hypouricemia, caused by impairment in the kidney's handling of uric acid, is often present in Fanconi syndrome, especially in adults. Urolithiasis from the uricosuria only rarely has been reported, probably because the urine flow and pH are increased, inhibiting uric acid crystallization.

Proteinuria

Proteinuria is usually minimal, except when Fanconi syndrome develops in association with the nephrotic syndrome. Typically, only low-molecular-weight proteins (<30,000 Da) are excreted, such as vitamin D and A binding proteins, enzymes, immunoglobulin light chains, and hormones. Therefore, significant albuminuria is often absent and urine dipstick may be negative for protein.

Treatment of Fanconi Syndrome

Therapy should be directed at the underlying causes of Fanconi syndrome when possible (see later discussion). This includes avoidance of the offending nutrient in galactosemia, hereditary fructose intolerance, or tyrosinemia; penicillamine or other copper chelators for Wilson disease; or chelation therapy for heavy metal intoxication. In these patients, resolution of Fanconi syndrome usually is complete.

In all patients with Fanconi syndrome, therapy is also directed at the biochemical abnormalities secondary to the solute losses and the bone disease often present in these patients. The proximal RTA (type 2 RTA) usually requires large doses of alkali for correction. Some patients benefit from hydrochlorothiazide to minimize the volume expansion associated with these large doses of alkali. Potassium supplementation usually is also needed, especially if there is significant RTA. If given in combination with a metabolizable anion, such as potassium citrate, lactate, or acetate, these supplements will also correct the acidosis. A few patients will require sodium supplementation along with potassium, and even fewer will require sodium chloride supplementation (especially those who have alkalosis as a result of volume contraction from large urinary NaCl losses). Magnesium supplementation may be required to correct the hypokalemia, and adequate fluid intake is essential. Correction of hypokalemia and its effect on the concentrating ability of the distal tubule may lessen the polyuria.

Bone disease is multifactorial, including urinary loss of vitamin D binding protein and vitamin D, decreased synthesis of calcitriol in some patients, hypercalciuria, chronic acidosis, and hypophosphatemia, which is the major factor. Hypophosphatemia should be treated with 1 to 3 g/day of oral phosphate with the goal of normalizing serum phosphate levels. Many patients with Fanconi syndrome will require supplemental vitamin D for adequate treatment of the rickets and osteomalacia. It is unclear whether standard vitamin D (calciferol [ergocalciferol]) or a vitamin D metabolite is better for supplementation, but most clinicians use a vitamin D metabolite, such as 1,25-dihydroxycholecalciferol (calcitriol). These metabolites obviate the concern of inadequate vitamin D hydroxylation by the proximal tubule mitochondria and reduce the risk for prolonged hypercalcemia because of their shorter half-life. Vitamin D therapy will also improve the hypophosphatemia and lessen the risk for hyperparathyroidism. Supplemental calcium is indicated in those with hypocalcemia after supplemental vitamin D is started. Hyperaminoaciduria, glycosuria, proteinuria, and hyperuricosuria usually do not require specific treatment. Carnitine supplementation, to compensate for the urinary losses, may improve muscle function and lipid profiles, but the evidence is inconsistent.

INHERITED CAUSES OF FANCONI SYNDROME

Cystinosis

Definition

Cystinosis, or cystine storage disease, is characterized biochemically by excessive intracellular storage, particularly in lysosomes, of the amino acid cystine.[2] Three different types of cystinosis can be distinguished based on clinical course, age at onset, and intracellular cystine content. Benign or adult cystinosis is associated with cystine crystals in

the cornea and bone marrow only, as well as the mildest elevation in intracellular cystine levels; no kidney disease occurs. Infantile or nephropathic cystinosis is the most common form of cystinosis and is associated with the highest intracellular levels of cystine and the earliest onset of kidney disease. In the intermediate or adolescent form, intracellular cystine levels are between those of the infantile and adult forms, with later onset of kidney disease.

Etiology and Pathogenesis

Nephropathic cystinosis is transmitted as an autosomal recessive trait localized to the short arm of chromosome 17, with an estimated incidence of 1 in 200,000 live births. The *CTNS* gene codes for a lysosomal membrane protein, cystinosin, that mediates the transport of cystine from the lysosome.[3] The benign and intermediate forms of cystinosis are also associated with *CTNS* mutations but still have some functional transport protein, leading to lower intracellular cystine levels and slower onset of kidney disease in the intermediate form and no kidney disease in the benign form. Cystinosin has been shown to play a role in other cellular processes besides lysosomal cystine transport, which may explain why Fanconi syndrome sometimes persists despite cystine depletion.[4]

Clinical Manifestations

The first clinical evidence of nephropathic cystinosis relates to Fanconi syndrome and usually appears in the second half of the first year of life. Subtle abnormalities of tubular function can be demonstrated earlier in families with index cases, but there always is a delay between birth and the first symptoms. Rickets is common after the first year of life, along with growth failure. The growth failure occurs before the GFR declines and despite correction of electrolyte and mineral deficiencies. The GFR invariably declines, and end-stage kidney disease (ESKD) occurs by late childhood.

Nephrocalcinosis is relatively common, and a few patients have kidney stones. Photophobia is another common symptom that occurs by 3 years of age and is progressive. Older patients with cystinosis may develop visual impairment and blindness. Children with cystinosis usually have a fair complexion and blond hair, but dark hair has been observed in some. Cystinosis has been observed in other ethnic groups but is less common than in Whites.

The diagnosis is based on the demonstration of elevated intracellular levels of cystine, usually in white blood cells or skin fibroblasts. Patients with nephropathic and intermediate cystinosis have intracellular cystine levels that exceed 2 nmol half-cystine per milligram of protein (normal <0.2 nmol half-cystine per milligram of protein). Heterozygotes for cystinosis have levels that range from 0.2 to 1 nmol half-cystine per milligram of protein. A slit-lamp demonstration of corneal crystals strongly suggests the diagnosis[2] (Fig. 50.4). A prenatal diagnosis can be made with amniocytes or chorionic villi.

Common late complications of cystinosis include hypothyroidism, splenomegaly and hepatomegaly, decreased visual acuity, swallowing difficulties, pulmonary insufficiency, and corneal ulcerations.[5] Less frequently, older patients have insulin-dependent diabetes mellitus, myopathy, and progressive neurologic disorders. Decreased brain cortex also has been noted on imaging in some patients. Older patients may develop vascular calcification, especially of the coronary arteries, which can lead to myocardial ischemia.

Kidney Pathology

The morphologic features of the kidney in cystinosis vary with the stage. Early in the disease, cystine crystals are present in tubular epithelial cells, interstitial cells, and rarely glomerular epithelial cells[6,7] (Fig. 50.5A). A swan-neck deformity or thinning of the first part of the proximal tubule is an early finding but is not unique to cystinosis. Later, there is pronounced tubular atrophy, interstitial fibrosis, and abundant crystal deposition with giant cell formation of the glomerular visceral epithelium, segmental sclerosis, and eventual glomerular obsolescence. Electron microscopy (EM) demonstrates intracellular crystalline inclusions consistent with cystine (see Fig. 50.5B). Peculiar "dark cells," unique to the cystinotic kidney, also have been observed. These are mostly macrophages and some podocytes and are probably dark because of a reaction of cystine with osmium tetroxide.

Fig. 50.4 Corneal Opacities in Cystinosis. Tinsel-like refractile opacities in the cornea of a patient with cystinosis under slit-lamp examination. (From Foreman JW. Cystinosis and the Fanconi syndrome. In: Avner ED, Harmon WE, Niaudet P, eds. *Pediatric Nephrology*. 5th ed. Lippincott Williams & Wilkins; 2004.)

Treatment

Nonspecific therapy for infantile cystinosis consists of vitamin D therapy and replacement of the urinary electrolyte losses, followed, in due course, by the management of the progressive kidney disease (Table 50.1). Cysteamine therapy can lower tissue cystine levels and slow the decline in GFR, especially in children with normal serum creatinine concentration who are treated before 2 years of age[8] (Fig. 50.6). Cysteamine therapy also improves linear growth but not Fanconi syndrome. The most common problems associated with cysteamine therapy are nausea, vomiting, and a foul odor and taste. Treatment should begin with a low dose of cysteamine soon after the diagnosis is made, increased during 4 to 6 weeks to 60 to 90 mg/kg/day in four divided doses as close to every 6 hours as possible. Slowly increasing the dose minimizes the risk for neutropenia, rash, and arthritis. Leukocyte cystine levels should be checked every 3 to 4 months to monitor effectiveness and compliance, with the goal of achieving and maintaining a cystine level less than 2.0 and preferably 1.0 nmol half-cystine/mg protein. A long-acting formulation of cysteamine is available that allows twice-daily dosing. This formulation is equally effective and may aid compliance, but is significantly more expensive than the standard formulation of cysteamine. Two preparations of topical cysteamine for treatment of the corneal crystals are available: an aqueous solution that is given every hour and a gel formulation that is applied four times a day. Studies are underway to assess the utility of a gene-edited autologous bone marrow transplant in treating cystinosis.

Treatment of ESKD in these children poses no greater problems than in other children. Successful kidney transplantation reverses the kidney failure and Fanconi syndrome but does not appear to improve the extrarenal manifestations of cystinosis. Cysteamine therapy should be continued after transplantation. Cystine does not accumulate in the transplanted kidney, except in infiltrating immunocytes.

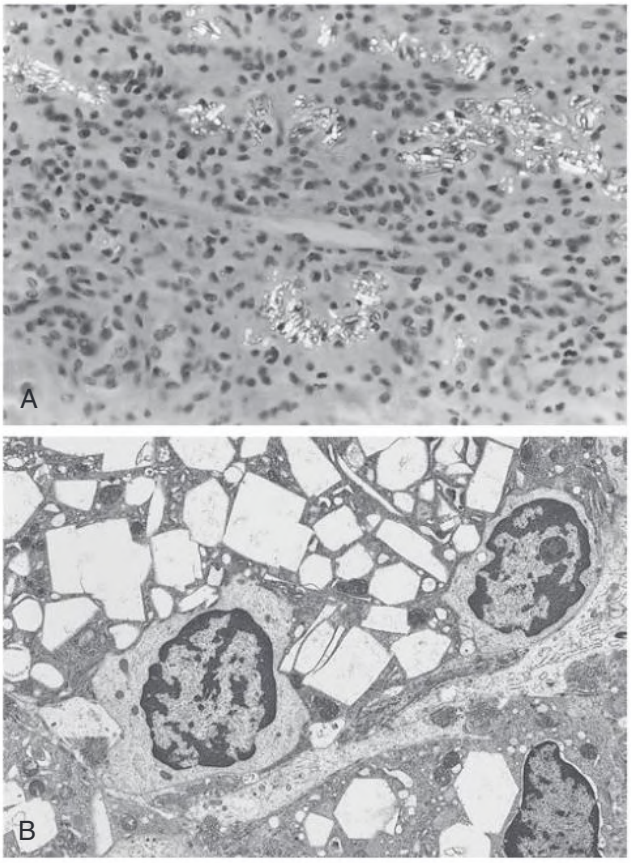

Fig. 50.5 Cystine Crystals in the Kidney in Cystinosis. (A) Crystals are seen in photomicrograph of alcohol-fixed nephrectomy specimen, taken through incompletely crossed polarizing filters. Birefringent crystals are evident in tubular epithelial cells and free in the interstitium. (B) Electron micrograph of a renal biopsy specimen shows hexagonal, rectangular, and needle-shaped crystals in macrophages within the interstitium. (Original magnification ×3000.) (A, From Schnaper HW, Cottel J, Merrill S, et al. Early occurrence of end-stage renal disease in a patient with infantile nephropathic cystinosis. *J Pediatr.* 1992;120:575–578. B, From Van't Hoff WG, Ledermann SE, Waldron M, Trompter RS. Early-onset chronic renal failure as a presentation of infantile cystinosis. *Pediatr Nephrol.* 1995;9:483–484.)

Galactosemia

Etiology and Pathogenesis

Galactosemia is an autosomal recessive disorder of galactose metabolism. It is most often the result of deficient activity of the enzyme galactose-1-phosphate uridyltransferase, the incidence of which is 1 in 62,000 live births.[9] Deficiency of this enzyme leads to the intracellular accumulation of galactose-1-phosphate, with damage to the liver, proximal renal tubule, ovary, brain, and lens. A less frequent cause of galactosemia is a deficiency of galactose kinase, which forms galactose-1-phosphate from galactose. Cataracts are the only manifestation of this form of galactosemia.

The pathogenesis of the symptoms of galactosemia is not clear. Accumulation of galactose-1-phosphate subsequent to the ingestion of galactose can inhibit pathways for carbohydrate metabolism, and its level correlates somewhat with clinical symptoms. Defective galactosylation of proteins also has been postulated. Formation of galactitol from galactose by aldose reductase is probably responsible for the cataract formation.

TABLE 50.1 Treatment of Cystinosis

Problem	Therapy
Removal of lysosomal cystine	Cysteamine, 0.325 g/m^2 q6h Delayed-release cysteamine, 0.65 g/m^2 q12h Goal: Maintain leukocyte cystine level <1 nmol half-cystine[a]/mg protein
Correction of Tubulopathy	
Dehydration	2–6 L/day fluid
Acidosis	2–15 mmol/kg/day K^+ citrate
Hypophosphatemia	1–4 g/day K^+ phosphate
Rickets	0.25–1 μg/day calcitriol
Adjunct therapies	NaCl, carnitine, indomethacin, hydrochlorothiazide
Later Therapies	
Growth failure	Growth hormone
Hypothyroidism	Thyroxine
Kidney failure	Renal replacement therapy, ideally kidney transplantation

[a]By convention, units are half-cystine because the cystine originally was converted to two cysteine molecules, or "broken in half," before measurement.

Clinical Manifestations

Affected infants ingesting milk containing lactose (the most common source of galactose in the diet) rapidly develop vomiting, diarrhea, and failure to thrive. Jaundice from unconjugated hyperbilirubinemia is common, along with severe hemolysis. Continued intake of galactose leads to hepatomegaly and cirrhosis. Cataracts appear within days after birth, although at first they often are detectable only with a slit lamp. Cognitive dysfunction or developmental delay may develop within a few months. Fulminant *Escherichia coli* sepsis has been described, possibly a consequence of inhibited leukocyte bactericidal activity.

In addition to these clinical findings, galactose intake leads within days to hyperaminoaciduria and albuminuria. Increased urine sugar excretion is principally due to galactosuria and not glycosuria. There seems to be little or no impairment in glucose handling by the proximal tubule. Galactosemia should be suspected whenever there is a urinary reducing substance that does not react in a glucose oxidase test. The diagnosis can be confirmed by demonstration of deficient transferase activity in red blood cells, fibroblasts, leukocytes, or hepatocytes. Most infants with galactosemia are found through newborn metabolic screening.

Treatment

Galactosemia is treated by elimination of galactose from the diet. Acute symptoms and signs resolve in a few days. Cataracts will also regress to some extent. Even with early elimination of galactose, developmental delay, speech impairment, ovarian dysfunction, and growth retardation are common. Profound intellectual deficits are rare even in infants treated late.

Hereditary Fructose Intolerance

Etiology and Pathogenesis

Hereditary fructose intolerance is another disorder of carbohydrate metabolism associated with Fanconi syndrome.[10] Fructose intolerance is inherited as an autosomal recessive trait, with an estimated incidence of 1 in 20,000 live births. It is caused by a deficiency of the B isoform of the enzyme fructose-1-phosphate aldolase, which cleaves

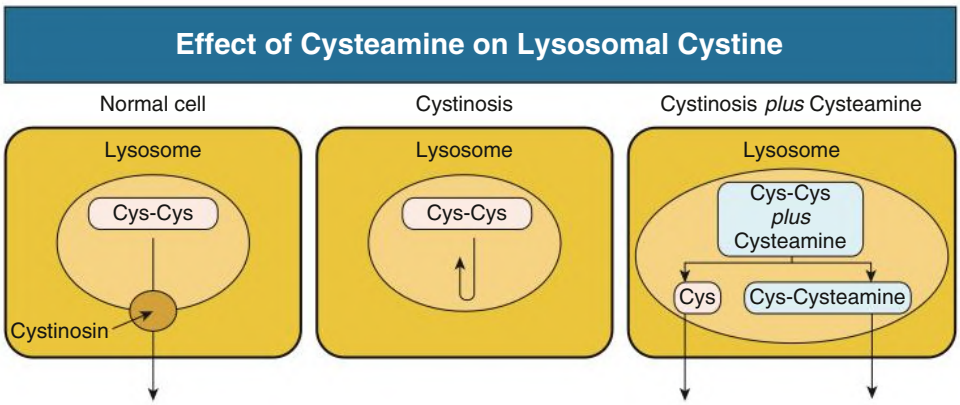

Fig. 50.6 Effect of Cysteamine on Lysosomal Cystine. In cystinosis, the transporter (cystinosin) for cystine (Cys-Cys) egress from the lysosome is defective, and cysteine accumulates. Cysteamine can easily enter the lysosome and combine with cystine, forming cysteine (Cys) and the mixed disulfide cysteamine-cysteine. Both these compounds can exit the lysosome through a transporter other than the cystine carrier.

fructose-1-phosphate into D-glyceraldehyde and dihydroxyacetone phosphate. Deficient activity of aldolase B leads to tissue accumulation of fructose-1-phosphate and reduced levels of adenosine triphosphate (ATP). Experimentally, mice with aldolase B deficiency can be rescued by blocking fructokinase, which prevents the accumulation of fructose-1-phosphate and maintains ATP.

Clinical Manifestations

Symptoms of hereditary fructose intolerance appear at weaning when fruit, vegetables, and sweetened cereals that contain fructose, sucrose, or sorbitol (the latter is converted to fructose in the body) are introduced. Affected children experience nausea, vomiting, and symptoms of hypoglycemia shortly after ingestion of fructose, sucrose, or sorbitol. These symptoms may progress to seizures, coma, and even death, depending on the amount consumed. When they are exposed to fructose, infants may have a catastrophic illness, with severe dehydration, shock, acute liver impairment, bleeding, and acute kidney injury (AKI). Concomitant serum biochemical findings after fructose ingestion are decreased glucose, phosphate, and bicarbonate and increased uric acid and lactic acid. Chronic exposure to fructose leads to failure to thrive, hepatomegaly and fatty liver, jaundice, hepatic cirrhosis, Fanconi syndrome, and nephrocalcinosis. Children with hereditary fructose intolerance quickly develop an aversion to sweets.

Diagnosis

The diagnosis should be suspected when symptoms develop after the ingestion of fructose. This can be confirmed by assaying the activity of fructose-1-phosphate aldolase in a liver biopsy specimen or through genetic testing of the aldolase B gene.

Treatment

Treatment of hereditary fructose intolerance involves strict avoidance of foods containing fructose and sucrose, but because most patients develop a strong aversion to such foods, this is usually easy. The greatest risk occurs during infancy, before those affected learn to avoid fructose.

Glycogenosis

Most patients with glycogen storage disease and Fanconi syndrome have an autosomal recessive disorder characterized by heavy glycosuria and increased glycogen storage in the liver and kidney, known as the *Fanconi-Bickel syndrome,* or *glucose-losing syndrome,* because the

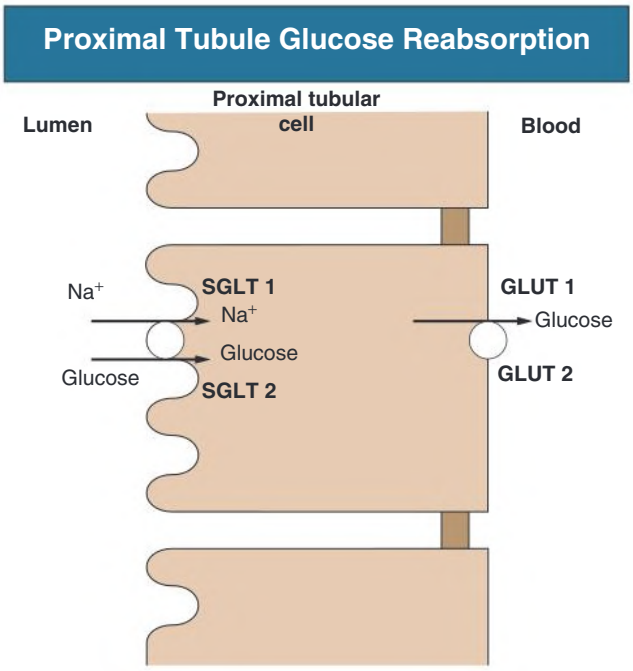

Fig. 50.7 Proximal Tubule Glucose Reabsorption. Glucose enters the proximal tubule cell coupled to Na^+ reabsorption from the lumen through a high-capacity, low-affinity transporter (SGLT2) in the early proximal tubule and a low-capacity, high-affinity transporter (SGLT1) in the late proximal tubule. Glucose exits the cell through the transporters (GLUT1 and GLUT2) located in the late and early proximal tubule, respectively. *GLUT1, -2,* Glucose transporter protein types 1, 2; *SGLT1,* sodium-glucose linked cotransporter type 1.

glucose losses can be massive.[11] These children have massive hepatomegaly, fasting hypoglycemia, and severe growth retardation in addition to Fanconi syndrome. The defect is deficient activity of the glucose transporter GLUT2 (Fig. 50.7). GLUT2 facilitates glucose exit from the basolateral side of the proximal tubule and intestinal cell and sugar entry and exit from the hepatocyte and pancreatic β cell. A few patients with type I glycogen storage disease have mild Fanconi syndrome but not Fanconi-Bickel syndrome. Treatment of this disorder is directed at the renal solute losses, treatment of rickets (which can be severe), and frequent feeding to prevent ketosis. Uncooked cornstarch has been shown to lessen the hypoglycemia and to improve growth.

Tyrosinemia

Definition

Hereditary tyrosinemia type I, also known as *hepatorenal tyrosinemia,* is a defect of tyrosine metabolism affecting the liver, kidneys, and peripheral nerves.[12]

Etiology and Pathogenesis

The cause of hereditary tyrosinemia type I is a deficiency of fumarylacetoacetate hydrolase (FAH) activity; it is an autosomal recessive disorder. Decreased or absent FAH activity leads to accumulation of maleylacetoacetate (MAA) and fumarylacetoacetate (FAA) in affected tissues. These compounds can react with free sulfhydryl groups, reduce intracellular levels of glutathione, and act as alkylating agents. Maleylacetoacetate and fumarylacetoacetate are not detectable in plasma or urine but are converted to succinylacetoacetate and succinylacetone. Succinylacetone is structurally similar to maleic acid, a compound that causes Fanconi syndrome experimentally in rats and may be the cause of Fanconi syndrome in humans affected with tyrosinemia.

Clinical Manifestations

The liver is the major organ affected, evident as early as the first month of life. Such infants usually have severe disease and die in the first year. All children with tyrosinemia will eventually develop macronodular cirrhosis, and many develop hepatocellular carcinoma. Acute, painful peripheral neuropathy and autonomic dysfunction also can occur. Proximal renal tubular dysfunction is evident in all patients with tyrosinemia, especially those presenting after infancy. Nephromegaly is very common, and nephrocalcinosis may be seen. Glomerulosclerosis and impaired GFR may be seen with time.

Diagnosis

The diagnosis should be suspected with elevated plasma tyrosine and methionine levels together with their *p*-hydroxy metabolites. The presence of succinylacetone in blood or urine is diagnostic of hereditary tyrosinemia type I.

Treatment

The institution of a diet low in phenylalanine and tyrosine dramatically improves the renal tubular dysfunction. Nitisinone, which inhibits the formation of MAA and FAA, dramatically improves the renal and hepatic dysfunction.[12] Liver transplantation has been successfully used to treat patients with severe liver failure and prevent the development of hepatocellular carcinoma. Liver transplantation leads to rapid correction of Fanconi syndrome.

Wilson Disease

Definition

Wilson disease is an inherited disorder of copper metabolism that affects numerous organ systems.[13,14] It has an overall incidence of 1 in 30,000 live births. About 40% of patients present with liver disease, 40% with extrapyramidal symptoms, and 20% with psychiatric or behavioral abnormalities.

Etiology and Pathogenesis

Wilson disease is caused by a defect in the P-type copper–transporting adenosine triphosphatase ATP7B, which is highly expressed in the liver, kidney, and placenta. It impairs biliary copper excretion and the incorporation of copper into ceruloplasmin. These abnormalities cause excessive intracellular accumulation of copper in the liver, with subsequent overflow into other tissues, such as the brain, cornea, and renal proximal tubule.

Clinical Manifestations

Patients typically present with chronic liver disease, often with relatively high serum bilirubin relative to alkaline phosphatase (bilirubin [mg/dL]/alkaline phosphatase >4). Excessive storage of copper in the kidney leads to renal tubular dysfunction in most patients and full-blown Fanconi syndrome in some. Hematuria also has been noted. Renal plasma flow and GFR decrease as the disease progresses, but death from extrarenal causes occurs before the onset of kidney failure. Fanconi syndrome usually appears before the onset of hepatic failure. Hypercalciuria with development of kidney stones and nephrocalcinosis also have been reported. Besides proximal tubular dysfunction, abnormalities in distal tubular function, decreased concentrating ability, and distal RTA (type 1 RTA) also have been observed. Neurologic abnormalities, such as dysarthria and gait disturbances, may be the presenting symptom in young adults with Wilson disease. Kayser-Fleischer rings, dense brown copper deposits around the iris, may be visible but typically can be seen only with a slit lamp.

Kidney Pathology

Histologic examination of the kidney in untreated Wilson disease shows either no alteration on light microscopy or only some flattened proximal tubular cells without recognizable brush borders. Electron microscopy shows loss of the brush border, disruption of the apical tubular network, electron-dense bodies probably representing metalloproteins in the subapical region of tubule cell cytoplasm, and cavitation of the mitochondria with disruption of the normal cristae pattern. Rubeanic acid staining shows intracytoplasmic copper granules. The copper content of kidney tissue is greatly elevated.

Diagnosis

The diagnosis of Wilson disease should be suspected in children and young adults with unexplained neurologic disease, chronic active hepatitis, acute hemolytic crisis, behavioral or psychiatric disturbances, or the appearance of Fanconi syndrome. In such patients, the presence of Kayser-Fleischer rings is an important clue in making the diagnosis. Serum ceruloplasmin levels are decreased in 96% of patients with Wilson disease. A greatly increased urinary copper level is also useful in making the diagnosis, especially if it increases significantly with D-penicillamine. Liver copper levels are increased in untreated patients. Mutational analysis is also available.

Treatment

Treatment with penicillamine 1 to 1.5 g/day reverses the kidney dysfunction and potentially the hepatic and neurologic disease, depending on the degree of damage before the onset of therapy. Recovery, however, is quite slow. Trientine also can chelate copper and is indicated in patients who cannot tolerate penicillamine. Tetrathiomolybdate is a potent agent in removing copper from the body and has been used in some patients with neurologic disease to prevent the immediate worsening of symptoms that can occur with penicillamine. Zinc salts, which induce intestinal metallothionein and blockade of intestinal absorption of copper, are useful in maintenance therapy. Liver transplantation has been successful in some patients but should be reserved for those with liver failure.

Lowe Syndrome

Lowe syndrome (oculocerebrorenal syndrome) is characterized by congenital cataracts and glaucoma, severe developmental delay, hypotonia with diminished to absent reflexes, and renal abnormalities.[15,16] Fanconi syndrome is followed by progressive kidney impairment. End-stage kidney disease usually does not occur until the third to fourth decade of life.

Lowe syndrome is transmitted as an X-linked recessive trait. Despite this inheritance pattern, Lowe syndrome has occurred in a few females. The defective gene codes for phosphatidyl inositol 4,5-bisphosphate 5-phosphatase, *OCRL1,* involved with cell trafficking and signaling.

Light microscopy of the kidney is normal early in the disorder, with endothelial cell swelling and thickening and splitting of the glomerular basement membrane seen by EM. In the proximal tubule cells, there is shortening of the brush border and enlargement of the mitochondria, with distortion and loss of the cristae. Only symptomatic treatment is available.

Dent Disease

Definition

Dent disease is an X-linked recessive disorder characterized by low-molecular-weight proteinuria, hypercalciuria, nephrolithiasis, nephrocalcinosis, and rickets.[17,18] Affected males often have aminoaciduria, phosphaturia, and glycosuria. Kidney failure is common and may occur by late childhood. Hemizygous females usually have only proteinuria and mild hypercalciuria. X-linked recessive nephrolithiasis and X-linked recessive hypophosphatemic rickets have similar features, and most have a defect in the renal ClC-5 chloride channel. Dent disease type 2 is a clinically similar disease affecting males, but there is a mutation in the same gene that causes Lowe syndrome, although patients with Dent type 2 do not have the brain or eye involvement seen in Lowe syndrome.[17]

Etiology and Pathogenesis

Most of these disorders are caused by a mutation in the *CLCN5* gene leading to inactive ClC-5 chloride channel function (see Fig. 50.2). The ClC-5 chloride channel spans the membrane of preendocytic vesicles just below the brush border of the proximal tubule. This channel plays a role in the acidification of these vesicles by a proton pump. Lack of this Cl^- channel interferes with protein reabsorption from the tubule through the megalin-cubilin receptor system and cell surface receptor recycling, which may explain the phosphaturia, glycosuria, and aminoaciduria.

The defective *OCRL1* in patients with Dent disease type 2 interferes with normal cell protein trafficking. The kidney disease is similar to that seen in Dent disease type 1. Although patients do not have the eye and brain disease seen in patients with Lowe, a few patients with Dent type 2 have a mild intellectual deficit, hypotonia, and subclinical cataracts.

Filtered PTH is also reabsorbed by the megalin-cubilin system for degradation in the lysosome. Decreased PTH reabsorption allows increased binding to luminal PTH receptors and increased endocytosis of luminal phosphate transporters, leading to increased phosphaturia.[1]

Mitochondrial Cytopathies

Definition

Mitochondrial cytopathies are a diverse group of diseases with abnormalities in mitochondrial DNA that lead to mitochondrial dysfunction in various tissues.[19]

Clinical Manifestations

Most of the mitochondrial cytopathies manifest with neurologic disorders such as myopathy, myoclonus, ataxia, seizures, external ophthalmoplegia, stroke-like episodes, and optic neuropathy. Other manifestations include retinitis pigmentosa, diabetes mellitus, exocrine pancreatic insufficiency, sideroblastic anemia, sensorineural hearing loss, pseudoobstruction of the colon, hepatic disease, cardiac conduction disorders, and cardiomyopathy.

The most common kidney manifestation associated with mitochondrial cytopathies is Fanconi syndrome, although a number of patients have been described with focal segmental glomerulosclerosis (FSGS) and corticosteroid-resistant nephrotic syndrome. All the patients with kidney abnormalities have had extrarenal disorders, mainly neurologic disease. Most patients present in the first months of life and die soon afterward.

Diagnosis

A clue to mitochondrial cytopathies is elevated serum or cerebrospinal fluid lactate levels, especially in association with an altered lactate-to-pyruvate ratio, suggesting a defect in mitochondrial respiration. The presence of "ragged red fibers," a manifestation of abnormal mitochondria, in a muscle biopsy specimen is another clue, especially with large abnormal mitochondria on EM of muscle tissue.

Treatment

There is little to offer these patients in terms of definitive therapy. Low mitochondrial enzyme complex III activity can be treated with menadione or ubidecarenone. Deficient mitochondrial enzyme complex I activity may be treated with riboflavin and ubidecarenone. Ascorbic acid has been used to minimize oxygen free radical injury. High-lipid, low-carbohydrate diet has been tried in cytochrome c oxidase deficiency.

Idiopathic Fanconi Syndrome

A number of patients develop the complete Fanconi syndrome in the absence of any known cause. Traditionally called *adult* Fanconi syndrome because it was thought that only adults were affected, it is now clear that children may be affected, and a more proper designation is *idiopathic* Fanconi syndrome. Not all the features of Fanconi syndrome may be present when the patient is first seen but do appear with time. Idiopathic Fanconi syndrome can be inherited in an autosomal dominant, autosomal recessive, or even X-linked pattern. However, most cases occur sporadically, with no evidence of genetic transmission. The prognosis is variable, and some patients develop ESKD 10 to 30 years after onset of symptoms. A few patients have undergone kidney transplantation; in some, Fanconi syndrome has recurred in the allograft without evidence of rejection, suggesting an extrarenal cause of the idiopathic form.

Renal morphologic descriptions of such cases are scanty. In some reports, no abnormalities were found, and, in others, tubular atrophy with interstitial fibrosis was interspersed with areas of tubular dilation. Greatly dilated proximal tubules with swollen epithelium and grossly enlarged mitochondria with displaced cristae also have been noted.

ACQUIRED CAUSES OF FANCONI SYNDROME

Numerous substances can injure the proximal renal tubule. Injury can range from an incomplete Fanconi syndrome to acute tubular necrosis (ATN) or ESKD. The extent of the tubular damage varies depending on the type of toxin, amount ingested, and host characteristics. A careful history of possible toxin exposure and recent medications is important in patients with tubular dysfunction. Box 50.1 lists the more common causes of acquired Fanconi syndrome.

Heavy Metal Intoxication

A major cause of proximal tubular dysfunction is acute heavy metal intoxication, principally lead and cadmium (see Chapter 65). In lead poisoning, renal tubular dysfunction, mainly aminoaciduria and mild glycosuria and phosphaturia, is usually overshadowed by the development of chronic kidney disease (CKD) and involvement of other organs, especially the central nervous system.[20] Fanconi syndrome associated with cadmium poisoning is associated with severe bone

pain, giving rise to the name itai-itai ("ouch-ouch") disease for its occurrence in Japanese patients affected by industrial contamination of the soil.[21]

Tetracycline

Outdated tetracycline causes reversible Fanconi syndrome even in therapeutic doses. Recovery is rapid when the degraded drug is stopped. The compound responsible for the tubule dysfunction is anhydro-4-tetracycline, formed from tetracycline by heat, moisture, and low pH.

Cancer Chemotherapy Agents

A number of cancer chemotherapy agents have been associated with Fanconi syndrome and renal tubular dysfunction, especially cisplatin and ifosfamide. Carboplatin has been associated with reduced GFR and magnesium wasting but not Fanconi syndrome. The nephrotoxicity of both cisplatin and ifosfamide is dose dependent and often irreversible. Besides the usual manifestations of Fanconi syndrome, cisplatin toxicity is characterized by hypomagnesemia, caused by hypermagnesuria, which can be extremely severe, persistent, and difficult to treat.[22,23] Ifosfamide is more often associated with hypophosphatemic rickets.[22] Chloroacetaldehyde, a metabolite of ifosfamide, appears experimentally to cause Fanconi syndrome. Both ifosfamide and cisplatin can also cause an irreversible reduction in GFR.

Other Drugs and Toxins

Exposure to a wide range of toxins may give rise to Fanconi syndrome, often in association with a reduced GFR, including 6-mercaptopurine, toluene (glue sniffing), and Chinese herbal medicines containing *Aristolochia* spp (see Chapter 79).[24] In addition, anecdotal reports have associated Fanconi syndrome with valproic acid (valproate), suramin, gentamicin, and ranitidine. Antiviral medications, especially antiretroviral agents such as tenofovir, are an increasingly common cause of Fanconi syndrome.[25]

Dysproteinemias

Dysproteinemia[26] from multiple myeloma, light-chain proteinuria,[27] Sjögren syndrome, and amyloidosis is sometimes associated with Fanconi syndrome, which appears to be correlated with urinary free light chains that can cause proximal tubule dysfunction through intracellular crystallization or lysosomal dysfunction.[28]

Glomerular Disease

Nephrotic syndrome is rarely associated with Fanconi syndrome. Most of these patients have FSGS, and the occurrence of Fanconi syndrome heralds a poor prognosis.

After Acute Kidney Injury

Tubular dysfunction can occur transiently during recovery from AKI from any cause, regardless of whether a known tubular toxin was originally implicated.

After Kidney Transplantation

Fanconi syndrome has appeared rarely after kidney transplantation. The pathogenesis probably is multifactorial, including sequelae of ATN, rejection, nephrotoxic drugs, ischemia from renal artery stenosis, and residual hyperparathyroidism.

FAMILIAL GLUCOSE-GALACTOSE MALABSORPTION AND HEREDITARY RENAL GLYCOSURIA

Definition

Renal glycosuria refers to the appearance of readily detectable glucose in the urine when the serum glucose concentration is in a normal range (see Fig. 50.3). When the serum glucose concentration is in a physiologic range, virtually all the filtered glucose is reabsorbed in the proximal tubule.[29] Filtered glucose enters the proximal tubule through two specific carriers (SGLT1 and SGLT2) coupled to sodium and exits the cell through the sugar transporters GLUT1 and GLUT2 (see Fig. 50.7). However, when the serum level exceeds the physiologic range, the filtered load exceeds the capacity of these carriers, and glucose begins to appear in the urine; this is termed the *renal threshold.*

Etiology and Pathogenesis

Familial glucose-galactose malabsorption is a rare autosomal disorder caused by mutations in the gene coding for the brush border sodium-glucose cotransporter SGLT1, which is found in the intestinal cell and the S_3 segment of the proximal renal tubule cell. The disorder is characterized by the neonatal onset of life-threatening diarrhea from the intestinal malabsorption of glucose and galactose, which resolves rapidly with the removal of glucose and galactose and its dipeptide, lactose, from the diet. These patients frequently also have mild renal glycosuria.

Familial renal glycosuria occurs with an incidence of 1 in 20,000 live births and can be inherited as a heterozygous, homozygous, or mixed heterozygous trait.[29] This disorder is caused by mutations in the *SLC5A2* gene that codes for the SGLT2 glucose transporter found in the early portion of the proximal tubule. Inhibitors of SGLT2, which mimic this genetic defect, have been used recently in type 2 diabetes to lower hyperglycemia without causing weight gain or aggravating hyperinsulinism (see Chapter 32).

In the past, renal glycosuria was divided into three types based on the reabsorption patterns observed during glucose infusion studies, but this typing system has been questioned because clearance data suggest patients with renal glycosuria have rates of glucose reabsorption that vary from virtually no reabsorption to near-normal rates, rather than three distinct types, reflecting different mutations in the *SLC5A2* gene and differing amounts of functional protein.

Natural History

Patients with familial glucose-galactose malabsorption appear to grow and develop normally with removal of the offending sugars from the diet. The clinical course of hereditary renal glycosuria is benign, except for a few patients with polyuria and salt wasting, and it is not a precursor to diabetes mellitus. Patients need to be aware of the condition in order not to receive unnecessary diagnostic investigations or even treatment for presumed diabetes mellitus.

AMINOACIDURIAS

As with glucose, amino acids are almost completely reabsorbed in the proximal tubule by a series of specific carriers. Studies have described a number of inherited disorders resulting in the incomplete reabsorption of a specific amino acid or a group of amino acids[30] (Table 50.2). Most do not result in kidney disease.

Cystinuria

Definition

Cystinuria is characterized by the excessive urinary excretion of cystine and the dibasic amino acids ornithine, lysine, and arginine and accounts for about 1% to 2% of all kidney stones and 6% to 8% of pediatric kidney stones.[31,32]

Etiology and Pathogenesis

These four amino acids share a transport system on the brush border membrane of the proximal tubule. Because of the relative insolubility

of cystine when its urine concentration exceeds 250 mg/L (1 mmol/L), patients with cystinuria have recurrent kidney stones.

Cystinuria is an autosomal recessive trait with a disease incidence of 1 in 15,000 births.[31,32] Early studies suggested there were three genetic types on the basis of in vitro studies of intestinal transport and amino acid excretion in heterozygotes. More recently, two genes (*SLC3A1* coding for the protein rBAT and *SLC7A9* for the protein $b^{0,+}$AT) have been identified that are defective in cystinuria. *SLC3A1* heterozygotes have normal excretion rates for cystine. *SLC7A9* heterozygotes have cystine excretion rates that range from normal to almost that of homozygous patients. Based on these data, a newer classification proposed type A for mutations in both *SLC3A1* genes and type B for mutations in *SLC7A9*.[31,32] Type AB is a compound heterozygote. Type A accounts for 38% of cystinuria patients, type B for 47%, and type AB for 14%.

Clinical Manifestations

Cystine stones (calculi) are typically yellow-brown (Fig. 50.8A) and radiopaque (see Fig. 50.8B). Cystine crystals appear as microscopic, flat hexagons in the urine (see Fig. 50.8C), and this is a clue to the diagnosis.

Diagnosis

Patients can be tested for cystinuria with the cyanide-nitroprusside test, but type B heterozygotes also may give a positive result. The definitive test is to quantify cystine and dibasic amino acid excretion in a 24-hour urine specimen. Homozygotes excrete more than 118 mmol cystine per mmol creatinine (250 mg/g creatinine). Genetic testing for mutations in the *SLC3A1* and *SLC7A9* is also readily available.

Treatment

The aim of therapy in cystinuria is to lower the urine cystine concentration to less than 250 mg/L (1 mmol/L).[31,32] The first step is to increase daily fluid intake to greater than 2 L/1.73 m^2 and restrict sodium intake. However, because most patients with cystinuria excrete 0.5 to 1 g/day of cystine, a urine output of 2 to 4 L/day is needed to achieve this goal. Cystine solubility increases in alkaline urine, but the urine pH must be > 7 to 7.5 to be effective. In patients with recurrent stone disease, thiols such as penicillamine and tiopronin are extremely useful through the formation of a more soluble, mixed disulfide of the thiol and cysteine from cystine. Tiopronin is the most commonly prescribed thiol because it has fewer side effects than penicillamine and is started at a low dose (100 mg bid) and slowly increased (doses >1000 mg/day have little added effect) to achieve a urine cystine concentration below 250 mg/L in conjunction with a high fluid intake. Penicillamine is also effective, and the dose should be slowly increased to minimize side effects. Captopril can be useful (an effect resulting from its thiol structure, not its angiotensin-converting enzyme inhibitor effect), but the dose range (75–150 mg/day) may be limited by its hypotensive effects.

TABLE 50.2 Inherited Aminoacidurias

Disease	Clinical Findings	Urine Amino Acids
Cystinuria	Urolithiasis	Cystine, lysine, ornithine, arginine
Hartnup disease	Rash, neurologic disease	Neutral amino acids
Iminoglycinuria	None	Proline, hydroxyproline glycine
Lysinuric protein intolerance	Hyperammonemia, vomiting, diarrhea	Dibasic amino acids

HEREDITARY DEFECTS IN URIC ACID HANDLING

Hereditary Renal Hypouricemia

Hereditary renal hypouricemia is a rare autosomal recessive disorder characterized by very low serum uric acid levels (<2.5 mg/dL [<150 μmol/L] in adult men and <2.1 mg/dL [<124 μmol/L] in adult women) and increased uric acid clearance, ranging from 30% to 150% of the filtered load.[33] In the normal kidney, uric acid is both reabsorbed and secreted in the proximal tubule by two different uric acid–anion exchange transporters and a voltage-sensitive pathway. In some patients, the defect is in the gene *SLC22A12* that codes for the protein URAT1; other patients have been found to have mutations in *SLC2A9 (GLUT9)*. Most patients do not have symptoms, and hypouricemia is found incidentally when a low serum uric acid concentration is noted during routine serum chemistry evaluation. About one-fourth of patients with renal hypouricemia have had kidney stones, but only one-third of these were uric acid stones. There also may be hypercalciuria, and a few patients have had exercise-induced AKI, thought to be caused by acute tubular injury by passage of uric acid "gravel" in association with volume depletion and reduced urine pH. Most patients require no treatment, but if forming uric acid stones, they should maintain a high fluid intake. Urine alkalinization and allopurinol can be used for patients with persistent uric acid stones.

Autosomal Dominant Tubulointerstitial Kidney Disease

Autosomal dominant tubulointerstitial kidney disease (ADTKD) is a group of rare disorders characterized by progressive loss of kidney function, bland urinary sediment, and autosomal dominant inheritance.[34] These diseases were previously classified as familial juvenile hyperuricemic nephropathy (FJHN) or medullary cystic kidney disease type 2 (MCKD2). However, as neither hyperuricemia nor renal cysts are pathognomonic, these disorders have been reclassified as ADTKD. There are four main genes that are known to cause ADTKD: *UMOD* (uromodulin), *MUC1* (mucin-1), *REN* (renin), and HNF1B (hepatocyte nuclear factor β).

The *UMOD* gene encodes for the Tamm-Horsfall/uromodulin protein, which is synthesized in the epithelial cells of the thick ascending limb (TAL) of the loop of Henle. Defective protein is retained in the endoplasmic reticulum and probably leads to inflammation, interstitial fibrosis, and functional abnormalities of the TAL. The defective protein also causes decreased salt and water reabsorption because *UMOD* plays a role in regulating the sodium-potassium-chloride transporter[35] and the rat outer medullary potassium channel.[36] The decreased salt and water reabsorption leads to increased proximal salt reabsorption and secondarily of uric acid, leading to hyperuricemia.

The *MUC1* gene encodes for mucin-1, a transmembrane protein, which is expressed in the loop of Henle, distal tubule, and collecting duct. The pathogenesis of how defective mucin-1 leads to tubulointerstitial fibrosis remains unclear. Patients with ADTKD-*MUC1* can develop hyperuricemia as well, but gout tends to be a later manifestation of the disease.

The *REN* gene encodes for preprorenin, which is then converted to prorenin and subsequently renin. Mutation in this gene leads to retention of preprorenin, prorenin, or renin protein in the endoplasm, depending on the location of the defect. As a result of a low renin state, patients with ADTKD-*REN* are at risk of mild hypotension, mild hyperkalemia, increased risk of AKI in the setting of volume depletion, and transient childhood anemia. Hyperuricemia and gout may also occur, though the exact mechanism is unclear.

The *HNF1B* gene encodes hepatocyte nuclear factor β, a transcription factor that regulates multiple genes located in the kidney, pancreas, and liver. Patients with *HNF1B* mutations have variable presentations and can present with extrarenal manifestations. The disease ADTKD-*HNF1B* occurs in a small subset of patients with *HNF1B* mutations and is characterized by kidney cysts, maturity onset diabetes of youth, genital abnormalities, pancreatic atrophy, and hypomagnesemia.

Diagnosis of ADTKD should be suspected in patients with CKD and family history of autosomal dominantly inherited CKD. In patients with ADTKD-*UMOD,* the diagnosis is suggested by a fractional excretion of uric acid of less than 5% (normal, 10%–15%). Definitive diagnosis can be made by genetic testing of the *UMOD, MUC1, REN* (renin), and HNF1B genes. There are no specific treatments for ADTKD, and management is largely based on CKD care (see Chapter 82). Controversy exists as to whether lowering of serum uric acid slows the progression of CKD; the studies reporting benefit have usually involved starting a xanthine oxidase inhibitor early in the disease.

More recently from genome-wide association studies, variants in the *UMOD* gene have been identified as risk factors for CKD and hypertension.[37] The variants are common, are in the noncoding regions of the *UMOD* gene, and lead to an increase in functional UMOD protein in contrast to the mutation in ADTKD.

SELF-ASSESSMENT QUESTIONS

A 3-year-old boy presents with failure to thrive and photophobia. His urine contains glucose and +1 protein with a pH of 5.5. Serum chemistries are as follows:

Na^+ 135 mmol/L
K^+ 2.5 mmol/L
Cl^- 111 mmol/L
HCO_3^- 15 mmol/L
Glucose 91 mg/dL (5 mmol/L)
Phosphorus 2.5 mg/dL (0.8 mmol/L) (normal for age, 4.5–5.5 mg/dL)
Creatinine 0.4 mg/dL (35 µmol/L)

1. Slit-lamp examination of his eyes shows tinsel-like refractile opacities in his cornea. What is the most likely diagnosis?
   A. Lowe syndrome
   B. Cystinosis
   C. Tyrosinemia
   D. Hereditary fructose intolerance
   E. Galactosemia
2. Cystinuria is associated with which amino acids in the urine besides cystine?
   A. Arginine, lysine, ornithine
   B. Arginine, lysine, histidine
   C. Lysine, ornithine, histidine
   D. Ornithine, glycine, alanine
   E. Ornithine, glycine, serine
3. What is the most common cause of Fanconi syndrome in adults?
   A. Multiple myeloma
   B. Medications
   C. Nephrotic syndrome
   D. Cystinosis
   E. Cadmium
4. The defect in familial glycosuria is an abnormality in which transporter?
   A. GLUT1
   B. ClC-5
   C. Na^+-K^+-$2Cl^-$
   D. Na^+/H^+
   E. SLGT2
5. Most patients with Dent disease have a mutation in which transporter?
   A. Na^+-K^+-$2Cl^-$
   B. GLUT2
   C. Na^+/H^+
   D. ClC-5
   E. Na^+-Cl^-

Sickle Cell Diseases and the Kidney

Claire C. Sharpe, Fatiu A. Arogundade

SICKLE CELL DISEASE

Epidemiology

Sickle cell disease (SCD) is an autosomal recessive inherited disorder that predominantly affects persons of African, Mediterranean, Indian, and Middle Eastern descent but was first recognized in West Africa. The high prevalence of SCD in this region probably represents a survival benefit, as the presence of the sickle cell gene protects against malaria. SCD is now a worldwide health problem because the carrier state has spread throughout Africa, around the Mediterranean, and to the Middle East and India, as well as to the Caribbean, North America, and northern Europe. The prevalence of the sickle cell gene is about 8% in African Americans and about 25% in adult Nigerians. Of babies born with SCD, 25% worldwide are born outside of sub-Saharan Africa.[1-3]

Genetics

The sickle hemoglobin (Hb) mutation (hemoglobin S, or HbS) results in the replacement of the normal glutamine by valine in the sixth position of the β-globin subunit, thereby changing the configuration of the Hb tetramer molecule in the homozygous person from $\alpha 2\beta 2$ to $\alpha 2\beta^S 2$. Sickle cell disease occurs in those homozygous for HbS (commonly referred to as *sickle cell anemia*) or in heterozygotes when HbS coexists with another abnormal or missing β-chain (e.g., HbC [$\alpha 2\beta^S\beta^C$] or HbSβ thalassemia [$\alpha 2\beta S$]). Sickle cell trait occurs in those heterozygous for HbS when the other Hb molecule is normal (HbAS [$\alpha 2\beta^A\beta^S$]).

Several HbS haplotypes—mutations of the HbS molecule—have been identified that have probably arisen independently of each other. There are four major types in Africa—the Benin, Senegal, Cameroon, and Bantu (or Central African Republic) haplotypes—and one Asian haplotype. Variations in these haplotypes determine disease severity; for example, the Senegalese haplotype is associated with a higher fetal Hb (HbF) concentration (a key driver of disease severity) and has a better prognosis than others. In a sample population of Nigerians, Benin haplotype was detected in 92%. Sex also influences disease severity; female HbSS patients with Benin haplotype have a higher HbF level than male patients.[4,5]

Pathophysiology

The driving pathophysiologic factor is HbS polymerization. During cellular or tissue hypoxia, dehydration, or oxidative stress, the mutated β-globin chains of the HbS molecule tend to crystallize to a polymer nucleus. Polymerization disrupts the architecture and changes the shape of the red blood cell (RBC) to a characteristic crescent or sickle, which increases its rigidity (Fig. 51.1). Polymerization is dynamic and depends on local oxygen tension. It is also promoted by acidosis (which decreases the affinity of HbS for oxygen) and hyperosmolarity (which increases RBC Hb concentration). As a consequence of repeated polymerization cycles, sickle RBCs exhibit abnormally high adhesion to activated endothelium, owing to acquired membrane changes and retained adhesion receptors on reticulocytes, especially the stress reticulocytes. This increases microvascular transit time, thereby stimulating further sickling. This results in premature destruction (hemolysis) of the RBCs and frequent, widespread vaso-occlusive episodes with subsequent acute and chronic organ damage.

The tendency of HbS to polymerize is influenced by the presence or absence of HbF, which contains γ-Hb chains in place of β-Hb ($\alpha 2\gamma 2$). In RBCs that contain HbF (known as F cells), the presence of HbF dilutes the concentration of HbS, thus increasing the threshold at which polymerization occurs. In addition, both HbF and its mixed hybrid tetramer ($\alpha 2\beta^S\gamma$) cannot enter the deoxy sickle Hb polymer phase, further limiting the degree of polymerization that can occur within a cell.[6] Therefore, the main determinant of disease severity is the rate and extent of HbS polymerization, which drives the two major pathophysiologic processes: vaso-occlusion with ischemia-reperfusion injury and hemolytic anemia (Fig. 51.2).[7]

Vaso-occlusion occurs in all patients, often triggered by inflammation, and is typically found in clinical states of infection, hypoxia, hypovolemia, hypothermia, acidosis, and hyperosmolality. Vaso-occlusion is probably caused by dynamic endothelial-leukocyte-RBC adhesive interactions in the postcapillary venules and precapillary obstruction by rigid, deformed RBCs. Episodic microvascular occlusion and ischemia can be interrupted by restoration of blood flow and reperfusion, which further promote inflammatory stress and tissue injury. In addition, hemolysis contributes to the development of progressive vasculopathy, characterized by endothelial dysfunction and proliferative changes in the intima and smooth muscle of blood vessels. An important role is ascribed to free Hb, which inactivates nitric oxide and generates reactive oxygen species. These separate pathologic processes have been used to explain the distinct subphenotypes of clinical complications of SCD whereby some patients present with frequent vaso-occlusive crises (VOCs), acute chest syndrome (ACS), and osteonecrosis, whereas others have more severe anemia, recurrent leg ulceration, pulmonary hypertension, priapism, and chronic kidney disease (CKD).[8]

Natural History and Clinical Manifestations

Sickle cell disease is a highly variable condition, though life expectancy is reduced in all subjects, especially in those with symptomatic disease. Median survival in some parts of sub-Saharan Africa may be as low as 5 years, whereas it is 45 to 55 years in the United States and Jamaica.[5,9] The clinical manifestations of SCD are individualized and age dependent (Fig. 51.3).[10] Newborn babies are asymptomatic for the first couple of months of life because fetal Hb predominates at this age. However, as γ-chains are rapidly replaced through β-chain synthesis, symptoms (often potentially life-threatening) begin

to occur, including dactylitis, ACS, overwhelming sepsis, and acute splenic sequestration. Stroke is also a feature of early childhood, with an incidence of 8% by age 14 years, rising to 11% by age 20 years. However, this has been largely mitigated in wealthy countries by screening at-risk children with transcranial Doppler (looking for increased blood flow velocity, which is suggestive of arterial stenosis) and the use of chronic transfusion for both primary and secondary prevention.[11] Human parvovirus B19 infection can lead to a severe and sudden fall in Hb in children and adolescents with SCD because the virus destroys RBC precursors for 8 to 10 days, which results in severe anemia. After the age of 5 years, when active bone marrow is withdrawn from the small bones, dactylitis is replaced by the

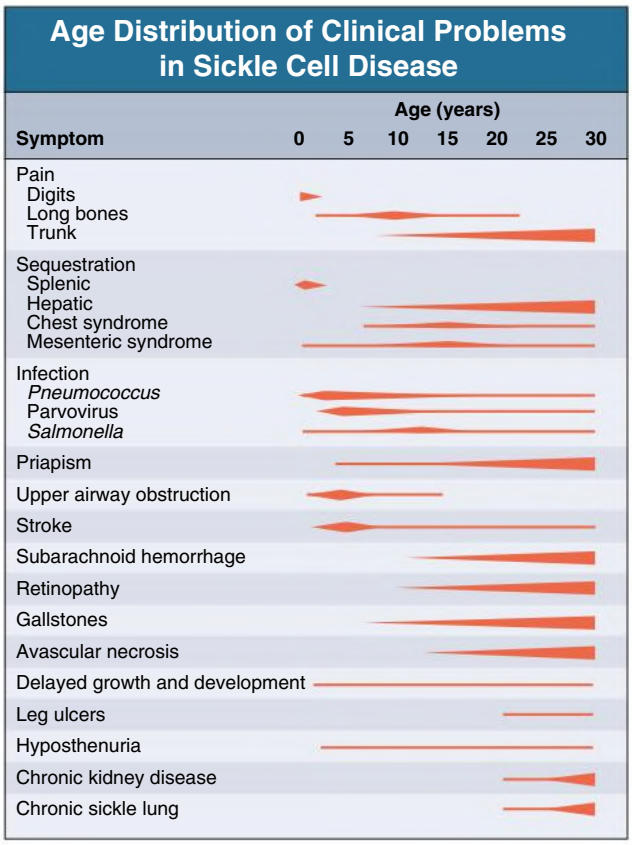

Fig. 51.3 Age distribution of clinical problems in sickle cell disease. (Modified from Davies SC, Oni L. Management of patients with sickle cell disease. *BMJ.* 1997;315:656–660.)

classic painful vaso-occlusive crises, which increases in frequency with increasing age. In addition, adolescence is associated with nocturnal enuresis, avascular necrosis of the hip, leg ulcerations, delayed puberty, and priapism. Over the age of 25 to 30 years, the frequency of VOC tends to reduce and is replaced with signs and symptoms of chronic organ damage, including heart failure, pulmonary hypertension, sickle hepatopathy, and sickle cell nephropathy.[5] In younger patients, the primary cause of death is usually infection, whereas in older patients the primary cause of death is commonly irreversible organ damage (Fig. 51.4).[12]

SICKLE CELL NEPHROPATHY

Sickle cell nephropathy (SCN) develops slowly, starting in the very young with glomerular hyperfiltration and leading to albuminuria in late childhood or early adulthood. Although many patients do not progress further, a number develop progressive CKD. These patients are at increased risk for acute kidney injury (AKI) complicating VOC or other interim illnesses, events that often precipitate a further decline in glomerular filtration rate (GFR). The prevalence of albuminuria is approximately 60% in those over 45 years, but only 4% to 12% of patients with SCD develop end-stage kidney disease (ESKD), though this figure may increase as the patient cohort ages.[12,13] In keeping with this, in 2008 advanced CKD was reported in 24% of patients with SCD who had survived to 60 years of age or more and was the cause of death in 45%.[14]

In general, SCN is more prevalent and more severe in those with HbSS-thalassemia and HbSβ^0-thalassemia than in those with milder forms of SCD such as HbSC.[9,15]

Genetic Modifiers of Risk for Developing Sickle Cell Nephropathy

Other genetic modifiers are also associated with disease severity and risk for developing SCN, often through their influence on HbF levels. A polymorphism in the *BCL11A* gene (a fetal Hb silencing factor) leads to higher HbF levels, reduced hemolysis, and amelioration of SCD-related complications. Coinheritance of α-thalassemia and SCD is found in approximately one-third of patients and is associated with reduced hemolysis and protection from albuminuria. Over the past decade, genetic risk factors for CKD have been identified in the African American population, the most important of which are haplotypes of the *APOL1* gene. These are associated with increased risk for hemolysis and, when combined with genotypes for α-thalassemia and BCL11A, can be used to stratify risk for progressive CKD in SCD patients.[16] Using estimated GFR as a marker of kidney function, the transforming growth factor-β/bone morphogenic protein (TGF-β/BMP) pathway[17] has been implicated as a cause of progressive kidney function loss in SCN.

Pathophysiology of Sickle Cell Nephropathy

The pathogenesis of SCN is directly related to the blood supply of the kidney and its circulation. In health the kidneys receive approximately 25% of the cardiac output to achieve effective filtration of the plasma at a rate of approximately 100 mL/min/1.73 m^2, despite representing less than 1% of total body weight. As a consequence, the cortex of the kidney is at risk for receiving excess oxygen, which is mitigated by shunting of oxygen from the afferent arteriole to the efferent arteriole. The vessels (vasa recta) that supply the medulla of the kidney branch off early from the efferent arteriole, taking only a fraction of the total renal blood flow (RBF) with them. Much of the blood that enters the kidney cortex is therefore delivered back to the venous circulation without entering the medulla at all. The maintenance of the relatively sluggish but intricate medullary blood flow is critical to maintaining the corticomedullary interstitial solute gradient generated by the countercurrent multiplier system of the loop of Henle, which drives water and solute reabsorption and allows for effective urinary concentration.[18] The resulting hypoxia (partial pressure of oxygen 10–35 mm Hg), acidosis, and hyperosmolarity of the inner medulla make it an ideal environment for the polymerization of deoxygenated HbS and subsequent sickling of erythrocytes. Over time, repeated cycles of sickling and sludging cause microinfarcts and ischemic injury leading to the chronic microvascular disease that is apparent in established SCN (Fig. 51.5).[19] Local activation of hypoxia inducible factor 1α (HIF1α) upregulates the expression of endothelin-1 which, in the presence of reduced nitric oxide, leads to an increase in reactive oxygen species and vasoconstriction, thus feeding into a cycle of chronic medullary hypoxia (Fig. 51.6).[20]

Despite reduced circulation in the kidney medulla, total RBF and GFR are paradoxically increased. The subsequent hyperfiltration eventually results in proteinuria and glomerulosclerosis, which together with tubulointerstitial fibrosis marks the onset of progressive CKD.[21] Although partially due to the increased cardiac output seen in patients with SCD, this increase in RBF cannot be completely explained by anemia or increased plasma volume, as it is not reversed by correction of the anemia with transfusion. One explanation involves the hemoxygenase–carbon monoxide system. Heme oxygenase-1 (HO-1) is upregulated in injured kidneys (and other tissues) in response to ongoing hemolysis in SCD, and is responsible for the conversion of heme to biliverdin with the subsequent release of carbon monoxide. Both biliverdin and carbon monoxide at these levels are potent antioxidants, and the carbon monoxide acts locally as a vasorelaxant, thus increasing both RBF and GFR.[22] This provides a possible link between the degree of hemolysis experienced by a patient and the likelihood of developing proteinuria.

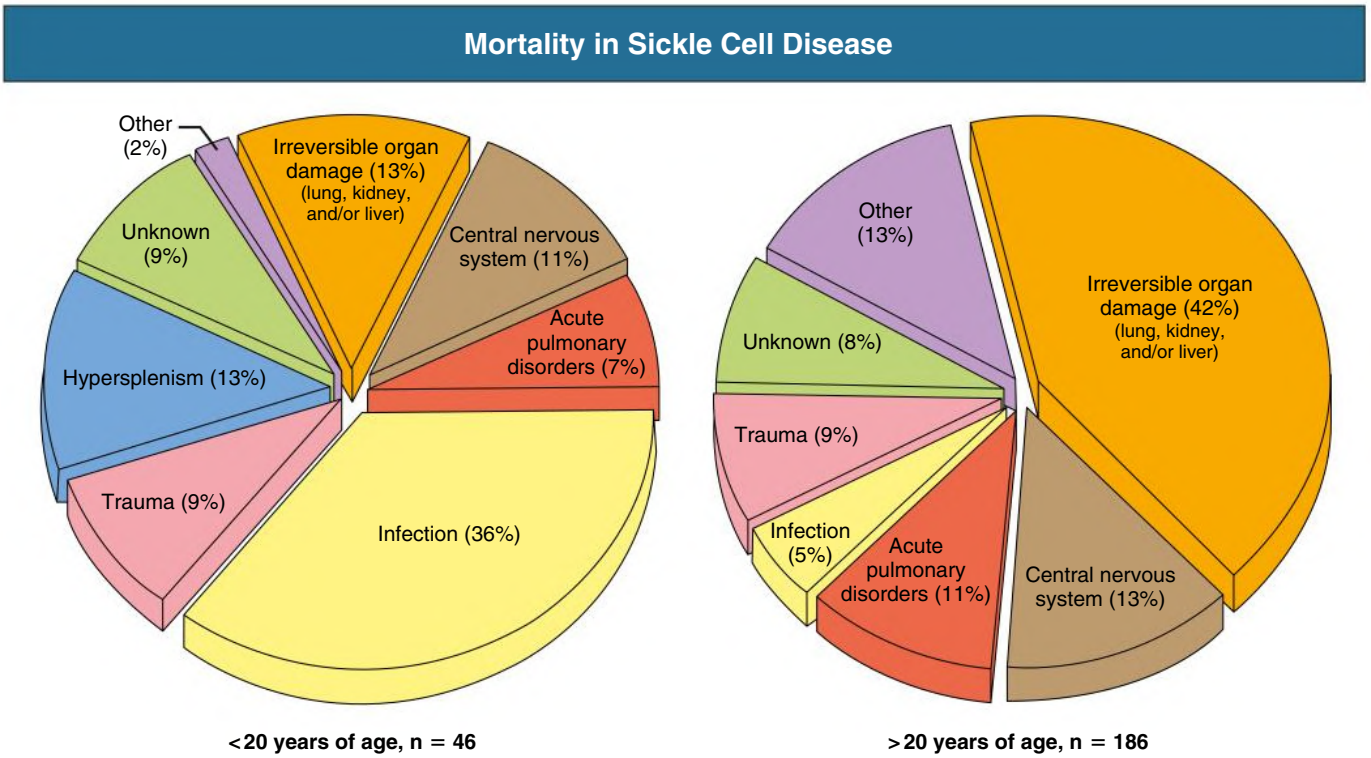

Fig. 51.4 Mortality in Sickle Cell Disease. Causes of death among 232 HbSS patients, comparing patients <20 years (46 died) with patients >20 years (186 died). The endothelial dysfunction and vasculopathic state of SCD described earlier is also pivotal to the development of SCN. Crosstalk between glomerular endothelial cells and podocytes is important to maintain healthy glomerular function; when the endothelium is dysfunctional, this could lead to podocyte injury and the development of glomerular lesions and proteinuria. FMS-like tyrosine kinase 1 is a receptor for vascular endothelial growth factor (VEGF), and increased levels of the soluble form (sFlt-1) have been associated with endothelial dysfunction in preeclampsia. Serum levels of sFlt-1 are raised in SCD and so may play a role in the development of proteinuria.[22]

CLINICAL MANIFESTATIONS OF SICKLE CELL NEPHROPATHY

Glomerular Abnormalities

Hyperfiltration

Glomerular hypertrophy is ubiquitous in SCD and has been reported in children as young as 1 to 3 years of age (Fig. 51.7).[23] Increased kidney growth is observed from infancy in children with SCD and accompanies the early rise in GFR.[24,25] Glomerular filtration rate continues to rise throughout childhood and early adulthood, often exceeding 200 mL/min/1.73 m^2. Although this hyperfiltration is not associated with an overt increase in systemic blood pressure (BP), recent studies suggest children with SCD may have a degree of masked hypertension which can be detected with ambulatory monitoring.[26,27] Persistent hyperfiltration can eventually lead to damage to the glomerular basement membrane and nephrosclerosis, feeding into a cycle of increasing single-nephron GFR, further nephron loss, and an overall decline in GFR during adulthood.

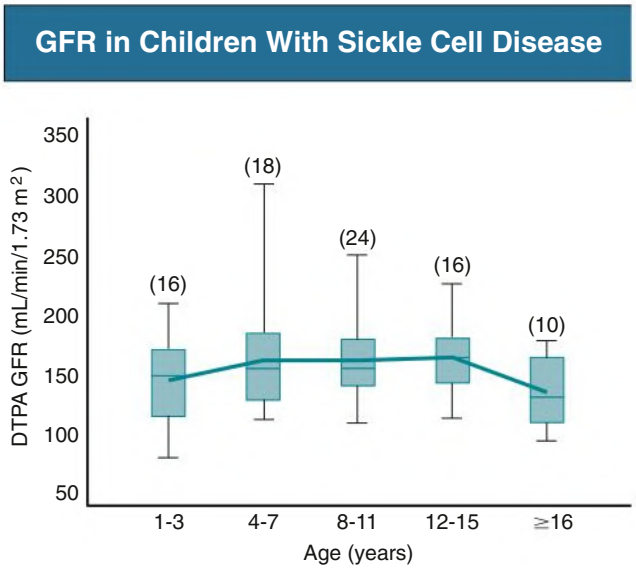

Fig. 51.7 Diethylenetriaminepentaacetic acid (DTPA) glomerular filtration rate (GFR) in children with sickle cell disease. (From Aygun B, Mortier NA, Smeltzer MP, et al. Glomerular hyperfiltration and albuminuria in children with sickle cell anemia. *Pediatr Nephrol.* 2011;26:1285–1290.)

Albuminuria and Proteinuria

Albuminuria occurs after a period of prolonged hyperfiltration and is apparent in some patients from late childhood.[28] Unlike hyperfiltration, the prevalence of albuminuria continues to increase with

age, reaching more than 60% of all patients with HbSS SCD over the age of 45 years.[13,29] In some patients, albuminuria progresses and occasionally reaches the nephrotic range (proteinuria >3.5 g/24 h), which is associated with increased mortality.[15] Nephrotic syndrome, although uncommon (~4% of all those with proteinuria), is associated with a very poor kidney prognosis. One rare cause of sudden onset of nephrotic syndrome in patients with SCD is recent infection with human parvovirus B19 (HPV B19). Although widespread in the community, this usually benign infection becomes significant in patients with SCD because it causes acute but self-limiting red cell aplasia. In combination with severe hemolysis, this leads to life-threatening anemia requiring supportive transfusion. Several reports have described patients in whom infection was followed by acute nephrotic syndrome within 2 to 3 months. In cases in which biopsy has been performed early, the collapsing variant of focal segmental glomerulosclerosis (FSGS) has been found (with or without evidence of direct HPV B19 infection). Although the acute features of the nephrotic syndrome are self-limiting, the sequelae of the condition are worsening glomerulosclerosis, tubulointerstitial fibrosis, and progressive kidney dysfunction.[30]

Tubular Abnormalities

Hyposthenuria

Hyposthenuria (the excretion of urine of low specific gravity secondary to inability of the kidney to concentrate the urine) is almost universal in people with SCD (who can rarely achieve a urine osmolality above 450 mOsm/kg, even under water-deprived conditions) and also occurs in older people with sickle cell trait. Hyposthenuria often leads to enuresis in children and can cause marked dehydration. It is primarily caused by sickling in the vasa recta, leading to microthrombi, infarction, and collateral formation of blood vessels. As a consequence, there is a defect in the countercurrent exchange mechanism resulting in insufficient trapping of solute in the inner medulla and leading to abnormalities in water conservation.[19] In addition, the increased delivery of salt and water in the tubular filtrate secondary to the high GFR and the intermittent hypoxia caused by sickling in the microvasculature lead to local endothelin-1 release. Endothelin-1 (ET-1) is a potent vasoconstrictor and also has marked natriuretic and diuretic properties through stimulation of ET type b receptors in the kidney collecting ducts, leading to increased salt and water loss.[31] Although hyposthenuria is reversible by blood transfusion until the age of 10 years, after this age it becomes irreversible and is associated with a permanently damaged microvasculature and increased urine output, leading to a tendency to dehydration.[19,32]

Increased Proximal Tubular Function

The increase in sodium and water loss from the nephron leads to a reactive increase in sodium and water reabsorption by the proximal tubule secondary to tubuloglomerular feedback. This reabsorption of sodium is the driving force for the reabsorption of other solutes such as phosphate and β2-microglobulin, and hence many patients have hyperphosphatemia. There is also an increase in proximal tubular secretion of other solutes, such as creatinine and uric acid. Despite this, serum levels of uric acid are often raised as a result of severe hemolysis and may result in episodes of acute gout. In contrast, up to 30% of the total creatinine excretion can arise from tubular secretion resulting in low serum creatinine levels and overestimation of GFR when creatinine-based formulas are used.[33] Increased sodium reabsorption requires increased oxygen consumption and hypermetabolism of the kidney tubules, a phenomenon that may exacerbate kidney hypoxia in SCD.[22]

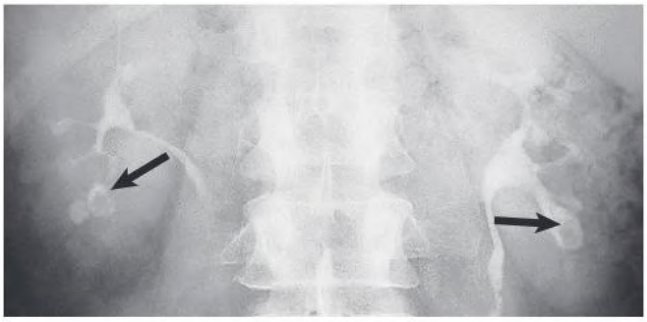

Fig. 51.8 Papillary Necrosis in Sickle Cell Disease. Intravenous urography shows abnormal calyces with filling defects *(arrows)*.

Acidification Defect

A retrospective study in 2014 of 411 homozygous SCD patients with eGFR greater than 60 mL/min/1.73 m^2 revealed that 42% had partial metabolic acidosis as assessed by serum levels of carbon dioxide (52% of women, 27% of men), apparently because of a lack of ammonia buffering capacity rather than a defect in the distal tubule. Although serum potassium levels were not linked to acidosis in this study, hyperkalemia is a common phenomenon in patients with SCD and has been attributed by others to hyperchloremic metabolic acidosis linked to type IV kidney tubular acidosis or resistance of the distal tubule to aldosterone.[22]

Hematuria, Papillary Necrosis, and Kidney Medullary Carcinoma

Hematuria is common in patients with SCD and sickle cell trait. It can range from painless microhematuria, through visible and painless, to visible and painful. It is usually self-limiting but occasionally can be severe enough to require transfusion. Microinfarcts, capillary congestion, and rupture are often the cause, but occasionally, complete occlusion of the vasa recta can lead to papillary necrosis with sloughing of the ischemic papilla, severe hemorrhage, and obstruction, which may be complicated by superimposed infection and painful clot colic (Fig. 51.8).[17] The left-sided predominance of hematuria has been attributed to the so-called nutcracker phenomenon, with compression of the left renal vein between the aorta and the superior mesenteric artery, increasing the pressure in the renal vein. This may contribute to the development of hematuria in patients with SCD, because the increased renal vein pressure could worsen anoxia in the kidney medulla, increasing the likelihood of sickling in the left kidney.

Renal medullary carcinoma (RMC) is an aggressive form of renal cell carcinoma that uniquely affects patients with sickle cell hemoglobinopathies, particularly sickle cell trait or HbSC, especially in teenagers and young adults. It is similar to but distinct from renal cell carcinoma with medullary phenotype (RCC-MP), which is found in individuals who do not carry a sickle gene, but both are characterized by loss of protein expression of the tumor suppressor gene *SMARCB1*. Chronic medullary hypoxia is thought to contribute to its pathogenesis. The tumors are resistant to chemotherapy and tend to be metastatic at diagnosis, with a reported postsurgical mean survival of only 15 weeks. It is not yet clear whether regular evaluation for RMC in young patients with SCD or trait could result in an early diagnosis and a better survival. Gross hematuria, flank pain, and weight loss are ominous signs of malignancy, particularly in young patients with sickle cell trait. The tumor is typically located deep in the parenchyma, unlike Wilms tumor or renal cell carcinoma.[34]

URINARY TRACT INFECTIONS

Patients with SCD have an increased susceptibility to bacterial infections; even low-grade bacteremia with a common organism may be fatal. In addition to the impaired immunity resulting from autosplenectomy, there is opsonic antibody deficiency, which predisposes to bacterial infections. Bacteriuria was found to be present in 26% of children with SCD presenting with fever in Nigeria, and urinary tract infection complicated pregnancy in 12% of mothers with SCD in a large UK cohort.[35,36]

Pyelonephritis and urosepsis, as with any infection, may precipitate a sickle cell crisis. The most common organisms isolated include *Escherichia coli, Klebsiella* spp, and other gram-negative Enterobacteriaceae.

CLINICAL SYNDROMES OF KIDNEY IMPAIRMENT

Acute Kidney Injury

Although much is known about CKD, there is less in the literature about AKI in patients with SCD. It is reported as a complicating factor in 2% to 8% of hospital admissions with painful vaso-occlusive crisis or acute chest syndrome. The severity of the AKI appears to be directly related to the severity of the acute sickling crisis. Other causes of AKI are rhabdomyolysis, sepsis, and drug nephrotoxicity. Less common causes of acute kidney dysfunction are kidney vein thrombosis and hepatorenal syndrome (caused by SCD-related hepatic failure). Volume depletion due to inability to concentrate urine makes patients more susceptible to AKI. Although most patients recover, repeated episodes of AKI increase the risk for CKD. After severe episodes, GFR on recovery is often lower than before the acute event.[3] In addition, patients with underlying CKD are more prone to AKI, making this a vicious cycle in patients with frequent hospital admissions.[37,38]

Progressive Chronic Kidney Disease

Progressive loss of kidney function in SCN is an increasingly large problem as life expectancy increases. Similar to diabetic nephropathy, patients with SCN progress through stages of tubular dysfunction and hyperfiltration, through mild to moderate albuminuria to severe albuminuria, and eventually loss of GFR. Over time, single-nephron GFR increases as other nephrons are lost, resulting in worsening damage to the glomeruli (manifested by FSGS), increasing albuminuria, and subsequent interstitial fibrosis and tubular atrophy. Although hypertension is less common in patients with SCD than in an age- and ethnicity-matched cohort, when it is present it has a marked impact on the rate of progression of CKD.[39] For this reason, it may be necessary to aim for lower blood pressure targets in these patients than might be advocated in people without SCD.

Predictors of CKD progression are hypertension, proteinuria, nephrotic syndrome, hematuria, increasingly severe anemia, and inheritance of the Bantu, or Central African Republic, β-globin gene cluster haplotype. In addition, younger age at diagnosis and higher duration of SCD were found to strongly predict the development of nephropathy.[40]

As GFR declines, the ability of the kidney to synthesize erythropoietin (EPO) also declines. Chronic anemia and tissue hypoxia are strong drivers for EPO synthesis, and patients with SCD with normal kidney function often have EPO levels well above the normal range. However, when the GFR falls below approximately 60 mL/min/1.73 m^2, their ability to produce sufficient endogenous EPO also begins to decline, resulting in worsening anemia. In patients who develop progressive kidney dysfunction secondary to SCN, the rate of decline can be quite rapid once the GFR falls below 40 mL/min/1.73 m^2, and so timely preparation for kidney replacement therapy (KRT) is very important. Many patients who have suffered frequent admissions to hospital often have very poor peripheral veins and so need expert surgical input when planning for dialysis access.

INVESTIGATION AND MANAGEMENT OF SICKLE CELL NEPHROPATHY

Serum cystatin C is promising as a more accurate marker of kidney function than creatinine in adults and children with SCD and may detect decline in GFR earlier.[26] However, it has yet to be fully validated against gold standard measures that calculate true GFR in SCD patients, so creatinine and creatinine-based equations continue to be used in the clinic. It is therefore the pattern and rate of change of either serum creatinine or eGFR that should be considered rather than the absolute value, bearing in mind that relatively modest changes in creatinine at higher levels of GFR can represent significant decline in kidney function. Kidney function and albuminuria should be monitored at least annually.[41] Creatinine levels are often low in people with SCD secondary to reduced muscle bulk, hyperfiltration, and increased proximal tubular secretion, resulting in a high eGFR. Increased rate of change of creatinine may therefore indicate declining GFR before the value moves out of the normal range. Anyone with an eGFR that is declining at more than 5 mL/min/yr or an absolute value less than 60 mL/min should be identified and referred to a nephrologist (Fig. 51.9). Rigorous BP control is recommended, as for other causes of CKD.[39] A BP of 140/90 is currently permissible for patients with a negative dipstick result or those with a urine albumin-to-creatinine ratio (uACR) less than 3.5 mg/mmol, but a target of 130/80 should be used for those with a uACR greater than 3.5 mg/mmol.[42] Urinary tract infections should be promptly treated with appropriate antibiotics. Glucose-6-phosphate dehydrogenase deficiency (G6PD deficiency), which may precipitate intravascular hemolysis, should be excluded because some antibiotics, including sulfonamides and nitrofurantoin, precipitate hemolysis by antagonizing folate synthesis. Long-term use of nonsteroidal antiinflammatory drugs should be avoided in patients with eGFR less than 60 mL/min/1.73 m^2; if unavoidable, regular monitoring of kidney function is recommended.

The population at risk for developing SCN is also at risk for other diseases that affect the kidneys, including lupus nephritis, various forms of glomerulonephritis, blood-borne viruses, renal carcinoma, myeloma, and kidney stones. This differential should be considered when investigating a patient with SCD and new-onset proteinuria or hematuria. Although it is common practice not to investigate patients with albuminuria (uACR >3.5 mg/mmol), patients with urinary protein-to-creatinine ratio (uPCR) greater than 50 mg/mmol should be evaluated for other causes of CKD (Fig. 51.9); if any of these investigations are abnormal, or the patient's signs and symptoms do not conform to those expected within the natural history of SCN as described previously, they should be referred for further evaluation. In particular, patients with sudden onset of heavy proteinuria, with or without nephrotic syndrome, warrant kidney biopsy to look for causes other than SCN. There is no pathognomonic lesion that defines SCN. Glomerular hypertrophy with distended capillaries is universally found but is not confined to those who have developed albuminuria or proteinuria. FSGS is the most common lesion associated with proteinuria, but it is not specific to SCN (Fig. 51.10). Other lesions that have been reported on kidney biopsy in SCD include thrombotic microangiopathy and membranoproliferative glomerulonephritis; neither is exclusive to SCN. The only characteristic interstitial lesion is abundant

hemosiderin granules in proximal tubular epithelial cells.[43] Kidney iron deposition also has been noted on magnetic resonance scans in patients with SCD but appears not to be related to liver iron concentration, a marker of total body iron load. Kidney iron does appear to be correlated with markers of hemolysis but has not been shown to be associated with kidney dysfunction or degree of albuminuria.[44]

Inhibition of the Renin-Angiotensin System

Only one small randomized, controlled trial evaluated angiotensin-converting enzyme (ACE) inhibition in patients with SCD and proteinuria; a more recent systematic review concluded that available evidence was insufficient to offer recommendations on treatment.[45] However, based on the evidence available for other causes of proteinuric kidney disease, ACE inhibitors or angiotensin receptor blockers (ARBs) are recommended for the treatment of adults and children with SCD and albuminuria.[41] These drugs must be introduced cautiously because many patients have a low or normal BP, and so moderate doses can cause postural hypotension, which can be partially circumvented by

taking the medication at bedtime. Patients have reported that this has the benefit of reducing nocturnal urinary frequency, presumably as a direct result of a functional drop in GFR. Patients with SCN are prone to hyperkalemia, which can be exacerbated by ACE inhibitor and ARB treatment and is often the dose-limiting factor. It is also important to inform patients and other caregivers that ACE inhibitors and ARB should be temporarily stopped during acute illnesses associated with dehydration to mitigate the risk for AKI.

Sickle Cell Disease Therapies and Blood Transfusion

Oral hydroxycarbamide (HC; also known as hydroxyurea) was the first licensed drug for the management of SCD. Although HC has pleotropic effects, it primarily acts to increase levels of fetal Hb that serve to dilute the levels of HbS and reduce risk for polymerization. However, there are no RCTs of HC use in the management or progression of SCN in adults and only one in infants, which showed no effect on hyperfiltration, though urinary concentrating ability was improved.[46] A number of observational trials of HC in older children and adults have shown a reduction in hyperfiltration and albuminuria.[3] HC therefore should be considered for patients with microalbuminuria/proteinuria or abnormal GFR together with an ACE inhibitor or ARB (or in those intolerant of this treatment). Over the past 5 years there have been a number of new treatments for SCD, some of which are now licensed for use in preventing VOC. Although none has yet to be proven to affect the progression of CKD, trials in this area are planned.[47]

There is little evidence for the benefits of long-term RBC transfusions on prevention of kidney complications of SCD. A retrospective analysis of 120 children with sickle hemoglobinopathies concluded that chronic transfusion protected against the onset of albuminuria when started before the age of 9 years. Two studies, however, found that chronic transfusion made no difference to onset of albuminuria and that prolonged courses of transfusion therapy can lead to iron overload, which is particularly difficult to treat in patients with CKD.[3]

Erythropoiesis-Stimulating Agents

Erythropoiesis-stimulating agents (ESAs) can be useful, particularly in combination with hydroxycarbamide in patients who are intolerant of hydroxycarbamide alone because of reticulocytopenia. They should be commenced when the Hb has fallen by approximately 10% to 15% from the normal baseline at steady state, though patients with CKD stages 3 to 4 often require very high doses of ESAs to have an impact on Hb levels. Although Hb targets should be lower than in the general population with CKD (80–100 g/dL) because of the increased risk for triggering VOC, they are rarely achieved, and most patients become transfusion dependent by the time they reach ESKD. However, it is often still beneficial to continue ESA therapy after the commencement of KRT because this can prolong the interval between RBC transfusion and minimize the risks for iron overload.[3] It is important to ensure that adequate iron stores are maintained to achieve maximum erythropoiesis. Intestinal losses of iron resulting from subclinical bleeding are significant in advanced CKD, and absorption of oral iron is reduced. Intravenous iron supplementation may be necessary therefore in patients deficient in iron, on ESAs, and not receiving iron through regular transfusions.

Hemopoietic Stem Cell Transplantation

Hemopoietic stem cell transplantation (HSCT) is potentially curative and may reduce hyperfiltration in the young[48] but has largely been limited to children with severe cerebrovascular complications, acute chest syndrome, or frequent VOC not responding to hydroxycarbamide therapy. The few reports of HSCT in adults with SCN have mixed kidney outcomes.[3]

KIDNEY REPLACEMENT THERAPY

Dialysis

Outcome data for patients with SCD on dialysis are few, but an early report from the United States showed that the average age of those reaching ESKD was very young (23.1 years in patients with HbSS), and the mean time to death after was only 4 years despite regular hemodialysis.[49] More recent data from France and the United States report that the 5-year mortality rate for patients with SCD with ESKD remains significantly higher than for patients without SCD. They have more complications, are admitted to hospital more frequently and are less likely to be offered a kidney transplant.[50,51] Infections and thrombosis of dialysis access were commonly encountered complications in the group with SCD.

Transplantation

Although there may be many obstacles in the path to kidney transplantation, it is probably the preferred modality for patients with SCD requiring KRT. Although long-term graft and patient survival are not quite as good as for patients with other causes of ESKD, the prognosis for individuals with SCN is far better after transplantation with a projected 7-year survival of 67% (vs. 83% for other African Americans) compared with a 10-year survival of only 14% for those who remain on dialysis.[21] Although outcomes after transplantation in SCD have improved over the last 20 years, it is not without complications. Delayed graft function and graft loss are more common than in other patient groups, and the recurrence of frequent VOC after transplantation as the Hb rises is problematic.[52] Treatment with regular exchange transfusion aimed at keeping the HbS level below 30% may help reduce the risk for these complications and does not appear to be associated with increased rejection rates but is associated with improved patient survival.[53]

SICKLE CELL TRAIT AND CHRONIC KIDNEY DISEASE

In patients with heterozygous sickle cell trait, approximately 40% of RBC Hb is HbS, and the rest is normal HbA. In general, these patients have normal Hb levels and do not have symptoms of hemolysis or vaso-occlusion. However, there have been reports of catastrophic VOC and sudden death in young people with sickle cell trait under extreme adverse conditions such as excessive exercise or exposure to severe hypoxia. In addition, renal medullary carcinoma is more common in patients with SCT than SCD, though the reasons for this are unclear. Nonmalignant microhematuria and macrohematuria are reported more frequently in patients with sickle cell trait than in the general population, and older patients exhibit a loss of urinary concentrating ability. Patients who coinherit sickle cell trait and adult polycystic kidney disease (APKD) have a more rapid decline to ESKD than family members with APKD who do not carry an HbS gene. Whether having sickle cell trait alone is a risk factor for progressive CKD has been debated, but a recent population-based study in the United States has shown that SCT is associated with both CKD and progression to ESKD (hazard ration 2.03), independent of APOL1 status.[54]

SELF-ASSESSMENT QUESTIONS

1. Patients with SCD:
   - **A.** often develop albuminuria before they are 5 years old.
   - **B.** have reduced urinary concentrating capacity.
   - **C.** have reduced total kidney blood flow in childhood.
   - **D.** are often hypokalemic.
2. Patients with SCD and ESKD:
   - **A.** have a lower mortality rate when on dialysis than patients with adult polycystic kidney disease.
   - **B.** who have a kidney transplant should avoid blood transfusion, as it is associated with increased rejection rates.
   - **C.** who are on dialysis should be prescribed erythropoietin, as this usually avoids the need for blood transfusion.
   - **D.** have a higher rate of delayed graft function after kidney transplantation than patients with ESKD of other causes.
3. Hydroxycarbamide:
   - **A.** should be avoided in patients with chronic kidney disease.
   - **B.** has been shown to reduce hyperfiltration in children with SCD in a randomized controlled trial.
   - **C.** works by increasing fetal hemoglobin production.
   - **D.** should not be given in combination with inhibitors of the renin-angiotensin system.

Congenital Anomalies of the Kidney and Urinary Tract

John O. Connolly, Melanie M.Y. Chan, Guy H. Neild

Congenital anomalies of the kidney and urinary tract (CAKUT) are a group of phenotypically diverse structural malformations characterized by defects in kidney and urinary tract development. CAKUT accounts for 20% to 30% of all developmental anomalies identified in the antenatal period and has a prevalence of 3 to 6 per 1000 births.[1] Although usually occurring in isolation, 30% are associated with extrarenal abnormalities, and CAKUT has been associated with more than 200 different syndromes, including Fraser syndrome, Kallman syndrome, and branchio-oto-renal (BOR) syndrome. CAKUT accounts for up to 50% of children with chronic kidney disease (CKD)[2] and is the leading cause of end-stage kidney disease (ESKD) in children, making up 34% to 43% of those requiring kidney replacement therapy (KRT).[2,3] CAKUT also contributes significantly to the burden of kidney disease in young adults, accounting for 26% and 17% of individuals requiring KRT at age 18 to 21 years and 22 to 31 years, respectively,[4] with a median age of KRT initiation of 31 years.[5] Reduced nephron mass secondary to a solitary functioning kidney or posterior urethral valves (PUV) are associated with a worse kidney outcome, with concurrent vesico-ureteral reflux (VUR) a poor prognostic sign.[6,7] Even with normal kidney function and blood pressure (BP) in adolescence, individuals with CAKUT have an increased lifetime risk of ESKD.[8]

CLINICAL PRINCIPLES

Congenital kidney and urinary tract anomalies may present in one of the following five settings:

1. Antenatal diagnosis by fetal ultrasound (US) screening
2. Failure to thrive in an infant or young child
3. Investigation of urinary tract infection (UTI)
4. An incidental finding in a child or adult
5. An adult with abnormal urinalysis, stones, hypertension, or reduced glomerular filtration rate (GFR)

The identification of these problems always poses the following questions:

- What is the cause?
- What is the natural history?
- Is surgical intervention required?

If there is a family history of structural malformations, a genetic cause may sometimes be identified, guiding surveillance for extrarenal manifestations, as in the case of *HNF1B*-related disease, as well as screening of first-degree relatives. Symptomatic UTIs are common in individuals with CAKUT and an increase in frequency of UTIs or deterioration in GFR should prompt investigations to exclude obstruction or bladder dysfunction that may require urologic intervention. Furthermore, as predicted by the Brenner hypothesis,[9] small dysplastic kidneys with reduced GFR develop all the features of glomerular hyperfiltration. The onset of progressive kidney impairment signaled by increasing proteinuria and hypertension should be treated according to standard CKD guidelines with initiation of renin-angiotensin system (RAS) blockade. The details of antenatal and pediatric management of these patients are beyond the scope of this chapter, which focuses on management in adolescence and adult life.

DEVELOPMENT OF THE KIDNEYS AND URINARY TRACT

The kidneys and urinary tract develop simultaneously from the endoderm-derived cloaca and intermediate mesoderm (Fig. 52.1).[10] Kidney development can be divided into three phases: the pronephros, mesonephros, and metanephros. The pronephros develops 22 days after conception and forms a transient, rudimentary, and nonfunctioning system that degrades by day 28. It elongates caudally to meet the cloaca by day 26, becoming the mesonephric (Wolffian) duct, which ultimately contributes to the formation of the urinary bladder and male genital system (epididymis and caudal vas deferens).[11] The mesonephros is derived from the intermediate mesoderm and develops functioning tubules, which start to excrete urine, although most of these subsequently degenerate. By the fifth week of fetal life, the ureteral bud branches from the caudal part of the mesonephric duct into the metanephric mesenchyme to become the metanephros, the precursor to the adult kidney (see Fig. 52.1A). This process is mediated by glial cell line–derived neurotrophic factor (GDNF)/RET signaling, disruptions of which can result in varying phenotypes, including kidney agenesis. Reciprocal induction between the ureteral bud and the metanephric mesenchyme results in branching morphogenesis and elongation of the ureteral bud to form the collecting system and mesenchymal epithelial transformation of the metanephric mesenchyme to generate primitive nephrons (see Fig. 52.1B–D). The metanephros starts to function 6 to 10 weeks after fertilization, with nephrogenesis complete by 36 weeks. Sixty percent of nephrons are formed in the last trimester, which has important clinical implications for preterm and low-birth-weight infants, who have increased long-term risk for CKD.[12] The extent to which reduced nephron number contributes to this increased risk relative to exposure to nephrotoxic insults and acute kidney injury as a neonate is not yet understood.

The lower urinary tract is formed from the endodermal cloaca, which is divided by the urorectal septum into ventral and dorsal parts that develop into the urogenital sinus and rectum, respectively (see Fig. 52.1E). The urogenital sinus gives rise to the early bladder, the urethra and vestibule of the vagina in females, and the posterior urethra in males. Growth of the anterior abdominal wall between the allantois and the urogenital membrane is accompanied by an increase in size and capacity of this bladder precursor. The allantois remains attached to the apex of the fetal bladder and extends into the umbilical root, although it loses its patency and persists as the urachal remnant, the

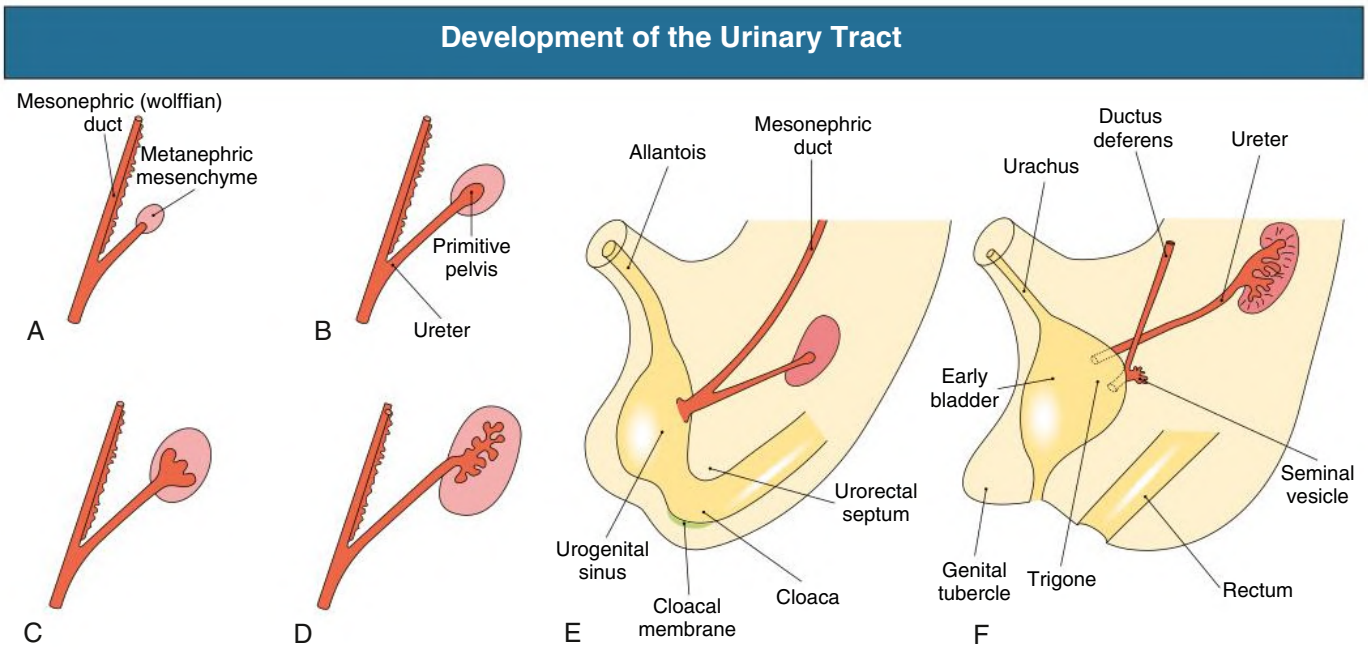

Fig. 52.1 Development of the Urinary Tract. Growth and development of the ureter, pelvis, and calyces are shown in parts A to D. (A) The metanephric kidneys first become detectable as small areas in the mesoderm close to the aorta. The primitive epithelial ureter buds off from the mesonephric duct and makes contact with the metanephric mesenchyme. (B) Under the influence of signals from the ureter, the mesenchyme condenses and proliferates around the ureteral tip, with simultaneous elongation and branching of the ureteral tip. (C–D) A primitive pelvis appears, then branches to form the divisions of the calyces. The branching process continues, with the epithelial system eventually differentiating into the nephrons of the kidney parenchyma. As the fetus grows, the kidney ascends because of the continuous rostral growth. (E) Growth and development of the cloaca during weeks 5 to 6 of gestation. (F) Growth and development of the urogenital sinus into bladder and outflow tract during weeks 8 to 9.

median umbilical ligament, which connects the bladder to the umbilicus (see Fig. 52.1F). By the seventh week, there is a separate opening of the distal mesonephric duct into the bladder at what will become the vesico-ureteral opening and the area known as the *trigone.* At the same time the paramesonephric (müllerian) ducts start to regress in males and fuse in females to become the uterovaginal cord, which opens into the urogenital sinus and will go on to develop into the vagina.

PATHOGENESIS

Familial clustering, monogenic syndromes associated with urinary tract malformations, and animal models suggest a strong genetic basis for CAKUT. US screening of asymptomatic first-degree relatives reveals structural urinary tract malformations in up to 23%.[13] The increasing availability of next-generation sequencing has led to the identification of over 50 monogenic CAKUT-causing genes, but genotype-phenotype heterogeneity and incomplete penetrance mean that a single-gene cause has been identified in less than 20% of individuals.[14] In addition, rare copy-number variation (CNV) has been reported in up to 40% of individuals with CAKUT, suggesting that gene dosage may also be an important mechanism.[15] Environmental factors, including preexisting and gestational maternal diabetes[16] and increases or decreases in maternal vitamin A levels,[17] have also been associated with an increased risk of anomalies, and it is likely that CAKUT results from the complex interplay of genetics and maternal and environmental factors.

Kidney and urinary tract development are tightly regulated by a network of transcription factors, growth factors, and adhesion molecules. Pathogenic variants in genes encoding all classes of these molecules, affecting different stages of nephrogenesis, have been identified in patients with CAKUT (Table 52.1). Variants in the transcription factors *HNF1B* (hepatocyte nuclear factor 1B) and *PAX2* (paired box gene 2) are two of the most common causes of CAKUT (both syndromic and isolated) and are associated with cystic kidneys and kidney hypodysplasia (Table 52.2), respectively.

- *HNF1B* mediates the development of the kidneys, liver, pancreas, and urinary tract. Haploinsufficiency resulting from whole-gene deletions (typically a 1.4 Mb 17q12 deletion) or pathogenic heterozygous variants can cause kidney cysts and diabetes syndrome (KCAD). A high frequency of de novo deletions means there may not be a family history. *HNF1B*-related disease is associated with a wide range of CAKUT phenotypes: kidney hypodysplasia, cystic kidneys, single and horseshoe kidneys, malformations of the collecting system, and autosomal dominant tubulointerstitial kidney disease (ADTKD-HNF1B).[18] Extrarenal manifestations include mature-onset diabetes of the young [MODY] type 5, pancreatic hypoplasia, genital malformations, hyperuricemia and early gout, abnormal liver function, and hypomagnesemia, highlighting the utility of a molecular diagnosis in guiding evaluation for possible nonrenal abnormalities.
- *PAX2* is a key regulator of multiple steps of kidney development, including ureteric bud induction, branching morphogenesis, and nephron differentiation.[19] Heterozygous variants in *PAX2* were first discovered in patients with renal-coloboma syndrome presenting with kidney hypodysplasia, optic nerve abnormalities, and hearing loss, but variants have now been identified in a wide range of phenotypes, including adult-onset focal segmental glomerulosclerosis (FSGS).[20]

TABLE 52.1 Monogenic Causes of CAKUT

Inheritance	Gene	Associated Phenotype
Autosomal recessive	*CHRM3*	Prune-belly like syndrome
	FRAS1	Fraser syndrome, kidney agenesis
	FREM1	Bifid nose, kidney agenesis
	FREM2	Fraser syndrome, kidney agenesis
	GFRA1	Bilateral kidney agenesis
	GRIP1	Fraser syndrome, kidney agenesis
	HPSE2	Urofacial syndrome, neurogenic bladder
	ITGA8	Bilateral kidney agenesis
	LRIG2	Urofacial syndrome, neurogenic bladder
	TRAP1	VACTERL
Autosomal dominant	*BNC2*	Congenital lower urinary tract obstruction/PUV
	EYA1	Branchio-oto-renal syndrome
	GATA3	HDR syndrome
	GLI3	Pallister-Hall syndrome
	GREB1L	Kidney agenesis
	HNF1B	Kidney cysts and diabetes syndrome
	PAX2	Renal-coloboma syndrome, FSGS
	PBX1	Kidney hypodysplasia
	RET	Kidney agenesis
	SALL1	Townes-Brocks syndrome, kidney hypodysplasia
	SIX5	Branchio-oto-renal syndrome
	TBX18	PUJO
	ZMYM2	Syndromic CAKUT
X-linked recessive	*ANOS1*	Kallmann syndrome, kidney agenesis

CAKUT, Congenital anomalies of the kidney and urinary tract; *FSGS,* focal segmental glomerulosclerosis; *HDR,* hypoparathyroidism, sensorineural deafness, and kidney disease; *PUJO,* pelvi-ureteral junction obstruction; *PUV,* posterior urethral valves; *VACTERL,* vertebral defects, anal atresia, cardiac defects, tracheo-esophageal fistula, renal (kidney) anomalies, and limb anomalies.

TABLE 52.2 Definitions of Kidney Malformations

Term	Characteristics
Kidney agenesis	Absence of the kidney or an identifiable metanephric structure.
Kidney aplasia	Severe dysplasia with extremely small kidney, sometimes identifiable only by histologic examination.
Kidney dysplasia	Abnormal differentiation of kidney parenchyma with development of abnormal structures, including primitive ducts surrounded by collars of connective tissue, metaplastic cartilage, variety of nonspecific malformations such as preglomeruli of fetal type, and reduced branching of collecting ducts with cystic dilations and primitive tubules. Dysplastic kidneys often contain cysts.
Kidney hypoplasia	Significantly reduced kidney mass with either normal or reduced (oligomeganephronia) nephron number without evidence of maldevelopment of parenchyma.
Kidney hypodysplasia	Reduced kidney mass and nephron number with dysplastic features. Previously thought to be secondary to scarring from reflux or reflux nephropathy but now considered to be primary dysplasia with associated reflux.
Kidney multicystic dysplasia	Severe cystic dysplasia with extremely enlarged kidney full of cystic structures; occurs as an isolated kidney lesion in response to ureteral atresia and urethral obstruction; 10% of patients have a family history.

KIDNEY PARENCHYMAL MALFORMATIONS

Congenitally abnormal kidneys may be enlarged or small, cystic or dysplastic, and absent or misplaced. These conditions were traditionally discussed based on findings on intravenous urography (IVU) but are now primarily investigated with US, computed tomography (CT), and magnetic resonance imaging (MRI). Functional assessment of obstruction and VUR are carried out using ^{99m}Tc-mercaptoacetyltriglycine (MAG3) scintigraphy and voiding cystourethrogram (VCUG), respectively.

Kidney Dysplasia

Table 52.2 presents the range of dysplastic and other malformations of the kidney. Abnormalities of the ureter, bladder, and urethra are often associated with kidney dysplasia, and evidence of concurrent VUR should always be sought. All types of kidney dysplasia can also occur as isolated developmental anomalies and although typically producing small, irregular kidneys, they can also be cystic or multicystic. US features of kidney dysplasia include increased echogenicity, poor corticomedullary differentiation, and parenchymal cysts.

Kidney Hypoplasia

Kidney hypoplasia is defined as a congenitally small kidney (two standard deviations below the expected mean) that lacks evidence of either parenchymal maldifferentiation (kidney dysplasia) or acquired disease sufficient to explain the reduced size. The term is often used loosely and includes small kidneys with a normal number of nephrons as well as oligomeganephronia. This is a type of kidney hypoplasia resulting from a congenital reduction in the number of nephrons. It results from arrested development of the metanephric blastema at 14 to 20 weeks of gestation with subsequent hypertrophy of glomeruli and tubules in the kidney. The hypertrophy and hyperfiltration result in progressive nephron injury and sclerosis later in life. Oligomeganephronia is recognized on kidney biopsy by the large size of the glomeruli and tubules and the small number of glomeruli seen despite a good core of kidney cortex.

Differential Diagnosis of Scarred Kidneys

Kidney hypodysplasia versus reflux. Progressive scarring and kidney failure were once considered to be caused by chronic parenchymal infection (so-called "chronic pyelonephritis") and were regarded as a consequence of VUR. The 1980s, however, saw a retreat from the paradigm of the primary role of infection, and emphasis was placed on scarring as a result of reflux and the progressive nature of the glomerular lesion associated with glomerular hypertension (or hyperfiltration), so-called "reflux nephropathy" (see Chapter 62). Current thinking is that scarring often follows from kidney dysplasia, and that the reflux is a secondary or incidental feature (Fig. 52.2). Thus, irregular kidneys with normal-caliber ureters are more likely to be caused by primary dysplasia, and no evidence of VUR may be seen.

Kidney scarring in adults. A practical clinical problem is the differential diagnosis of scarred, asymmetric kidneys. Genetic testing

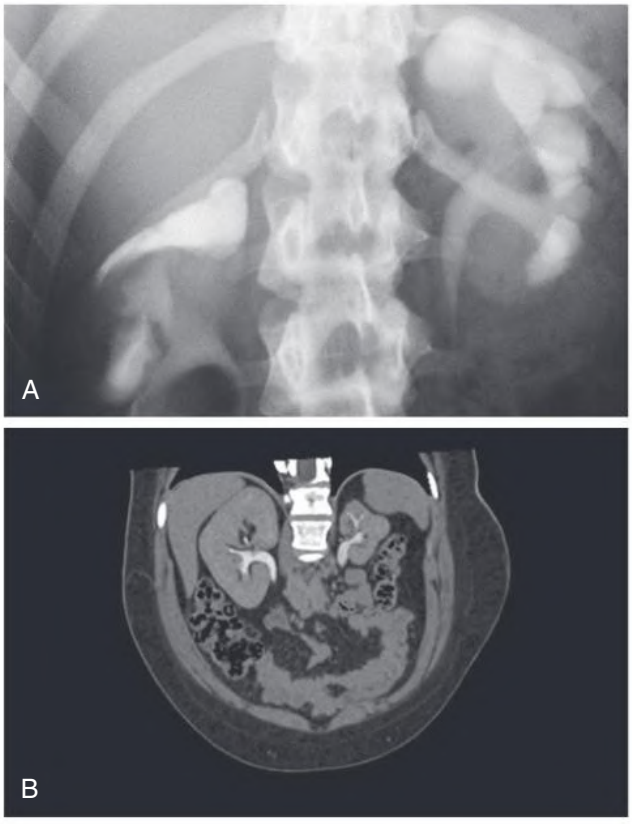

Fig. 52.2 Kidney Dysplasia. (A) Intravenous urogram *(IVU)* shows gross bilateral scarring in a 20-year-old woman who has been followed since the age of 2 years. Progressive scarring has been observed in the absence of urinary tract infections and obstruction. This probably represents primary kidney dysplasia. (B) Computed tomography IVU shows gross scarring of right kidney. (Courtesy Dr. A. Kirkham, University College Hospitals, London.)

may be useful in younger patients, particularly in those with a family history of kidney disease. With older patients, the differential diagnosis of scarred or "lumpy, bumpy" kidneys widens. Sometimes attributed to other diagnoses, including analgesic nephropathy, this appearance is often designated reflux nephropathy. In older patients, multiple scarring from atheromatous arterial disease and embolization of the kidney is an increasingly important cause of kidney failure. The diagnosis has historically been made by the radiologic features on IVU, but CT and magnetic resonance (MR) urography are now the gold standard, with scarring best demonstrated by technetium 99m–labeled dimercaptosuccinic acid (^{99m}Tc-DMSA) scintigraphy.

Absent Kidneys

Unilateral Kidney Agenesis

Complete absence of one kidney occurs in approximately 1 in 3000 live births and may result from involution of a multicystic dysplastic kidney (MCDK) or true kidney agenesis. It can be inherited as an autosomal dominant trait with incomplete penetrance and variable expression, associated with heterozygous variants in *RET* and *GREB1L*, or biallelic variants in *FRAS1* and *FREM2*.[1]

Agenesis occurs when the ureteric bud fails to develop and induce formation of the metanephros; typically, there is no ureter, and the ipsilateral half of the bladder trigone is missing. A blind-ending ureter may be seen in cases of MCDK. The remaining kidney is usually hypertrophic, but it may be ectopic, malrotated, or hydronephrotic with a megaureter and associated VUR. The more severe the dysplasia of the remaining kidney is, the earlier the presentation. The ipsilateral testis and seminal tract are usually absent, and in 10% of cases, the adrenal gland is also missing. Females can have an absent fallopian tube or ovary or malformation of the vagina or uterus. Other associations seen in 30% to 50% of those affected include imperforate anus and malformations of the vertebrae and cardiovascular system.

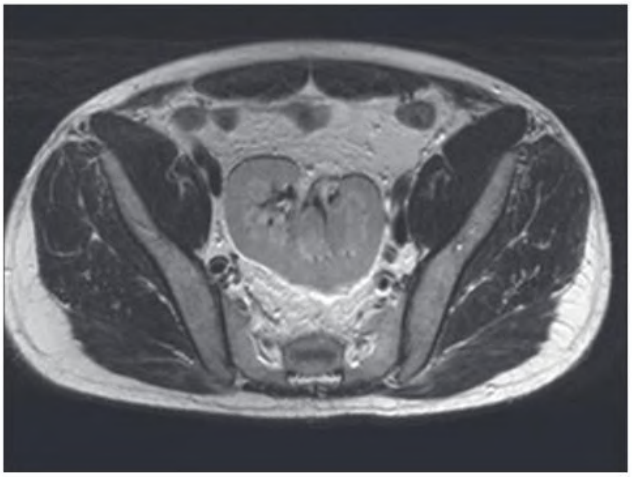

Fig. 52.3 Single Pelvic Kidney. Magnetic resonance scan, transverse section, shows single midline pelvic kidney. (Courtesy Dr. A. Kirkham, University College Hospitals, London.)

Normality of the single kidney should be confirmed by ^{99m}Tc-DMSA scintigraphy and isotopic GFR. Compensatory glomerular hyperfiltration means that lifelong follow-up is necessary to monitor for proteinuria, hypertension, and CKD, which can be seen in up to 20% of individuals. Evaluation for urogenital anomalies is recommended in all first-degree relatives of individuals with kidney agenesis.

Bilateral Kidney Agenesis

Bilateral kidney agenesis is lethal. Although usually sporadic, biallelic variants in *ITGA8* and *GFRA1* have been reported. It is associated with pulmonary hypoplasia and a characteristic facial appearance (Potter facies) caused by intrauterine compression, which is a consequence of oligohydramnios. The prevalence is about 1 in 10,000 births, with risk for occurrence in siblings of about 3%, unless there is a family history of agenesis, in which case risk rises to 15% to 20%.

Misplaced Kidneys

Kidney Ectopia, Malrotation, and Crossed Fused Kidneys

The starting position of the fetal kidney is deep in the pelvis. Kidneys that fail to ascend properly and therefore remain lower than usual occur in 1 in 1000 births (Fig. 52.3). By the eighth week of gestation, the kidney ascends, and the pelvis comes to face more medially. The most common anomaly is for the pelvis to face forward. Those that do not migrate past the pelvic brim are called pelvic kidneys. The more ectopic the kidney is, the more severe the rotation is and the more abnormal the appearance. In more than 90% of ectopia, there is fusion of both kidneys, which may cross the midline (crossed fused ectopy). This is best visualized on CT or MR urography (Fig. 52.4). Symptoms and complications, if any, are usually caused by associated VUR, but in the absence of additional anomalies or obstruction, no follow-up is required.

Horseshoe Kidney

If both kidneys are low, they may fuse at the lower pole and are usually drained by two ureters (Fig. 52.5). The kidneys lie lower than normal,

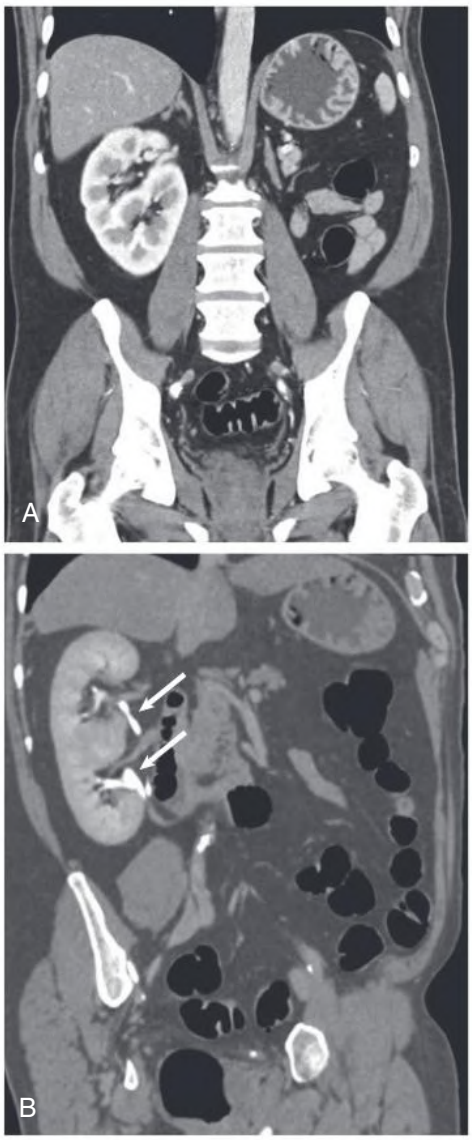

Fig. 52.4 Crossed Fused Ectopia. (A) Magnetic resonance scan shows fused kidneys on right. (B) There are two ureters *(arrows)*. (Courtesy Dr. A. Kirkham, University College Hospitals, London.)

Fig. 52.5 Horseshoe Kidney. (A) Intravenous urogram soon after pregnancy in a 25-year-old woman shows the horseshoe kidney joining in the midline as well as dilated ureters as a transient effect of pregnancy. (B) Dimercaptosuccinate scan shows a horseshoe kidney and the urinary bladder.

and further ascent is prevented by the root of the inferior mesenteric artery. Horseshoe kidney occurs in 1 in 600 to 1800 births and is more common in males (2:1). VUR and pelvi-ureteral junction (PUJ) obstruction are commonly seen with kidney calculi also occurring in up to 20%. Hydronephrosis in a horseshoe kidney should be investigated with a ^{99m}Tc-MAG3 renogram to differentiate obstruction from urinary stasis and urologic opinion sought if necessary. In most cases, individuals remain asymptomatic and do not require nephrologic follow-up.

Calyceal Abnormalities

Hydrocalyx and Hydrocalycosis

Dilated calyces are usually caused by obstruction. Focal dilation also can be caused by congenital infundibular stenosis, extrinsic compression from vessel or tumor, stones, or tuberculosis. If obstruction is excluded, the appearance is likely to be a congenital abnormality and can be an incidental finding. Moreover, if the GFR is normal and the divided function of the kidneys is 50:50, surgery to improve the anatomy should not be attempted.

Megalycosis

In megalycosis, there is bizarre dysplasia of the calyceal system with an increase in the number of calyces. There is no obstruction, and the cause is malformation of kidney papillae. Megalycosis is congenital, usually unilateral, and an incidental finding. It is much more common in males (6:1). Bilateral disease is confined to males and segmental, unilateral disease to females, which suggests an X-linked partially recessive gene with reduced penetrance in females. There may be an associated ipsilateral segmental megaureter, usually affecting the distal third.

Calyceal Diverticulum (Calyceal Cyst)

A calyceal diverticulum is a cavity peripheral to a minor calyx that is not a closed cyst but rather is connected to the calyx by a narrow channel (Fig. 52.6). It is usually an incidental finding and may manifest with symptoms relating to stones or infection within the cavity.

Bardet-Biedl Syndrome

Multiple calyceal clubbing and calyceal diverticula are the characteristic features of the kidney dysplasia seen in Bardet-Biedl syndrome (formerly known as *Laurence-Moon-Biedl syndrome*). This rare autosomal recessive condition is characterized by retinitis pigmentosa, polydactyly, obesity, hypogonadism, learning difficulties, and kidney anomalies in 80%. Calyceal malformation is associated with parenchymal

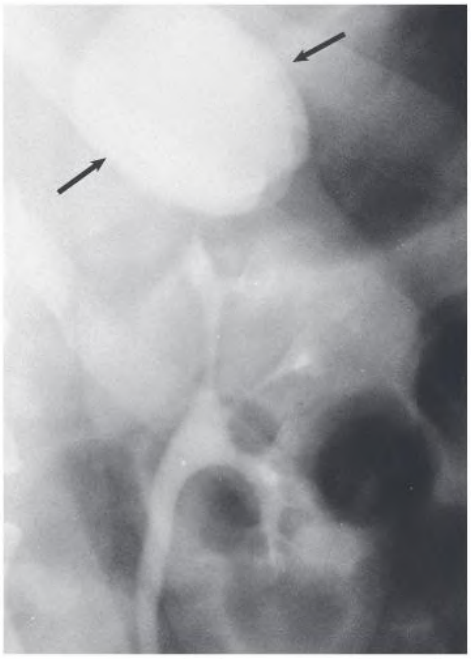

Fig. 52.6 Calyceal Cyst. Intravenous urogram shows an upper pole calyceal cyst filled with contrast *(arrows).* Plain abdominal radiograph showed a group of stones in the floor of the cyst.

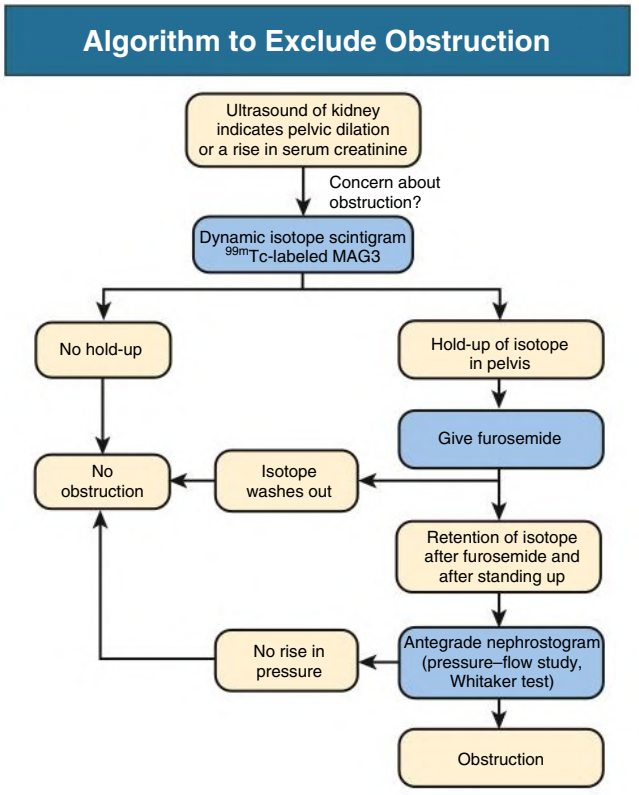

Fig. 52.7 Algorithm to Exclude Pelvi-Ureteral Junction (PUJ) Obstruction. Diagnostic path used to differentiate between significant PUJ obstruction and congenital ectasia of renal pelvis. *MAG3,* Mercaptoacetyltriglycine.

dysplasia, fetal lobulation, kidney cysts, horseshoe kidneys, and VUR; kidney failure in early adult life is common. Bardet-Biedl syndrome is caused by a defect of the basal body of ciliated cells,[21] and mutations in 22 genes coding for different proteins located in the basal body and primary cilia of the cell have been reported, making the syndrome an archetypal ciliopathy.

COLLECTING SYSTEM ABNORMALITIES

Pelvi-ureteral Junction Obstruction

PUJ obstruction occurs in 1 in 1500 live births and is one of the most common causes of antenatally detected hydronephrosis. It is seen more frequently in males (2:1), preferentially affecting the left kidney. The condition is usually congenital, caused by intrinsic stenosis or kinking of the proximal ureter at the PUJ, but can have an acquired mechanical basis as a result of external compression from an aberrant or accessory lower pole vessel or adhesions. Associated abnormalities are common, and up to 50% of infants have another urologic abnormality, such as contralateral PUJ obstruction, contralateral dysplastic and multicystic kidney, minor degrees of VUR, and contralateral kidney agenesis.

Older children can present with an abdominal mass or with intermittent flank pain that worsens during a brisk diuresis (e.g., after consumption of caffeine or alcohol), a phenomenon called Dietl's crisis. Hematuria secondary to mild trauma and UTIs may also occur. Hypertension is unusual but can occur temporarily after surgical correction.

^{99m}Tc-MAG3 diuretic renogram should be used to differentiate between significant obstruction that requires surgical correction and congenital ectasia of the renal pelvis, in which case surgery is not indicated (Fig. 52.7). Kidneys with good function can generally be left alone, and pyeloplasty is indicated only when function is clearly deteriorating (>10% decrease in split kidney function) or for symptomatic relief of pain, infection, or stones.[22]

Duplex Collecting System

Partial or complete duplication of the ureter and renal pelvis is a common anomaly, with an incidence of about 1 in 150 births; unilateral duplication is six times more frequent than bilateral. It is more common in females. If duplication has been detected in a patient, the likelihood of another sibling with duplication rises to 1 in 8.

Pathogenesis

If the ureteral bud bifurcates after its origin from the mesonephric duct but arises at a normal site, an incomplete ureteral duplication with a Y ureter will develop. Complete ureteral duplication occurs if there are two ureteral buds, one in the normal location and the other in a low position. The normal bud ends in a correct site on the trigone in the bladder and is nonrefluxing. The lower bud, representing the ureter of the lower pole of the kidney, ends in the bladder as a lateral orifice with a short submucosal tunnel. The lower pole ureter is therefore often associated with VUR.

If there are two ureteral buds, one with a normal location and one with a high position, the upper ureter can be incorporated into the developing bladder, ending more distally and medial to the normal one, or inserted ectopically elsewhere. The ectopic ureter can result in obstruction or VUR, and there is often associated dysplasia of the upper pole moiety.

Clinical Manifestations

In most adult patients, ureteral duplication is asymptomatic and causes no long-term problems. Children with ureteral duplication often have VUR. The spontaneous disappearance of reflux is less common in duplex ureters than in patients with a single ureter. Duplex ureters are

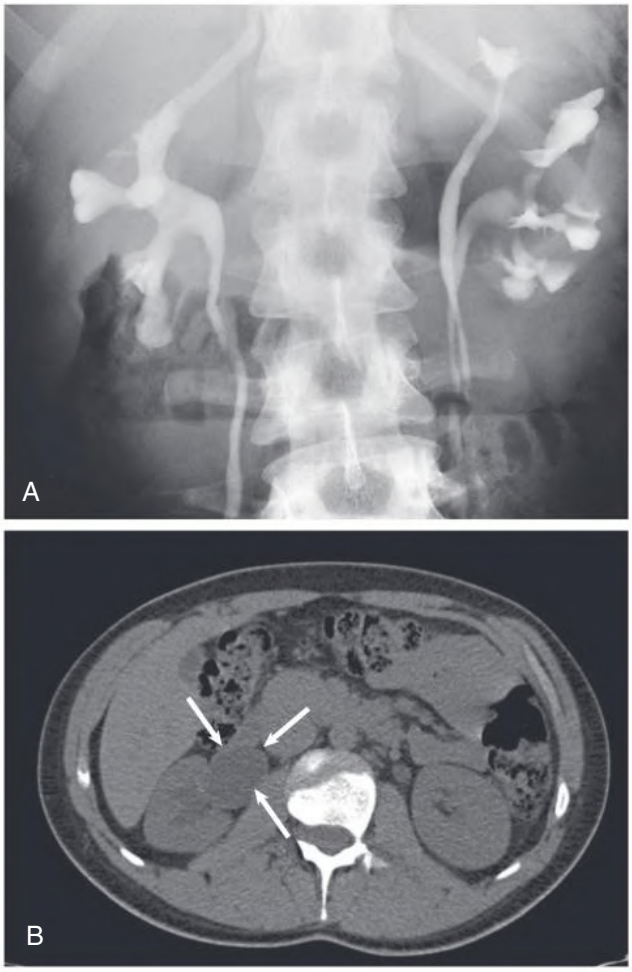

Fig. 52.8 Duplex Kidney. (A) Intravenous urogram shows a duplex left kidney. The lower pole is scarred and shows evidence of reflux damage. The two ureters enter the bladder separately, with the lower pole ureter in the abnormal location. The right kidney also shows features of reflux, with clubbing of the calyces and some scarring. (B) Computed tomography scan shows an isolated right-sided megaureter *(arrows)*.

best diagnosed by CT urogram. PUJ obstruction of the ureter draining the lower pole of the kidney can occur. Associated conditions, such as ectopic ureters and ureterocele (see later discussion), usually cause problems in early life and therefore have been addressed by adolescence. Upper pole scarring is associated with an ectopic ureter and lower pole scarring with VUR (Fig. 52.8A).

Ectopic Ureters

Ectopic ureters are almost always associated with ureteral duplication and insert along the developing mesonephric system; 10% are bilateral and there is a female-to-male ratio of 7:1. The ectopic ureter comes from the upper pole and inserts into the bladder more distally and toward the bladder neck or opens into the upper urethra. In females, the ureter may end in the bladder neck or upper urethra, vagina, cervix, or uterus, and patients present with incontinence, UTIs, or a persistent vaginal discharge, particularly if the external sphincter is damaged, as during labor.

Ectopic ureters are rare in males and manifest as UTI. Usually, there is a single ureter associated with a dysplastic kidney, which ends in the posterior urethra, seminal vesicle, or vas deferens. Males are usually continent because the ureter is proximal to the external sphincter.

Ectopic ureters are best visualized by CT or MR urography. A voiding cystourethrogram shows reflux into the lower pole of the kidney in 50% of patients.

Ureterocele

Ureteroceles are cystic dilations of the terminal segments of the ureter. Ureteroceles affect females more than males (4:1), and 10% are bilateral. Ectopic ureters and ureters with ureteroceles frequently (80%) drain the upper pole of a duplex collecting system and are often associated with dysplastic or nonfunctional kidney tissue. These usually present in childhood with infection; when large, they can obstruct the bladder neck or even the contralateral ureter. In adults, ureteroceles typically manifest with stones in the lower ureter.

First-line management of ureteroceles is endoscopic decompression, although partial nephroureterectomy, ureteral reimplantation, or ureterocele excision and bladder neck reconstruction may be required. There are usually no medical sequelae.

Megaureter

Primary megaureter occurs in 3 to 4 per 10,000 live births, is seen more frequently in males, and is bilateral in 30% to 40% of cases. Isolated dilation of the ureter does not necessarily imply obstruction. There are three broad groups of conditions with widely dilated ureters, as follows:

1. *Obstruction of the ureter itself.* This may be intrinsic (e.g., stone) or extrinsic (e.g., retroperitoneal fibrosis); it is not associated with reflux.
2. *Bladder outflow obstruction, with secondary ureteral obstruction.* Examples include a neuropathic bladder and posterior urethral valves; this may or may not be associated with reflux.
3. *A dilated but nonobstructed ureter.* This often occurs without reflux, and there can be normal kidney function; this may be caused by an adynamic segment of the lower ureter (see Fig. 52.8B).

Pathogenesis

In the normal ureter, there is a characteristic helical orientation of muscle fibers. When the megaureter is secondary to bladder outflow obstruction, there is muscle hyperplasia and hypertrophy of the ureteral wall. In primary megaureter, a variety of abnormalities of muscle orientation are described or there may be absence of muscle fibers at the proximal end of the undilated segment. Electron microscopy shows an increase in collagen between the muscle bundles at the level of the obstructing segment. Obstruction appears to be caused by a failure of peristalsis through the distal ureteral segment.

Clinical Manifestations

Most cases of megaureter associated with obstruction present in childhood with severe infections, often complicated by septicemia. These patients have a high incidence of other congenital abnormalities. In less severe cases or with no obstruction, patients can present with abdominal pain, loin pain, hematuria, and UTI. Kidney stones can form easily in the dilated systems. The exclusion of obstruction is often established only by an antegrade pressure-flow study (Whitaker test), in which a nephrostomy is placed in the renal pelvis and contrast material infused at 10 mL/min.[23]

Treatment

It must be definitively determined whether obstruction exists (see Fig. 52.7). The current view is that patients with asymptomatic nonobstructed disease should be managed conservatively, and most do well with this approach, with spontaneous remission rates of up to 85%.

Vesico-ureteral Reflux

VUR describes the retrograde passage of urine from the bladder to the upper tract. Such patients fall into two broad groups. First, there is a group of patients who appear to have normal bladders without outflow obstruction and normal caliber ureters when not micturating, described as having primary VUR resulting from a congenitally shortened intravesical ureter. The remainder have some form of anatomic or functional bladder outflow dysfunction that causes secondary VUR and dilated upper urinary tracts, the most common cause of which is PUV in males. VUR has an incidence of around 1%, is seen more frequently in females, and usually spontaneously regresses with age. Although previously believed to cause "reflux nephropathy" or "chronic pyelonephritis," where recurrent infection leads to acquired kidney scarring, advances in genetics and developmental biology indicate that kidney impairment is usually the result of associated primary kidney dysplasia rather than reflux itself.

Pathogenesis

There is a strong familial association with primary VUR; 27% of siblings and 36% of offspring of affected parents have been found to have VUR.[23] Linkage and genome-wide studies have yet to identify any robust genetic associations, highlighting the heterogeneity of this often-undiagnosed condition.

Clinical Manifestations

VUR is usually diagnosed after a febrile UTI by voiding cystourethrogram (VCUG). Severity is graded I to V with grades IV and V (high-grade VUR) defined by gross dilation of the ureter and collecting system, blunting of the calyces, and tortuosity of the ureter (see Chapter 62). The higher the grade, the less likely it is that spontaneous resolution will occur and the higher the prevalence of recurrent symptomatic UTI. US and DMSA imaging should be undertaken to look for associated kidney anomalies, differential function, and cortical defects. Concurrent lower urinary tract symptoms may also occur.

Treatment

Management of VUR aims to prevent recurrent infections and preserve kidney function. In children, antibiotic prophylaxis reduces the risk of recurrent UTI but has not been shown to have an effect on kidney scarring.[24] Indications for surgical intervention include grade III to V reflux, which does not spontaneously remit and is associated with breakthrough infections on prophylaxis. Endoscopic injection of a bulking agent around the intravesical ureter (DEFLUX) or open ureteric reimplantation are valid options, although VUR is more likely to recur after endoscopic correction. Current guidelines do not recommend the screening of siblings or offspring because of uncertainty regarding the clinical importance of asymptomatic VUR.

BLADDER AND OUTFLOW DISORDERS

Prune-Belly Syndrome

Prune-belly syndrome (PBS) nearly always affects males and is characterized by the absence of anterior abdominal wall muscles, bizarre malformations of the urinary tract with gross dilation of the bladder and ureters, and bilateral undescended testes.[25] When the disorder is diagnosed early, kidney outcome is related to the degree of kidney dysplasia. There are incomplete forms of PBS (pseudoprune). Rarely, a similar megacystis or megaureter may be seen in a male or female patient.

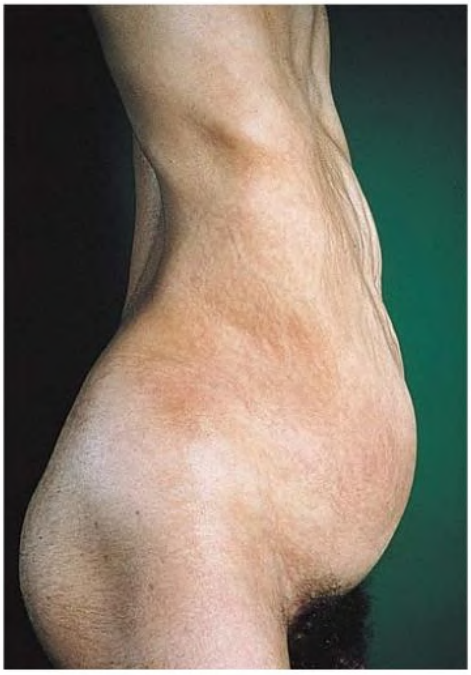

Fig. 52.9 Prune-Belly Syndrome. Note the lax abdominal musculature leading to a pot-bellied appearance. There is also marked thoracic cage deformity. (Courtesy Prof. C.R.J. Woodhouse, University College Hospital, London.)

Pathogenesis

The incidence of PBS varies from 1 in 35,000 to 1 in 50,000 live births. Some familial cases have been reported, implicating genes affecting smooth muscle function. Biallelic loss-of-function mutations in *CHRM3*, a muscarinic acetylcholine receptor involved with parasympathetic-mediated detrusor contraction, have been identified in one family with prune-belly–like syndrome.[26] There is also evidence for a primary, localized arrest of mesenchymal development, supported by the lack of prostatic differentiation; the epithelial element in the prostate is absent or hypoplastic. Ultrastructure studies of the ureter show massive replacement of smooth muscle with fibrous and collagen tissue and the absence of nerve plexuses. An almost identical syndrome can result from fetal urethral obstruction, including urethral atresia.

Clinical Manifestations

The prognosis depends on the degree of kidney dysplasia and injury. Three prune-belly groups can be distinguished.[25] In group I (20%), complete urethral obstruction causes stillbirth or neonatal death. In group II (20%), acute, early presentation requires diversion and reconstruction. In group III (60%), good health and kidney function continue despite urologic appearances.

There is complete absence or incomplete formation of the rectus abdominis and other muscles, which leads to the wrinkled abdominal wall of the prune infant (see Fig. 52.10C). This gives way to a fairly smooth "pot belly" in later life (Fig. 52.9). Reconstructive surgery is not normally required. The patients grow up physically active and strong but cannot sit up directly from a supine position. Abnormalities of the thoracic cage, such as pectus excavatum, are common.

Although true outflow obstruction may be present, the gross and irregular dilation of the urinary tract characteristic of PBS is primarily caused by a developmental defect with a variable degree of smooth muscle aplasia leading to aperistaltic ureters (Fig. 52.10A–B).

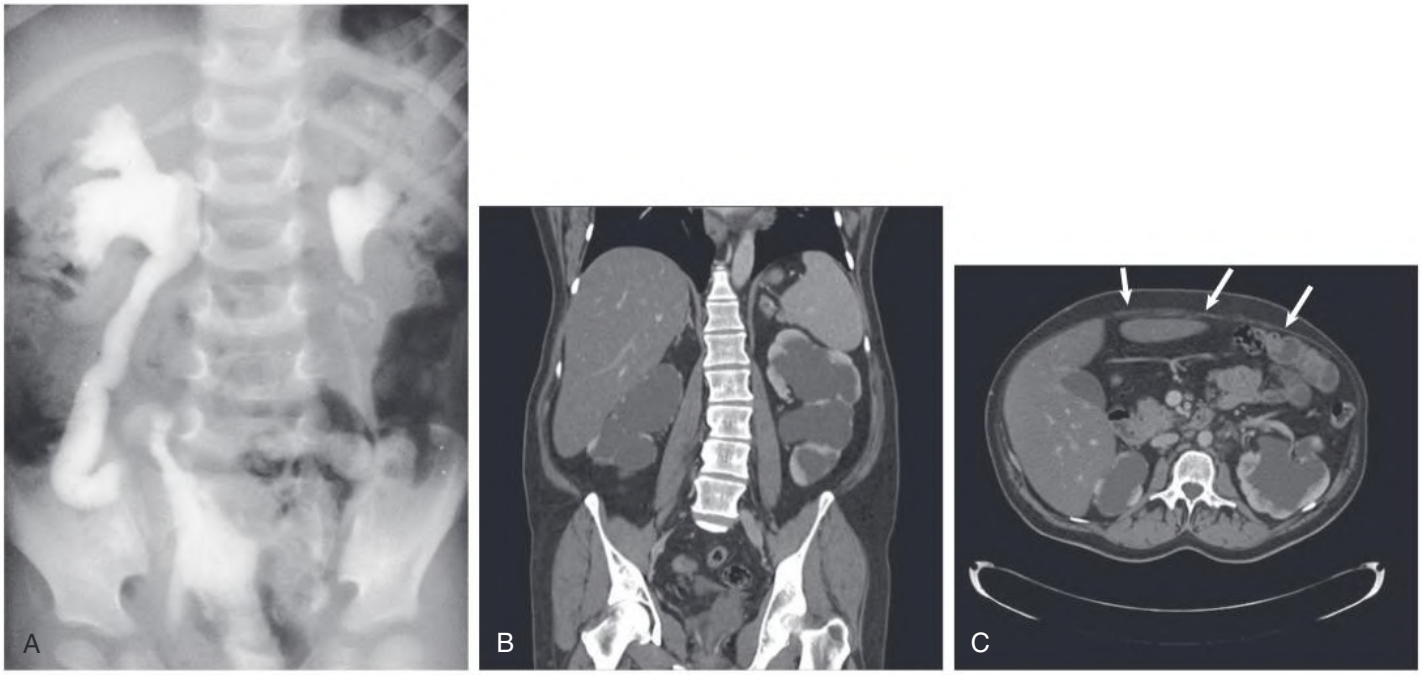

Fig. 52.10 Prune-Belly Syndrome. (A) Typical intravenous urogram appearance of a patient with prune-belly syndrome and good kidney function. Often, the ureters are extremely dilated and tortuous. (B) Computed tomography urogram showing gross bilateral hydronephrosis. (C) Absence of anterior abdominal wall musculature *(arrows)*.

Urodynamic studies are often difficult to interpret because of gross VUR, but typically there is a low-pressure bladder with significant residual urine volumes. With late manifestation, some patients have detrusor instability. UTIs are common as a result of VUR and urinary stasis with constipation resulting from a defective Valsalva maneuver also increasing susceptibility.

Differential Diagnosis

In severe cases of megacystis or megaureter with gross impairment of kidney function (often with dysplastic kidneys), the differential diagnosis of PBS includes PUV, kidney dysplasia with or without multiple congenital defects, or neuropathic bladder.

Natural History

Once any outflow obstruction is addressed, usually in infancy, the GFR should remain stable despite the frightening radiologic appearances. In PBS patients observed in our unit for up to 40 years, kidney deterioration and hypertension have been rare. In the small number who have progressed, recurrent infection, hypertension, and proteinuria have been warning signs of impending trouble. Kidney scarring should be assessed by isotopic DMSA scintigraphy and kidney function followed by serial isotopic GFR measurements. Lifelong attention to blood pressure, UTIs, and stones is necessary.

Treatment

In all children with PBS, even with good kidney function, a careful search for obstruction should begin with the urethra and work up to the PUJ. Often, however, no obstruction is found, and no surgery is required. In many other patients, the floppy bladder is not anatomically obstructed, but bladder emptying is improved by urethrotomy ("functional obstruction"). In infancy, there is debate about the need for reconstructive surgery. Certain patients born with severely compromised kidney function require reconstruction after stabilization by early diversion.

The current view is that the testes should be brought down to the scrotum (orchiopexy) in infancy in the hope that earlier surgery will produce proper germ cell development and thus preserve fertility. Although men with PBS have azoospermia, and are by definition infertile, there are case reports of successful paternity using intracytoplasmic sperm injection.

Bladder Exstrophy (Ectopia Vesicae)

Classic bladder exstrophy is the failure of the anterior abdominal wall and bladder to close, resulting in an open, inside-out appearance. These anomalies form part of the bladder exstrophy-epispadias complex (BEEC), which range from epispadias of an otherwise normal penis to major cloacal abnormalities (Fig. 52.11). The condition occurs in 1 in 50,000 births. The male-to-female ratio is 2:1.

Pathogenesis

Failure of growth of the lower abdominal wall between the allantois and the urogenital membrane coupled with breakdown of the urogenital membrane leaves a small, open bladder plate, a low-placed umbilical root, and diastasis of the pubic bones (Fig. 52.12B). The genital tubercle is probably placed lower in these patients, and the cloacal membrane ruptures above it, leading to a penis with an open dorsal surface that is continuous with the bladder plate. A midline closure defect causes a failure of fusion of the lower anterior abdominal wall, including the symphysis pubis, lower urinary tract, and external genitalia. Familial clustering suggests a genetic basis for the disorder, and association with the *ISL1* locus and 22q11.2 duplications have been reported.[27]

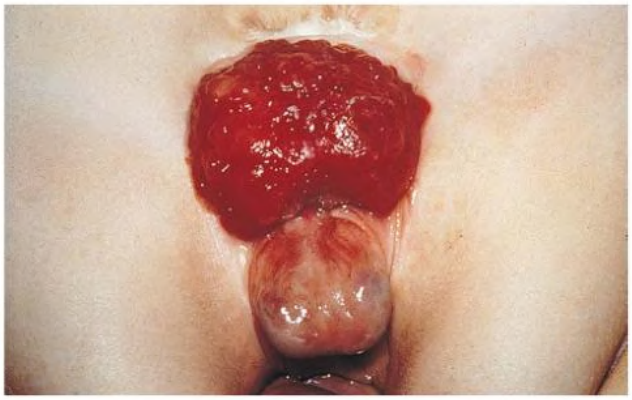

Fig. 52.11 Bladder Exstrophy. The entire length of the penis is also open (epispadias). (Courtesy Prof. C.R.J. Woodhouse, University College Hospital, London.)

Clinical Manifestations

In severe cases, the bladder mucosa lies exposed on the lower abdominal wall, with the bladder neck and urethra laid open. The prostate and testes are normal. Most patients have normal kidneys at birth, but approximately 18% are reported to have duplex, ectopic, or hypodysplastic kidneys.[28] Kidney function may be preserved after urinary diversion, although reflux is common (see Fig. 52.12A). Other congenital abnormalities affecting the heart, abdomen, skeleton, and joints are seen in approximately 50%.[28] More severe cloacal abnormalities are associated with imperforate anus and high or low rectal atresia.

Natural History

Long-term kidney outcome depends on the bladder. In a study with 12-year follow-up, the kidneys survive much better with a well-functioning bladder; 13% of those with a good bladder had significant kidney damage compared with 82% with ileal conduits, 22% with non-refluxing colonic conduits, and 33% with ureterosigmoidostomy.[29] Currently, the bladder is most commonly augmented (enterocystoplasty, ileocystoplasty, caecocystoplasty) or occasionally replaced by bowel (intestinal reservoir). In a study of 53 such patients monitored for more than 10 years, kidney function deteriorated (GFR decrease ≥20%) in only 10 patients.[30]

Treatment

When the infant is born, the three urologic treatment goals are to close the abdominal wall, establish urinary continence to preserve kidney function, and reconstruct cosmetically acceptable genitalia. Surgery can be performed using either a staged or complete primary repair approach. The aim of initial surgery is to close the bladder, posterior urethra, and abdominal wall and convert the defect to a complete epispadias (Fig. 52.13). Repair of the epispadias is carried out later in infancy followed by reconstruction of the bladder neck and bilateral ureteral implantation at the age of 4. If the bladder is small, intestinal augmentation is required. Patients may be able to void, but many have to use catheters. Incontinence may be a long-term problem.

Neurogenic Bladder

In childhood, the most common cause of a neurogenic bladder is myelomeningocele, although with antenatal diagnosis and termination of affected pregnancies, as well as folate supplementation, it is becoming less common. A neurogenic bladder may also be seen without associated neurologic or other obvious causes (Table 52.3). The principal consequences are incontinence, infection, and reflux with upper tract dilation and subsequent kidney failure. Early urodynamic assessment is essential (Fig. 52.14). Three different patterns of bladder behavior are seen: contractile, intermediate, and acontractile.

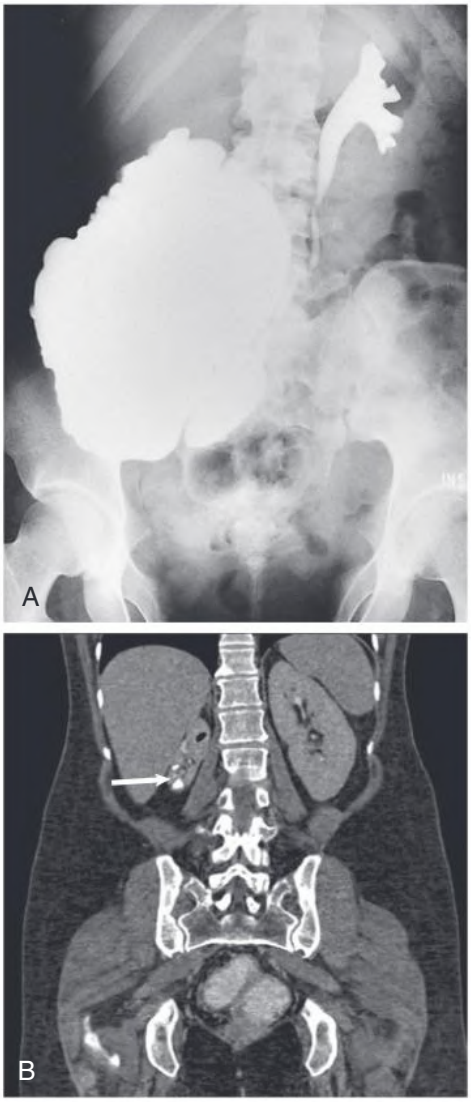

Fig. 52.12 Cystography in Bladder Exstrophy. (A) A 26-year-old woman with bladder exstrophy who has a continent Mitrofanoff system (see Fig. 52.18) with use of the colon to create a reservoir. There is reflux into the left kidney. Reflux also occurs into the right kidney, but the kidney is obscured by the full reservoir. Glomerular filtration rate is 130 mL/min. (B) Magnetic resonance scan of a patient with bladder exstrophy shows a scarred, small left kidney with several kidney calculi *(arrow)*. Note widely splayed symphysis pubis.

Contractile Behavior

An overactive detrusor (hyperreflexia) can produce some bladder emptying (incontinence). Unfortunately, 95% of patients have sphincter dyssynergia (inability to relax the urethral sphincter), which results in no relaxation and incomplete emptying of the bladder. Patients with incomplete lesions may have some control of the distal sphincter and normal anal and sacral reflexes. Ironically, although this latter group has the least neurologic deficit, they have the worst bladder situation, generating high pressures and great risk for kidney injury. The bladder becomes progressively hypertrophic, fibrotic, and poorly compliant.

Fig. 52.13 Epispadias. Result of multiple surgeries to close the epispadias and to lengthen the penis. (Courtesy Prof. C.R.J. Woodhouse, University College Hospital, London.)

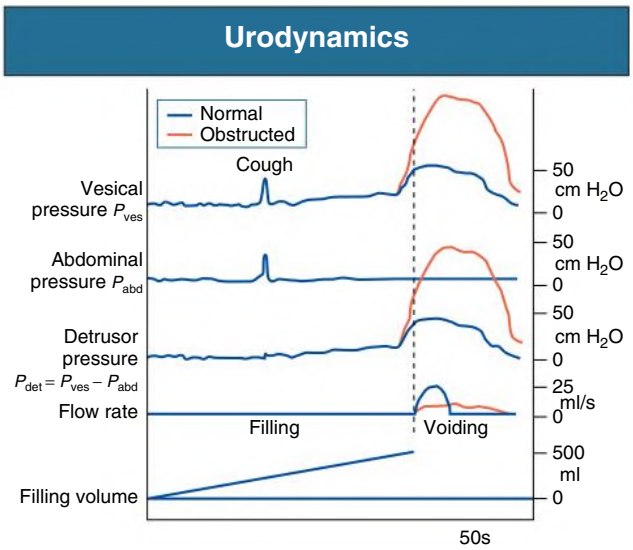

Fig. 52.14 Urodynamic Assessment by Cystometrography. The vesical pressure is measured simultaneously with the abdominal pressure through the rectum; the detrusor pressure is the difference. A cough is used as a marker to show that the system is working. During filling, the first desire to void is normally at a detrusor pressure of <10 cm H_2O. This point is noted. The voiding pressure should normally be <40 cm H_2O (and is lower in women). Detrusor instability is an unstable (spontaneous) contraction occurring with a detrusor pressure >15 cm H_2O. Higher pressure can cause incontinence. In combination with radiologic imaging (videocystometrography), the following are recorded: bladder neck, closed or open; bladder pressure, end filling; voiding detrusor pressure; bladder stability; compliance; flow rate, maximum; sensation, first; volume, voided and residual. (Courtesy Prof. M. Craggs, University College London.)

TABLE 52.3 Causes of Neurogenic Bladder

Site of Lesion	Causes
Cerebral	Cerebrovascular accident, cerebral palsy, encephalopathy, trauma, Parkinson disease, dementia
Spinal	Isolated (no other neurologic features), trauma, multiple sclerosis, compression, spina bifida, spinal dysraphism, tethered cord, sacral agenesis, sacral teratoma
Peripheral nerve	Pelvic surgery, diabetes

Botulinum toxin A can be injected into the bladder wall to improve compliance and reduce bladder pressure; it is increasingly being used in children with neurogenic bladders to delay or avoid the need for augmentation cystoplasty.

Intermediate Behavior

These patients have some detrusor activity but not sufficient to empty the bladder. These intermediate bladders are poorly compliant, and patients have no voluntary control of their sphincters. Any rise in bladder pressure tends to cause incontinence, or the high intravesical pressures lead to kidney injury.

Acontractile Behavior

About 25% of patients have no detrusor activity, and the bladder overflows when it is sufficiently full. This acontractile bladder is not usually associated with kidney failure.

Myelodysplasia

Myelodysplasia refers to a group of neural tube anomalies that primarily affect the lumbar and sacral segment of the spinal cord and are the most common cause of neurogenic bladder dysfunction in children. *Spina bifida* reflects defective fusion of the posterior vertebral arches, of which there are several different types. *Meningocele* implies that the meninges extend beyond the confines of the vertebral canal with no neural elements contained inside. The most severe type of spina bifida is *myelomeningocele,* which has neural tissue protruding with the meningocele. Closed s*pinal dysraphism* (spina bifida occulta) defines a group of structural anomalies of the caudal end of the spinal cord that do not result in an open vertebral canal but are associated with incomplete fusion of the posterior vertebral arches and are usually asymptomatic. *Sacral agenesis* is a rare anomaly in which part or all of two or more vertebral bodies is absent. It occurs early in fetal development when there is failure of ossification of the lowest vertebral segments. and is strongly associated with maternal type 1 diabetes.[31] Partial sacral agenesis can be associated with an anterior meningocele.

Pathogenesis

The neural tube normally forms as the neural folds close over and fuse, starting in the cervical region and progressing caudally. The embryologic defect is likely an incomplete tubularization of the neural tube, with inadequate mesodermal invagination and subsequent arrest of vertebral arch formation.

The incidence of myelodysplasia varies from 1 to 7 in 1000 live births, but there are wide geographic variations. Monozygotic twins are often discordant for spina bifida, but siblings are at increased risk (1:10–1:20), and children of affected parents have a 4% chance of having a similarly affected child. Myelomeningocele accounts for more than 90% of myelodysplastic infants. Folic acid supplements taken during the first trimester reduce the incidence of myelodysplasia by 70%.[32]

Clinical Manifestations

All causes of tethered cord can produce a variable neurologic deficit. During development, some children experience progressive neurologic disturbance with bladder dysfunction, bowel dysfunction, scoliosis, and a syndrome of pes cavus and limb growth failure. Learning

difficulties may also be seen in individuals with myelomeningocele, especially those who have required ventriculoperitoneal shunting for associated hydrocephalus.

Bladder dysfunction. Nearly all individuals with myelomeningocele have a neurogenic bladder, which may result in urinary incontinence and an adverse impact on the upper tracts. It can be an isolated problem with abnormal urodynamic studies but a normal neurologic examination.

Bowel dysfunction. Bowel dysfunction is often present and needs to be treated accordingly. There may be severe constipation and overflow incontinence. First-line management involves the use of laxatives, suppositories, and enemas, followed by transanal irrigation or antegrade continent enterostomy for those who have refractory symptoms. The appendix is brought out to the abdominal surface, and thus the colon can be irrigated antegrade with saline.

Natural History

About 14% of patients have kidney complications at birth and are at high risk in the next few years. Ultimately, 26% will develop CKD and 1.3% ESKD by early adulthood, with continence achieved in 37%.[33] Poor kidney outcome can be predicted by urodynamic findings, with worst outcomes related to increased bladder wall thickness, degree of reflux, urethral pressures above 70 cm H_2O, and reduced bladder capacity (Fig. 52.15). VUR occurs in 3% to 5% of newborns with detrusor hypertonicity or dyssynergia. Without treatment, this increases to 30% to 40% by age 5 years.[34]

Treatment

Management of the bladder depends on the urodynamic findings. In the 1970s, clean intermittent self-catheterization was introduced, but before that time, urinary diversion was the usual treatment. Currently, management is early initiation of intermittent self-catheterization, and antimuscarinic drugs (e.g., oxybutynin) are used for high pressure, hyperreflexic bladders with VUR to increase bladder compliance. Intravesical administration of oxybutynin should be considered in individuals with severe side effects (dry mouth, facial flushing, blurred vision, heat intolerance). With persisting symptoms related to bladder storage or detrusor overactivity, bladder wall injection with botulinum toxin type A1 is offered, with effects lasting 15 months on average.[35] In the presence of deteriorating kidney function or intractable symptoms, ileal or colonic bladder augmentation and creation of continent catheterizable channels may be required.[36]

Bladder Outflow Obstruction

Congenital bladder outflow obstruction is rare and is usually caused by a neurogenic bladder, PUV, or an ectopic ureterocele.

Posterior Urethral Valves

PUV are the most common cause of severe subvesical obstruction, occurring in 1 in 4000 male births.[37] As a result, bilateral hydronephrosis and megaureter occur. Obstruction is caused by a diaphragm that extends from the floor to the roof of the urethra at the apex of the prostate. Valves appear as mucosal folds in the posterior urethra below the verumontanum. There is dilation of the proximal urethra and bladder wall hypertrophy and trabeculation. Above the valves, the prostatic urethra dilates, undermining the bladder neck. The valves obstruct flow only in one direction, and therefore a catheter can be passed without difficulty.

Pathogenesis

The urethra develops in two parts: differentiation of the urogenital sinus (posterior urethra) and tubularization of the urethral plate (anterior urethra). Persistence of the urogenital membrane and abnormal integration of the mesonephric (Wolffian) duct into the posterior urethra have been proposed as potential mechanisms underlying PUV. Monogenic defects appear to be rare, although heterozygous variants in *BNC2*, a zinc finger protein expressed in the embryonic urethra, have been identified in familial PUV.[27]

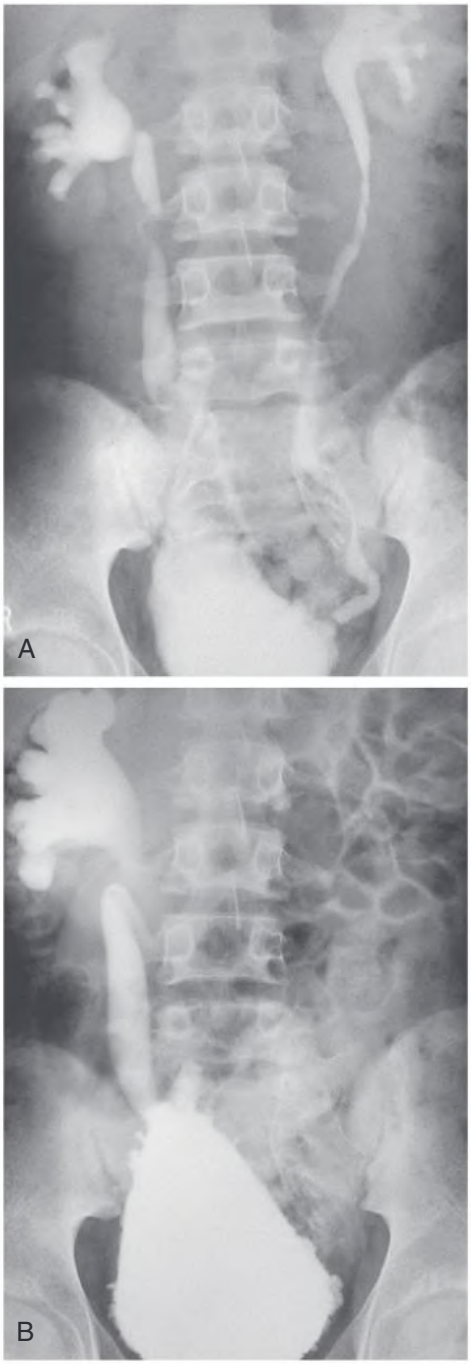

Fig. 52.15 Sacral Spina Bifida With Neuropathic Bladder. (A) Intravenous urogram shows evidence of a previous hydronephrosis and subsequent scarring of the right kidney. The architecture of the left kidney is well preserved. (B) Micturating cystogram. The typical tapering, hypertrophied, trabeculated bladder gives the characteristic "pinecone" appearance. Note the gross reflux on the right side. This is probably helping to protect the left kidney by acting as a "pop-off" mechanism. This is analogous to the protection that can occur in males with posterior urethral valves.

Clinical Manifestations

Most cases of PUV are detected antenatally on US as evidenced by bilateral hydronephrosis, dilated bladder, posterior urethra (keyhole sign), and, in severe cases, oligohydramnios. Infants present with a palpable distended bladder and enlarged kidneys, abnormal urine stream, or failure to thrive as a result of kidney failure. Kidney dysplasia is common and around a third of children also have VUR.[38] Children with less severe disease present with poor stream, incontinence, UTI, or kidney failure. However, late presentation is also associated with worse outcome.[39]

Three abnormal features can help protect the kidney, reducing the high pressures generated during voiding: massive unilateral reflux, usually with ipsilateral kidney dysplasia (thereby protecting the other kidney); large bladder diverticulum; and urinary extravasation, often with urinary ascites. These protective mechanisms are referred to as *pop-off mechanisms* (see Fig. 52.15B).[40] US can show the bladder thickening, dilated system, and dilation of the posterior urethra. A specific diagnosis should be documented by videocystometrography (see Urodynamics).

Natural History

In the 1960s, 25% of children with PUV died within the first 12 months, and 25% died later in childhood, including fatalities because of ESKD. By the late 1990s, early mortality was less than 5%,[41] and lifetime risk of ESKD is now estimated at 28.5%, reached in the majority before the age of 30.[42] The bladder may become stretched, resulting in poor emptying, or unstable, leading to poor compliance, unsuppressed detrusor contractions, and high storage pressure. Both situations are exaggerated by progressive polyuria. Such patients may have a daily urine volume of 5 L. Urodynamic follow-up studies suggest that instability decreases with time; bladder capacity increases, but there are unsustained voiding contractions. Prognosis correlates with the nadir serum creatinine value once obstruction has been relieved and with the degree of bladder dysfunction.[43] Despite adequate early treatment, CKD as a result of bladder dysfunction and associated kidney dysplasia develops in many children.[42,43]

Treatment

All children have endoscopic transurethral resection of their valves in infancy. Bladder diversion should be avoided. Bladder instability and poor bladder compliance must be treated, regardless of whether symptoms result. Males with substantial residual volumes can be managed by clean intermittent self-catheterization, but adherence is often poor because of urethral discomfort or because previous urethral surgery has made the passage of catheters difficult. Adherence is a particular problem with adolescents who are continent and for whom kidney failure is too abstract a concept. Continence often improves spontaneously at puberty but can be helped by imipramine. Deterioration in GFR will require further examination of urine flow rate and exclusion of urethral stricture.

Urethral Diverticulum

Urethral diverticulum usually occurs in males and is rare. It may manifest with UTI, obstruction, or stones. The two types are anterior and posterior. The anterior type can be associated with anterior urethral valves and obstruction.

Other Congenital Causes of Bladder Outflow Obstruction

Urofacial Syndrome

Urofacial syndrome (UFS), or Ochoa syndrome, is a rare autosomal recessive disease characterized by facial grimacing when attempting to smile and failure of the urinary bladder to void completely, despite a lack of anatomic bladder outflow obstruction or overt neurologic damage.[27] Patients present with enuresis and UTI and all the features of a neurogenic bladder together with dilated upper tracts. They are at risk for kidney failure. Biallelic mutations of *HPSE2* and *LRIG2* have been reported. The proteins they encode are detected in nerves found in the fetal bladder, implying UFS may be a peripheral neuropathy of the bladder.[27] UFS is part of a spectrum of congenital bladder disorders that include nonneurogenic neurogenic bladder or Hinman syndrome.

BOX 52.1 General Principles of Management of Congenital Urinary Tract Abnormalities

- Educate to encourage adherence.
- Review urologic status.
- Find cause of urinary tract obstruction and treat.
- Control blood pressure.
- Monitor kidney function and proteinuria.
- Treat acidosis.
- Prevent bone disease.
- Check for stones.
- Institute clean intermittent self-catheterization for chronic urinary retention.
- Maintain bladder storage pressure <40 cm H2O.
- Maintain bladder volume <400 mL.

Gonadal Dysgenesis

Disorders of sex development, gender identity, and micropenis are beyond the scope of this chapter and rarely encountered in adult practice. Patients will be met, however, with ESKD who are phenotypically female but are genotype XY and have mutations of *WT1* (Denys-Drash and Frasier syndromes). They have gonadal dysgenesis and must have their streak ovaries removed; otherwise, gonadoblastomas will develop.

GENERAL MANAGEMENT OF CONGENITAL KIDNEY AND URINARY TRACT ABNORMALITIES

The principles of management of congenital urinary tract abnormalities are shown in Box 52.1. The most important part of the management is ensuring that the patient, family, and primary care physician know what can and must be done. First, they must understand the necessity of long-term follow-up at least annually. ESKD often occurs when a patient is lost to follow-up, often manifesting later with accelerated hypertension and rapid loss of GFR.

Clinical Evaluation

By the time the adolescent attends an adult clinic, it is assumed that the urinary tract is not obstructed and that further surgery is not required. Nevertheless, it is the responsibility of the nephrologists and urologists who care for these young people to review this aspect periodically.

Symptomatic UTI is common and must be treated promptly. Increase in frequency or severity of infections must lead to investigations to find the cause.[44] The BP must be monitored regularly and kept normal. Finally, kidney function must be monitored, proteinuria assessed, and the cause of any deterioration identified. As in any kidney condition, the residual GFR may decline inexorably, which is associated with increasing proteinuria and hypertension. As with other kidney conditions, kidney function is usually stable when proteinuria is minimal or absent. Deterioration in the absence of proteinuria must alert the physician to the likelihood of obstruction or the adverse effect of a nephrotoxic drug.

TABLE 52.4 Monitoring Patients With Congenital Urinary Tract Abnormalities: Routine Investigations for Assessment of Clinical Status

Baseline Measurements	Reason for Test
Radiology	
CT KUB	Exclude stones
Ultrasound	
Ultrasound of kidneys	Assess kidney size and hydronephrosis
Ultrasound of bladder after micturition	Assess residual volume
Urine flow rate	Ensure adequacy
Scintigraphy	
Glomerular filtration rate: ^{51}Cr-labeled EDTA	Baseline kidney function
Dynamic isotope scan: ^{99m}Tc-labeled MAG3 or DTPA	Assess outflow obstruction
Static isotope scan: ^{99m}Tc-labeled DMSA	Assess scarring and divided function
Biochemistry	
Urine protein-creatinine ratio	Assess proteinuria

^{51}Cr, Chromium-51; *CT,* computed tomography; *DMSA,* dimercaptosuccinic acid; *DTPA,* diethylenetriaminepentaacetic acid; *EDTA,* ethylenediaminetetraacetic acid; *KUB,* kidney, ureter, bladder; *MAG3,* mercaptoacetyltriglycine; *^{99m}Tc,* technetium-99m.

The routine investigations performed to document the current situation act as a reference point for the future (Table 52.4). If the bladder empties completely with an adequate flow rate (15 mL/s), no problems should arise. If there is any doubt about the condition of the bladder, urodynamic investigations are necessary. If the clinical situation changes, further investigations are required. An increase in UTIs might suggest a stone or increase in residual urine. With an unexpected decline in kidney function, obstruction again must be excluded.

The patient should keep a 24-hour urine volume diary every 6 to 12 months, recording the time of voiding and volume passed. It is best to ask patients to do this on 2 consecutive days to determine the maximum bladder capacity and the total 24-hour urine volume. This should be done before urodynamic investigations because results can be misleading if the bladder is not filled to capacity.

Exclude Obstruction

Obstruction must always be excluded if there is a decline in GFR. The possibility of obstruction may be raised by a routine US (see Fig. 52.7) and should be pursued with ^{99m}Tc- MAG3 scintigraphy to exclude obstruction (Fig. 52.16).

In patients with conduits, obstruction can be excluded by infusion of contrast material into the loop (loopogram) and demonstration of reflux up the ureter.

Rarely, in patients with large bladders or in transplant recipients, the kidney may become obstructed when the bladder reaches a certain volume. This can be investigated by filling the bladder by catheter and performing ^{99m}Tc-labeled MAG3 scintigraphy, initially with the bladder full. If there is no excretion, the bladder volume can be reduced in 100-mL increments until there is flow down the ureter (Fig. 52.17).

Urodynamics

Any urodynamic investigation should start with a free urine flow rate. Provided the flow rate is normal and the bladder empties completely (leaving no residual volume on postmicturition US), it can be assumed that there is no significant bladder outflow obstruction.

Complete investigation of abnormalities of bladder and urethral function requires synchronous recordings of intravesical and intrarectal pressures taken during bladder filling and emptying (see Fig. 52.14). Combined with radiologic imaging, the study is known as *videocystometrography* (VCMG).

Surgical Correction of the Urinary Tract

A normal bladder acts as a low-pressure, good-volume urine reservoir that is continent, is sterile, and empties freely and completely. Any other form of urine reservoir aims to recreate such an environment. When this is not achieved in either a natural or a reconstructed bladder, complications such as sepsis and kidney dysfunction can occur.

A variety of conduits and continent reservoirs have been developed to replace unusable bladders. Ileal conduit diversion has been most widely used for native kidneys, although deterioration in kidney function frequently results from long-term complications, including urosepsis, kidney calculi, and, most often, stenosis, leading to obstruction or reflux with ureteral dilation. There is an overall complication rate of 45%, but with a high index of suspicion and an aggressive diagnostic and therapeutic approach, many of these problems can be detected and treated early, with resultant good long-term function of native kidneys. Similar results may be obtained when kidney transplantation is performed in these patients.[45] Other forms of urinary diversion that are continent and therefore more socially acceptable to patients are now widely used in general urologic practice and are being encountered in kidney transplantation (see Fig. 52.12A). These forms include augmented bladders draining through the urethra and augmented or intestinal bladders draining through continent stomas.

COMPLICATIONS

Urinary Tract Infections

Symptomatic UTIs are common. Risk factors include stagnation of urine, stones, foreign bodies (stents, catheters), previous infections, and kidney scarring. UTIs must be treated promptly after a urine culture specimen (midstream or catheter specimen) has been taken. Recurrent UTIs, particularly after a period of stability, must lead to further investigations to exclude stones or obstruction, including CT kidney, ureter, bladder (KUB); kidney US, and postmicturition bladder US.

Asymptomatic UTIs often do not require treatment (except during pregnancy). For patients with urinary diversions, it is important to obtain a catheter specimen of urine because urine taken from a bag is invariably infected. Cloudy, malodorous urine should be treated initially with increased fluid intake and frequency of self-catheterization (every 1–2 hours for 12 hours).

It is sometimes appropriate to give prophylactic antibiotics, such as trimethoprim or nitrofurantoin, in the context of recurrent UTIs (≥3/yr). Nitrofurantoin should be avoided if eGFR is less than 45 mL/min/1.73 m^2 because its efficacy relies on excretion into the urinary tract. Quinolones should not be used for prophylaxis, if possible, because of the risk for inducing resistance. Antibiotic prophylaxis in children has been shown to reduce the incidence of repeat symptomatic UTI but has little impact on "kidney scarring."[46] When foreign bodies such as stones remain, attempts to sterilize the urinary tract are unlikely to be successful. If prophylactic antibiotics are no longer effective at preventing infection, it is advisable to stop all antibiotics and give the patient a supply of antibiotics to treat symptoms arising at home.

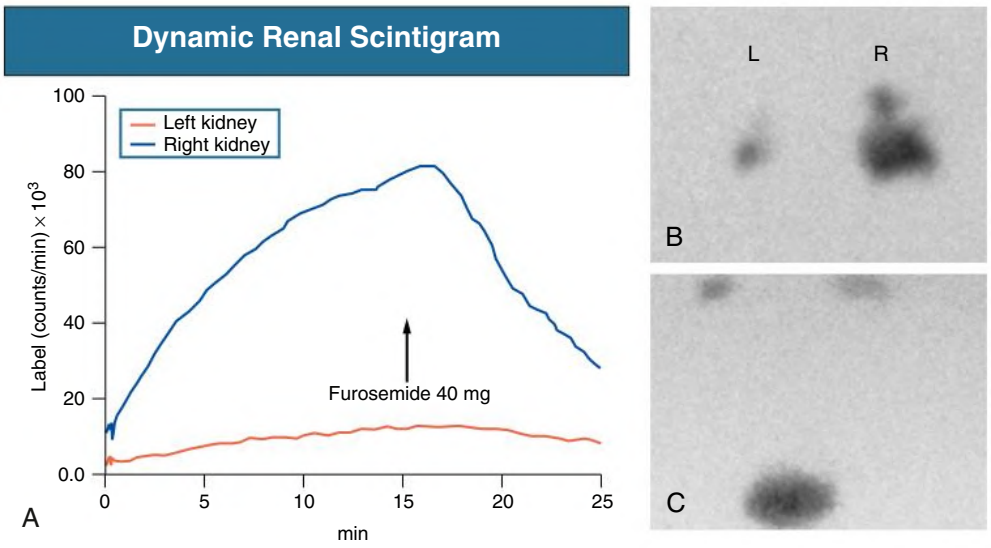

Fig. 52.16 Dynamic ^{99m}Tc-Labeled Mercaptoacetyltriglycine Kidney Scintigram. (A) Time-activity curve showing accumulation of isotope in right kidney that washes out after furosemide, thus excluding significant obstruction. (B–C) Images from the same study showing holdup of isotope in dilated right *(R)* renal pelvis (B) that washes out into the bladder after furosemide (C), excluding significant obstruction.

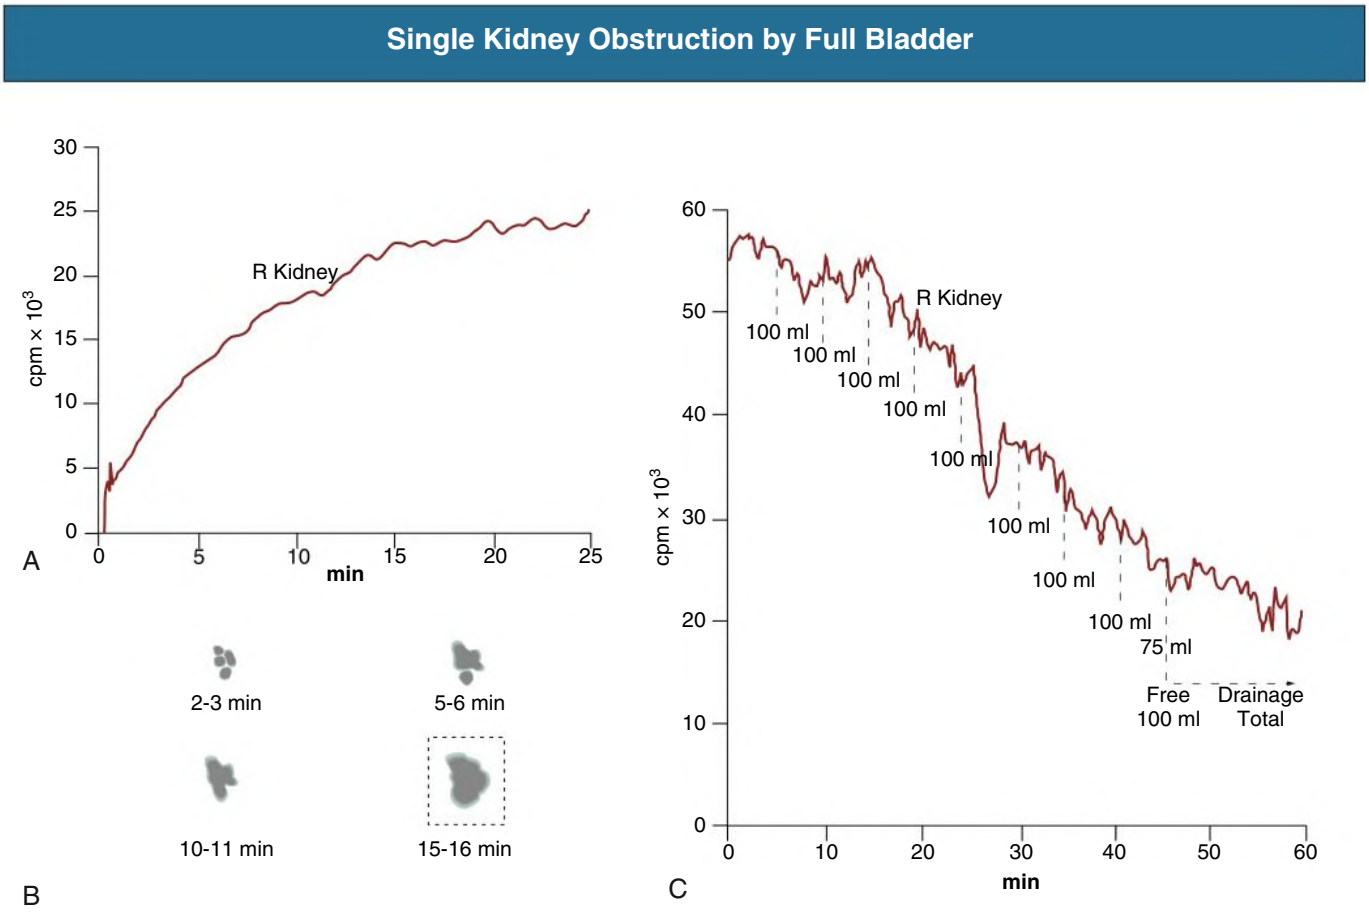

Fig. 52.17 Dynamic Isotope Scan (Mercaptoacetyltriglycine) Starting with Bladder Full in a Patient With a Solitary Right Kidney. (A) Rising curve of tracer accumulating in kidney and showing no excretion. (B) Accumulation of isotope in hydronephrotic pelvis without excretion to bladder. (C) The 100-mL increments of fluid removed from bladder result in eventual free drainage of the kidney. *cpm,* Counts per minute.

Glomerular Hyperfiltration

If kidney function is declining with proteinuria and hypertension, glomerular hyperfiltration is likely, although all other causes of kidney dysfunction must be excluded. Patients should be treated with RAS blockade with angiotensin-converting enzyme (ACE) inhibitors or angiotensin receptor blockers (ARBs).

Proteinuria and Progressive Kidney Failure

Can progression to ESKD be predicted, and does treatment with ACE inhibitors delay or prevent this? We investigated this in a retrospective review of patients with scarred irregular kidneys caused by primary kidney dysplasia or abnormal bladder function.[47,48] All patients had at least 5 years of follow-up, and when ACE inhibitors were started, eGFR was less than 60 mL/min/1.73 m^2 (mean, 41 mL/min), with mean proteinuria of 1.7 g/24 h. ESKD developed in 46% of patients but in none with proteinuria less than 0.5 g/24 h and in only 2 of 18 patients with eGFR greater than 50 mL/min/1.73 m^2.[47] The outcome of the two groups was similar whether there was primary kidney dysplasia or abnormal bladder function. ACE inhibitor treatment slowed decline in kidney function at all levels of function.[48] The similar outcome of the two groups indicates that progressive kidney failure in young males born with abnormal bladders is caused by intrinsic kidney pathophysiologic processes, in contrast to the view that it is a result of poor bladder function.

Hypertension

Hypertension is common in the presence of scarred kidneys, but it is usually controlled easily with one or two drugs. Patients in whom CKD is secondary to obstruction tend to have volume contraction and therefore often have normal BP or only mild hypertension. ACE inhibitors or ARBs are preferred for patients with proteinuria and progressive kidney failure. Diuretics should not be used if the patient is volume-contracted.

Stones

Stones that form in the presence of infected urine are typically magnesium ammonium phosphate (struvite) or calcium phosphate (hydroxyl apatite, carbonate apatite, calcium hydrogen phosphate [brushite], tricalcium phosphate [whitlockite]). These salts are poorly soluble in alkaline urine. In 90% of patients, the infecting organism is *Proteus* spp., but other urea-splitting organisms (including some staphylococci and *Pseudomonas* spp.) also generate ammonia.

Stones, usually calcium phosphate, are common in conduits because of the alkaline environment and occur in 5% to 30% of ileal conduits.[49] Stones must be suspected if UTIs recur or become more frequent, if kidney function suddenly deteriorates, or if there is an unexplained sterile pyuria.

Tubular Dysfunction

Patients whose kidney failure is secondary to obstruction have significant tubular injury. This may cause problems, in particular with urinary concentration, acidification, and sodium reabsorption.

Polyuria

Nocturia is one of the most significant symptoms in the assessment of patients in whom obstruction or tubular dysfunction is suspected. Overfilling of the bladder or reservoir is an important cause of intermittent upper tract obstruction and deteriorating function. The 24-hour urine volume diary is a simple way to assess this.

Salt Depletion

Patients with tubular damage may have a salt-losing tendency. Patients typically have a cool periphery and constricted hand veins with no peripheral edema. Increasing salt intake can relieve cramps, improve kidney function, and reduce hyperuricemia, but at the cost of increasing BP. With patients who are salt depleted, it is important to give sodium chloride because it is the chloride anion that is deficient and responsible for the reduction in circulating volume.

Metabolic Acidosis

There is often a metabolic acidosis disproportionate to the degree of kidney impairment, particularly in individuals with a ureterosigmoidostomy (see later). This is secondary both to a proximal tubular failure of bicarbonate reabsorption and a distal tubular failure to secrete hydrogen ions. It is our practice to give sufficient sodium bicarbonate to correct the serum bicarbonate into the normal range.

Bone Disease

In addition to the typical bone disease of progressive CKD, acidosis contributes significantly to osteomalacia. Growing children are particularly vulnerable to osteomalacia, and great care must be taken to correct acidosis and actively manage bone disease.

Urinary Diversions

Ureterosigmoidostomy

Fortunately, it is now rare to meet a patient who has a ureterosigmoidostomy, which was widely used as a technique for urinary diversion until the 1970s. The ureters were anastomosed directly into the sigmoid colon with no disruption of bowel continuity. This technique was most often used in patients with bladder exstrophy. Although patients start with normal kidney function, there is frequently deterioration in function. In one series of 25 patients, significant kidney damage occurred in 50%. Stones, infection, and ureteral strictures are common, and patients remain at risk for colonic carcinoma, with a 10% incidence of carcinoma at 20-year follow-up.[50] However, this diversion is probably best known for the hyperchloremic, hypokalemic acidosis that occurs. Once the urine is in contact with the colonic mucosa, the urinary sodium exchanges for potassium and the chloride for bicarbonate via the SLC26A3 anion exchanger, with large quantities of ammonium ions produced by the action of fecal bacteria on urinary ammonia. Ammonium ions are absorbed both with chloride and in exchange for sodium. The severe acidosis is caused by ammonium ion retention and stool loss of bicarbonate. Patients are managed with large doses of oral sodium bicarbonate, which is titrated to keep plasma bicarbonate in the normal range (>22 mmol/L).

Ileal Conduits

Unlike the sigmoidostomy, in which urine enters a reservoir, the ileal conduit is free flowing, with rapid urinary transit and no reservoir. Therefore, metabolic complications are much less common, although again the bowel can exchange sodium and chloride for potassium and bicarbonate. B12 deficiency and diarrhea secondary to impaired bile acid absorption can occur. A number of other complications of ileal and colonic conduits can lead to progressive loss of kidney function (Box 52.2).

Enterocystoplasty and Intestinal Urinary Reservoirs

In 53 patients with bladder exstrophy and intestinal reservoirs, monitored more than 10 years with serial isotopic GFRs, kidney function deteriorated (GFR decrease ≥20%) in only 10 (~20%).[30] Loss of GFR

was caused principally by chronic urinary retention with or without infection in poorly compliant patients who did not catheterize regularly. Patients also must be checked regularly to ensure that anastomotic stenoses and high-pressure reservoirs do not occur. Stones are common and occur in up to 52% of patients.[51] An increased risk of malignancy is also seen in augmentation cystoplasty, predominantly adenocarcinomas occurring at the entero-urinary anastomosis after a median of 19 years. Macroscopic hematuria should trigger prompt referral for cystoscopy.

BOX 52.2 Long-Term Complications of Urinary Diversion

- Pyelonephritis and recurrent urinary tract infections
- Calculi
- Obstruction
- Strictures
- Bladder mucus causing obstruction
- Cancer at intestinal-ureteral anastomosis
- Hyperchloremic acidosis
- Delayed linear growth in children
- Effects of intestinal loss from gastrointestinal tract (e.g., vitamin B12 deficiency)
- Complications related to abnormal pelvic anatomy (e.g., in pregnancy)
- Psychological and body image problems

END-STAGE KIDNEY DISEASE AND TRANSPLANTATION

This group of patients presents two important problems if they develop ESKD. First, because of multiple abdominal surgeries, continuous ambulatory peritoneal dialysis (CAPD) is often challenging, although if there is any doubt and the patient is interested, CAPD should be attempted. Second, the bladder and urinary reservoir must be suitable for kidney transplantation. If a bladder has just destroyed two good native kidneys, it is likely to do the same to a transplant kidney. Most patients will be maintained on hemodialysis, but it is frequently difficult to establish a good arteriovenous fistula because of chronic hypovolemia and venoconstriction. Patients receiving dialysis often continue to pass 1 L or more of urine per 24 hours, and they also remain at risk for serious UTI and pyelonephritis.

Pretransplantation Assessment

Transplantation into the abnormal lower urinary tract requires careful evaluation and follow-up. Thorough preoperative assessment of bladder function is essential (Fig. 52.18). Patients considered to have normal bladders require at least postmicturition bladder US and urinary flow rate.

All patients with abnormal bladders or reservoir must have a full VCMG to ensure that the bladder reservoir is large and adequately compliant. If the bladder is small or has not been used for some time, bladder cycling, which involves periodically filling and distending the

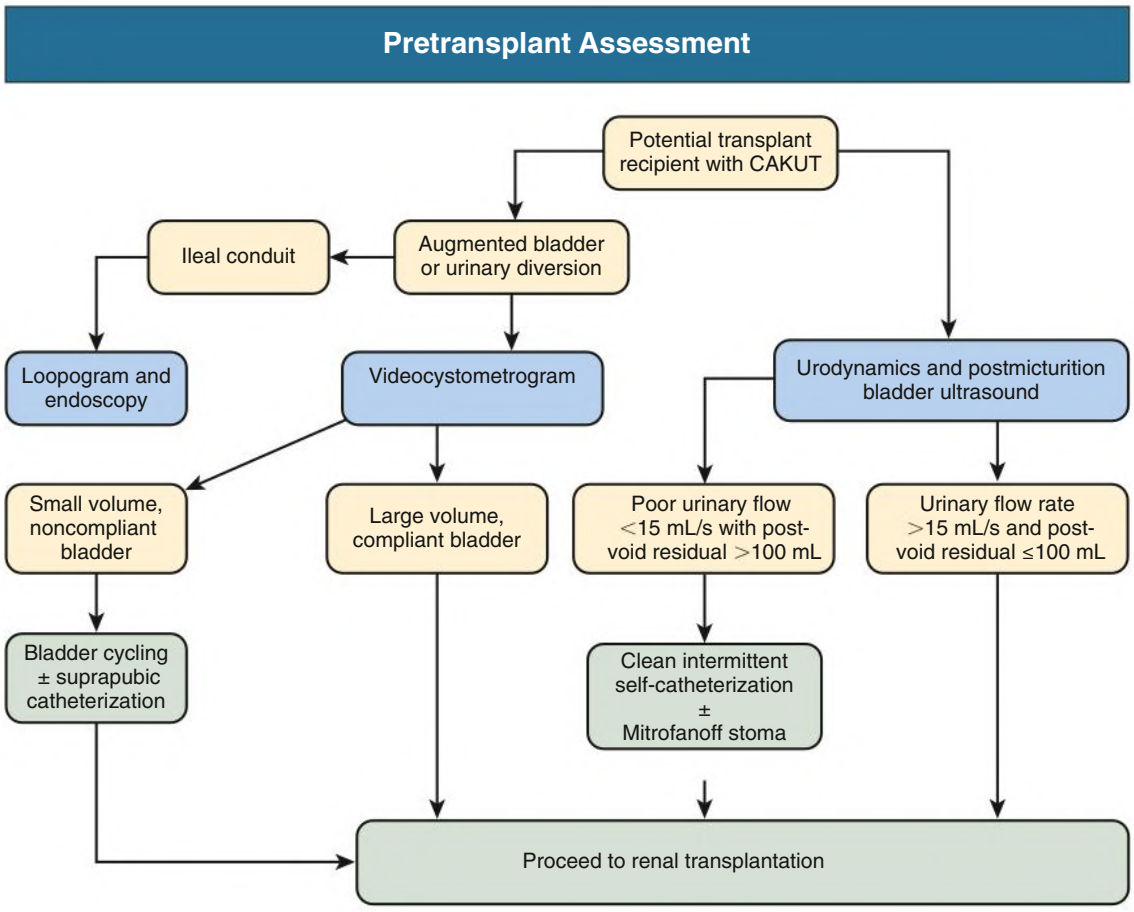

Fig. 52.18 Pretransplant assessment of patients with an abnormal lower urinary tract. *CAKUT*, Congenital anomalies of the kidney and urinary tract.

bladder through a suprapubic catheter, may be required. A urodynamic study before transplantation indicated that poor bladder function, as shown by small bladder volumes, is a predictor of graft loss even in patients with previously normal bladder function.[52] Intermittent self-catheterization is safe and effective for a patient with a poor flow rate who fails to empty the bladder. This, however, is possible only with a normal urethra and a cooperative patient. When this is not practical, we attempt to establish suprapubic drainage through a continent channel, such as a Mitrofanoff stoma (Fig. 52.19). If a conduit is to be used, a loopogram and endoscopy must ensure it is in good condition. We do not remove native kidneys unless they are causing recurrent UTI.

Fig. 52.19 Mitrofanoff Stoma. This patient was born with bladder exstrophy and has had a successful kidney transplant for 22 years. Her kidney is plumbed into a colonic reservoir, and she catheterizes herself through a continent Mitrofanoff stoma, which is covered by a small bandage in the photograph.

Transplant Outcome

In an 18-year experience, we performed transplantation in 65 patients with abnormal bladders, with a total of 72 kidney transplants.[53] In 52 cases the ureters were transplanted into unaugmented bladders; in 20 cases, there was some form of augmentation or diversion. Results were compared with 59 transplants in 55 patients who had kidney failure from kidney dysplasia and whose bladder function was considered normal. There was no difference in actuarial graft survival in the two groups at 10 years (abnormal bladders, 66%; normal bladders, 61%), although longer follow-up showed an advantage for normal bladders, with graft survival of 29 to 33 years compared with 15 years for the abnormal bladders. UTIs were relatively common in all patients but produced problems only in patients with abnormal bladders. A recent study also reported comparable 10-year graft survival rates of 70% to 76% for individuals with kidney hypodysplasia and PUV, but an increased risk of graft loss for PUV after this time point.[54] This suggests that although short-term outcomes appear to be equivalent in individuals with normal and abnormal bladders, longer-term graft survival may be limited by bladder dysfunction.

Short-term outcomes after transplantation have been shown to be more favorable in both children and adults with CAKUT compared with individuals with primary glomerular or non-CAKUT diseases at 5 to 10 years, although recipients were more likely to be younger and receive a preemptive transplant.[5,55,56] Young adulthood (15–24 years) is also a particularly challenging time, and the high rates of graft loss and eGFR decline observed during this period may be exacerbated by nonadherence to CISC in adolescents with bladder dysfunction.[57]

Management

A double-J ureteral stent should be placed routinely at the time of transplant surgery. Adequacy of urinary drainage must be assessed frequently, even when graft function seems to be good. Two months after transplantation, when the ureteral stent has been removed, we recommend performing a baseline postmicturition US of the transplant kidney and bladder, in addition to a dynamic ^{99m}Tc-MAG3 scintigraphy scan in patients with abnormal bladders.

US and ^{99m}Tc-MAG3 scintigraphy are then repeated when clinically indicated. The protein-to-creatinine ratio is measured on a random urine sample at every outpatient visit. If there is kidney dysfunction, imaging tests are repeated, and if there is a change from baseline, kidney biopsy is performed to exclude an immunologic cause of graft dysfunction. If there is deterioration in GFR in the absence of rejection or calcineurin inhibitor toxicity, the DMSA scan is repeated (to see whether new scarring has occurred) and the bladder reassessed urodynamically.[58]

Complications

UTIs must be detected and treated early, and recurrent UTIs may require long courses of antibiotics or even removal of the native tracts. Symptomatic UTIs are common in the first 3 months after transplantation (63%); fever and systemic symptoms occur in 39% of patients with normal bladders and 59% with abnormal bladders. UTI directly contributes to graft loss in patients with abnormal bladders but causes no consequences in those with normal bladders.[44] Prophylactic administration of antibiotics for the first 6 months significantly reduces the subsequent incidence of UTI. When UTIs recur, a cause must be sought with ultrasound of the kidneys and bladder. A CT KUB can be done to look for stones in native or transplant kidneys and the bladder or urinary diversion. If there is a residual volume after double micturition, the patient must be instructed to perform clean intermittent self-catheterization. With these measures, good results are obtained.

SELF-ASSESSMENT QUESTIONS

1. Which statement about unilateral kidney agenesis is *false?*
   - **A.** It occurs in 1 in 10,000 births.
   - **B.** Typically, there is no ureter.
   - **C.** The fallopian tube may be absent in females.
   - **D.** Kidney ultrasound is recommended in first-degree relatives.
   - **E.** It can be part of a syndrome.
2. Which statement about prune-belly syndrome is *false?*
   - **A.** It usually occurs in males only.
   - **B.** The muscles of the anterior abdominal wall are absent.
   - **C.** Gross dilation of the bladder occurs, with normal ureters.
   - **D.** Males have bilateral undescended testes.
   - **E.** Patients are usually infertile.
3. Ureterosigmoidostomy may lead to all of the following *except:*
   - **A.** Hyperchloremia
   - **B.** Hyperkalemia
   - **C.** Acidosis
   - **D.** Ammonium ion retention
   - **E.** Colonic carcinoma

4. Which of the following statements about posterior urethral valves is *false?*
   - **A.** They are usually detected antenatally.
   - **B.** Patients require urethral surgery.
   - **C.** Progressive kidney failure is associated with proteinuria.
   - **D.** Posterior urethral valves may be confused with urofacial (Ochoa) syndrome.
   - **E.** Posterior urethral valves occur in males and females.

5. Which of the following statements about urinary tract infection (UTI) in an augmented bladder is *false?*
   - **A.** The patient with UTI does not require treatment when asymptomatic.
   - **B.** UTI often causes calcium oxalate stones.
   - **C.** Recurrent UTIs should be investigated with ultrasound, including assessment of postvoid residual volume.
   - **D.** UTI may indicate poor bladder emptying.

Urinary Tract Infections in Adults

Dimitri Drekonja, Thomas Hooton

DEFINITION

Most episodes of urinary tract infection (UTI) in adults can be categorized into six common categories: females with acute uncomplicated cystitis, females with recurrent cystitis, females and males with acute uncomplicated pyelonephritis, males with cystitis, complicated UTI, and asymptomatic bacteriuria (Box 53.1).[1] Additionally, UTIs in chronic kidney disease (CKD), those needing urethral catheterization or other indwelling devices, and patients with a spinal cord injury require different approaches to diagnosis and management. Chapter 44 discusses UTI in pregnancy, and Chapter 62 describes vesicoureteral reflux (VUR) in children. UTI in autosomal dominant polycystic kidney disease is discussed in Chapter 46.

Complicated UTI is defined as UTI occurring in a patient with a condition that increases the risk for treatment failure or recurrence. Potentially complicating conditions are presented in Box 53.2; not all of these conditions confer a similar risk for treatment failure or recurrence. Complicated UTIs may require different pretreatment and posttreatment evaluation than do uncomplicated UTIs, and type and duration of antimicrobial treatment may also differ. On occasion, complicated UTIs are diagnosed only after a patient has a poor response to treatment and the underlying condition is identified.

EPIDEMIOLOGY

Several million episodes of acute uncomplicated cystitis and at least 250,000 episodes of acute pyelonephritis occur annually in the United States. The incidence of cystitis in sexually active young females is about 0.5 per 1 person-year.[2] Acute uncomplicated cystitis may recur in 27% to 44% of healthy females.[3] The incidence of pyelonephritis in young females is about 3 per 1000 person-years.[4] The self-reported incidence of symptomatic UTI in postmenopausal females is about 10% per year.[5] The incidence of symptomatic UTI in adult males younger than 50 years is lower than in females, ranging from 5 to 8 per 10,000 males annually.

Complicated UTIs occur in a wide range of settings (see Box 53.2). Nosocomial UTIs are a common type of complicated UTI and occur in 5% of admissions in the university tertiary care hospital setting; catheter-associated infections account for most of the infections. Catheter-associated bacteriuria is the most common source of gram-negative bacteremia in hospitalized patients.[6]

Asymptomatic bacteriuria is defined as the presence of two separate consecutive clean-voided urine specimens, both with 10^5 or more colony-forming units per milliliter (cfu/mL) of the same uropathogen in the absence of symptoms referable to the urinary tract.[7] Asymptomatic bacteriuria occurs in 5% of young adult females, but rarely in males younger than 50 years. The prevalence increases to 16% of ambulatory females and 19% of ambulatory males older than 70 and up to 50% of elderly females and 40% of elderly males who are institutionalized.[7] In clinical practice, asymptomatic bacteriuria is rarely confirmed by two consecutive specimens. Asymptomatic bacteriuria may be persistent or transient and recurrent, and many patients have had previous symptomatic infection or develop symptomatic UTI soon after having asymptomatic bacteriuria. Asymptomatic bacteriuria is generally benign but occasionally may lead to serious complications.

PATHOGENESIS

Uncomplicated Infection

Most uncomplicated UTIs in healthy females begin with uropathogens (typically *Escherichia coli*) colonizing the rectal flora entering the urethra and then the bladder, after an interim phase of introital colonization. Colonizing uropathogens also may come from a sex partner's vagina, rectum, or penis. Hematogenous seeding of the urinary tract by potential uropathogens such as *Staphylococcus aureus* is the source of some UTIs, but this is more likely to occur in the setting of persistent bloodstream infection or urinary tract obstruction.

Many host behavioral, genetic, and biologic factors predispose healthy young females to uncomplicated UTI (Table 53.1).[2,8] Factors protecting individuals from UTI include the host's immune response; maintenance of normal vaginal flora, which protects against colonization with uropathogens; and removal/prevention of bladder bacteriuria by micturition.[9] Uropathogenic *E. coli,* the predominant pathogens in uncomplicated UTI, are a subset of extraintestinal pathogenic *E. coli* that have enhanced virulence[10] (see Table 53.1). P-fimbriated strains of *E. coli* are associated with acute uncomplicated pyelonephritis, and their adherence properties may stimulate epithelial and other cells to produce proinflammatory factors that stimulate the inflammatory response.[11] Other virulence determinants include adherence factors (type 1, S, and Dr fimbriae), toxins (hemolysin), immune evasion, iron acquisition (aerobactin), flagella, and serum resistance.[10,12] Bacterial determinants associated with cystitis and

BOX 53.1 Categories of Urinary Tract Infection in Adults

- Acute cystitis in females
- Recurrent cystitis in females
- Acute pyelonephritis in females and males
- Acute cystitis in males
- Complicated urinary tract infection[a]
- Asymptomatic bacteriuria

[a]This is a selected list of complicating factors. Some factors complicate urinary tract infections through several mechanisms.

BOX 53.2 Selected List of Potential Complicating Factors for Urinary Tract Infections

- Male sex
- Pregnancy
- Poorly controlled diabetes mellitus
- Obstruction or other structural factor: Urolithiasis, malignancies, ureteral and urethral strictures, bladder diverticula, renal cysts, fistulas, ileal conduits, other urinary diversions
- Functional abnormality: Neurogenic bladder, vesicoureteral reflux
- Foreign bodies: Indwelling catheter, ureteral stent, nephrostomy tube
- Other conditions: kidney failure, kidney transplantation, immunosuppression, multidrug-resistant uropathogens, health care–associated (includes hospital-acquired long-term care facility acquired infection, prostatitis-related infection, upper tract infection in an adult other than a healthy female, other functional or anatomic abnormality of urinary tract)

Data from Nicolle LE. A practical guide to the management of complicated urinary tract infection. *Drugs.* 1997;53:583-592.

asymptomatic bacteriuria are less characterized, and triggers for urinary symptoms are unclear.

Factors affecting the large difference in UTI prevalence between males and females include the greater distance between the anus and the urethral meatus in males, the drier environment surrounding the male urethra, and the greater length of the male urethra. Risk factors associated with UTIs in healthy males include intercourse with a female partner colonized or infected with a potential uropathogen, anal intercourse, and being uncircumcised, although these factors are often not present in males with UTI. Most uropathogenic strains infecting young males are highly virulent, suggesting that the urinary tract in healthy males is relatively resistant to infection.

Complicated Infection

The initial steps leading to uncomplicated UTI discussed earlier probably also occur in most individuals who develop a complicated UTI. Factors that predispose individuals to complicated UTI generally do so by causing obstruction or stasis of urine flow, facilitating entry of uropathogens into the urinary tract by bypassing normal host defense mechanisms, providing a nidus for infection that is not readily treatable with antimicrobials, or compromising the host immune system (see Box 53.1).[1] UTIs are more likely to become complicated if host defense is impaired, as occurs with indwelling catheter use, VUR, obstruction, neutropenia, and immune deficiencies. Diabetes mellitus is associated with several UTI syndromes, including renal and perirenal abscesses, emphysematous pyelonephritis and cystitis, papillary necrosis, and xanthogranulomatous pyelonephritis.[12] Uropathogen virulence determinants are less important in the pathogenesis of complicated UTIs compared with uncomplicated UTIs. However, infection with multidrug-resistant uropathogens is more likely with complicated UTI, and the causative organisms are also more varied.

TABLE 53.1 Factors Modulating Risk for Acute Uncomplicated Urinary Tract Infections in Females

Host Determinants	Uropathogen Determinants
Behavioral: Sexual intercourse, use of spermicidal products, recent antimicrobial use, suboptimal voiding habits *Genetic:* Innate and adaptive immune response, enhanced epithelial cell adherence, antibacterial factors in urine and bladder mucosa, nonsecretor of ABO blood group antigens, P1 blood group phenotype, reduced *CXCR1* expression, previous history of recurrent cystitis *Biologic:* Estrogen deficiency in postmenopausal females, glycosuria (including from SGLT-2 inhibitors)	*Escherichia coli* virulence determinants: P, S, Dr, and type 1 fimbriae; hemolysin; aerobactin; serum resistance

ETIOLOGIC AGENTS

Uncomplicated upper and lower UTI are caused by *E. coli,* present in 70% to 95% of infections, and *Staphylococcus saprophyticus,* present in 5% to more than 20%. Other organisms are less common (Table 53.2).[7] *S. saprophyticus* only rarely causes acute pyelonephritis.[13] Among healthy nonpregnant females, the isolation of lactobacilli, enterococci, group B streptococci, and coagulase-negative staphylococci other than *S. saprophyticus* usually represents contamination of the urine specimen[14] unless found in voided midstream urine in high counts and pure growth in symptomatic females.

A broader range of bacteria can cause complicated UTI, many demonstrating resistance to multiple antimicrobial agents. Although *E. coli* is most commonly isolated, *Citrobacter* spp., *Enterobacter* spp., *Pseudomonas aeruginosa,* enterococci, and *S. aureus* account for a higher proportion of cases relative to uncomplicated UTIs (see Table 53.2).[1] The proportion of infections caused by fungi, especially *Candida* spp., is increasing (see Chapter 55). Patients with chronic conditions, such as spinal cord injury and neurogenic bladder, are more likely to have polymicrobial and multidrug-resistant infections.

CLINICAL SYNDROMES

Acute Uncomplicated Cystitis in Young Females

Females with acute uncomplicated cystitis generally present with dysuria, frequency, urgency, or suprapubic pain. The differential diagnosis for acute dysuria in a sexually active young female is acute cystitis; acute urethritis from *Chlamydia trachomatis, Neisseria gonorrhoeae,* or herpes simplex virus infections; or vaginitis caused by *Candida* spp. or *Trichomonas vaginalis.*[6] These three entities can usually be distinguished by the history, physical examination, and simple laboratory tests. New vaginal discharge supports urethritis or vaginitis and should prompt a vaginal exam, whereas its absence is more consistent with

TABLE 53.2 Bacterial Etiology of Urinary Tract Infections

	URINARY TRACT INFECTION (%)	
Organisms	**Uncomplicated**	**Complicated**
Gram-Negative Organisms		
Escherichia coli	70–95	21–54
Proteus mirabilis	1–2	1–10
Klebsiella spp.	1–2	2–17
Citrobacter spp.	<1	5
Enterobacter spp.	<1	2–10
Pseudomonas aeruginosa	<1	2–19
Other	<1	6–20
Gram-Positive Organisms		
Coagulase-negative staphylococci *(Staphylococcus saprophyticus)*	5–20+	1–4
Enterococci	1–2	1–23
Group B streptococci	<1	1–4
Staphylococcus aureus	<1	1–2
Other	<1	2

cystitis. Skin lesions may provide a clue that herpes simplex virus is the cause of the dysuria. Pyuria is present in almost all females with acute cystitis and in most females with urethritis caused by *N. gonorrhoeae* or *C. trachomatis,* and its absence strongly suggests an alternative diagnosis. Hematuria (microscopic or gross) is common in females with UTI but not in females with urethritis or vaginitis.

Definitive diagnosis of UTI requires the presence of significant bacteriuria, the traditional standard for which is up to 10^5 uropathogens per milliliter of voided midstream urine. A minority of females with cystitis have lower colony counts, which are missed with use of the traditional definition.[15] Despite their central role in the definitive diagnosis of UTI, urine cultures are generally not indicated in females with uncomplicated cystitis, in particular for females with a prior culture-confirmed UTI. For these females, history is highly reliable in establishing the diagnosis,[16] the causative organisms are predictable, and the culture results usually become available only after therapeutic decisions have been made and treatment is nearly complete.

E. coli isolates from outpatients with UTI are increasingly resistant to commonly used antibiotics, including sulfonamides, amoxicillin, trimethoprim, and trimethoprim-sulfamethoxazole (TMP-SMX).[17–19] In the United States, TMP-SMX resistance among *E. coli* isolates causing uncomplicated UTI range from 15% to 42% in different regions,[17] with a similar range among European countries and Brazil.[18] Many drug-resistant *E. coli* strains are clonal and have been hypothesized to enter new environments by contaminated products ingested by community residents.[20] Because of increasing resistance to TMP-SMX and other antimicrobials, clinicians have turned to agents with more predictable activity. Nitrofurantoin is active against most *E. coli* isolates, with resistance rates of less than 5%. With *E. coli* being the most isolated organism for females with uncomplicated cystitis, nitrofurantoin is a first-line agent for this syndrome. Fluoroquinolones remain active against most *E. coli* strains causing uncomplicated cystitis, although resistance is increasing in most locations and use for cystitis is discouraged.[17,18,21] In an antimicrobial susceptibility study of more than 12 million *E. coli* isolates from U.S. outpatients, fluoroquinolone resistance increased from 3% to 17% over 10 years.[22] In addition, infections caused by extended-spectrum β-lactamase (ESBL)-producing strains are increasingly common, even for uncomplicated cystitis.

Recommended management of acute uncomplicated cystitis is summarized in Fig. 53.1 and Table 53.3. Updated Infectious Diseases Society of America (IDSA) guidelines emphasize the importance of considering ecologic adverse effects of antimicrobial agents (i.e., selection for colonization or infection with multidrug-resistant organisms—so-called collateral damage) when selecting a treatment regimen.[21] Short-course regimens are recommended as first-line treatment for acute uncomplicated cystitis because of comparable efficacy, better compliance, lower cost, and fewer adverse effects than with longer regimens. Given the benign nature of uncomplicated cystitis along with its high frequency, the IDSA guidelines give equal weight to the risk for ecologic adverse effects and drug effectiveness in the recommendations. Nitrofurantoin is well tolerated and has good efficacy when given twice daily for 5 days, and it has a low propensity for ecologic adverse effects.[23] Despite concern about the high prevalence of resistance to TMP-SMX, this combination medication remains effective for infections caused by susceptible isolates and is inexpensive and well tolerated. Fosfomycin is also considered a first-line regimen because of its low propensity for ecologic adverse effects and single-dose administration, even though it appears to be slightly inferior to TMP-SMX and fluoroquinolones, and is often considerably more expensive than other options.[21] Moreover, both nitrofurantoin and fosfomycin appear to have a role as therapeutic agents effective against ESBL *E. coli* UTIs.[24,25] Pivmecillinam, an extended gram-negative spectrum penicillin used only for treatment of UTI, is an appropriate choice for therapy in regions where it is available (primarily European countries) because of minimal resistance and propensity for collateral damage and activity against ESBL-producing organisms.[26] The choice of an antimicrobial agent should be individualized based on the patient's allergy and medication preferences, local practice patterns, prevalence of resistance in the local community (if known), availability, cost, and how comfortable the patient and provider are with increased risk for treatment failure associated with the use of an antimicrobial agent that may cause less collateral damage but is less effective than another drug.[21] If first-line antimicrobial agents are not suitable because of one or more of these factors, fluoroquinolones or β-lactams are reasonable alternatives, although their use should be minimized because of concerns for increasing the risk for drug resistance.[21] Thus, although fluoroquinolones (3-day duration) are highly effective in the treatment of cystitis, many experts recommend that they be considered as second-line therapy for uncomplicated cystitis to help preserve their usefulness in the treatment of other more serious infections.[21] Moreover, in the United States, the Food and Drug Administration (FDA) has stated that the risks of systemic fluoroquinolones outweigh their benefits for uncomplicated cystitis.[27] In general, β-lactam antibiotics have been inferior to TMP-SMX or fluoroquinolones in regimens of the same duration.[28]

Although broad-spectrum oral β-lactams (e.g., cefixime, cefpodoxime, cefprozil, cefaclor, amoxicillin-clavulanate) demonstrate in vitro activity against most uropathogens causing uncomplicated cystitis, clinical data are sparse. Trials have shown that cure rates with 3-day regimens of amoxicillin-clavulanate[29] or cefpodoxime proxetil[28] were lower than a 3-day regimen of ciprofloxacin. Moreover, there are concerns about the possibility of ecologic adverse effects with oral broad-spectrum cephalosporins, as has been observed with parenteral cephalosporins. Routine posttreatment cultures in females are not indicated unless the patient is symptomatic. If the patient remains symptomatic and persistent infection is confirmed, a longer course of culture-directed therapy (usually with a fluoroquinolone) should be used. Detecting and treating asymptomatic bacteriuria in healthy females is useful only in pregnancy and before urologic instrumentation or surgery.[7]

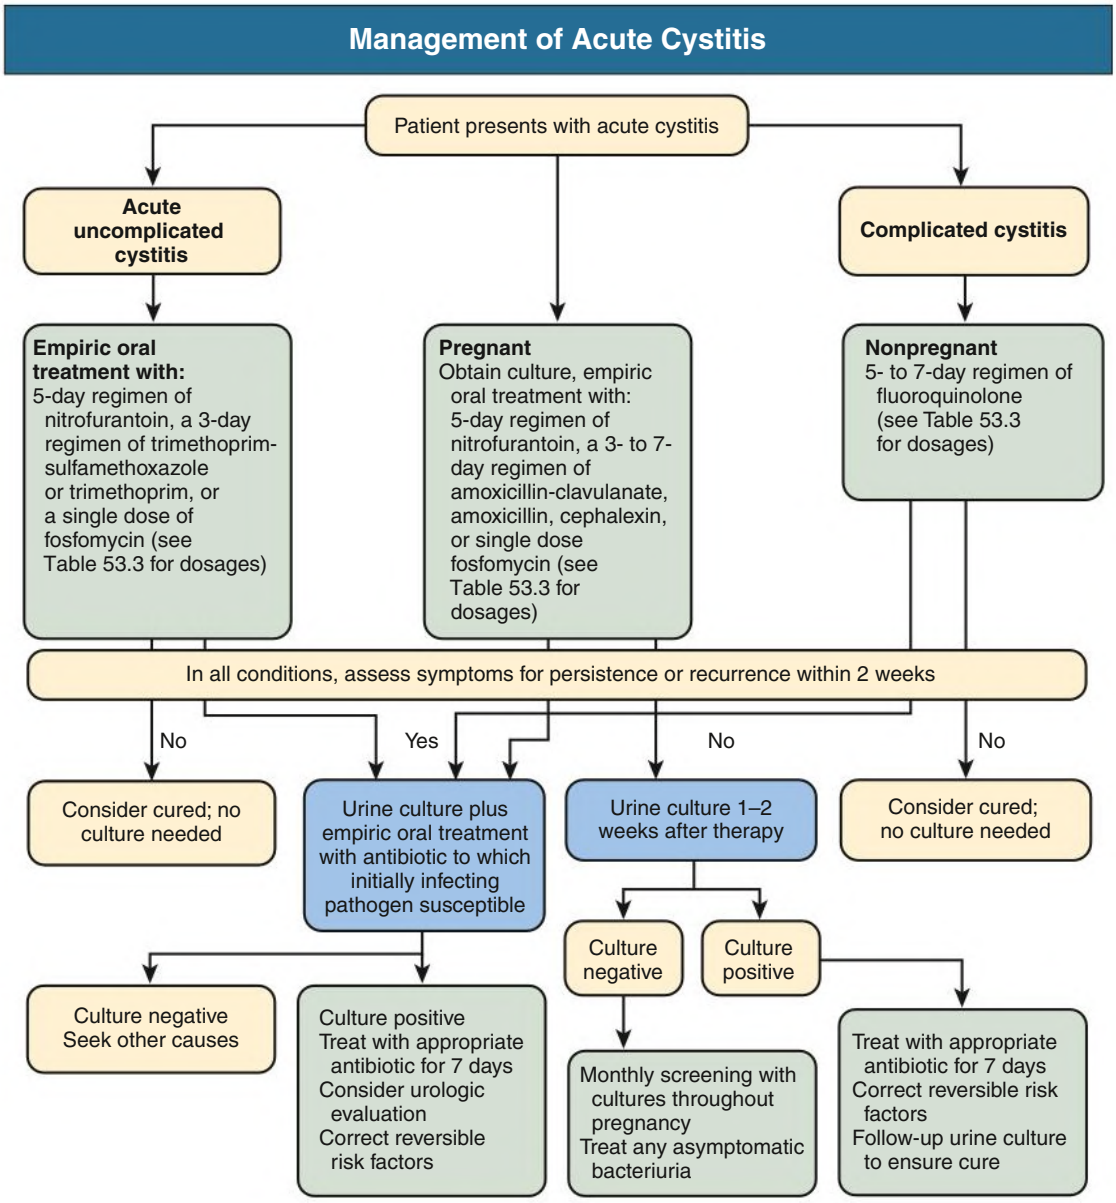

Fig. 53.1 Algorithm for management of acute cystitis.

TABLE 53.3 Oral Antimicrobial Agents for Acute Uncomplicated Cystitis

Drug	Dose (mg)	Interval[a]	Comment
Nitrofurantoin			Less active against *Proteus* spp.
Monohydrate/macrocrystals	100	q12h	
Macrocrystals	50	q6h	
TMP-SMX	160/800	q12h	If used in pregnancy (not approved use), avoid in first trimester.
Trimethoprim	100	q12h	If used in pregnancy (not approved use), avoid in first trimester.
Fosfomycin	3000	Single dose	Less effective than fluoroquinolone or TMP-SMX.
Pivmecillinam	400	q8–12h	Availability limited to some European countries; not available for use in North America. Associated with minimal resistance and propensity for collateral damage, but efficacy rates are lower than other agents.
Cefpodoxime proxetil	100	q12h	Comparable to TMP-SMX, inferior to ciprofloxacin in 3-day regimen.[28]
Amoxicillin-clavulanate	500/125	q12h	Inferior to ciprofloxacin in 3-day regimen.[29]
Amoxicillin	500	q12h	Used only when causative pathogen is known to be susceptible or for empiric treatment of mild cystitis in pregnancy.
Fluoroquinolones			
Ciprofloxacin	250	q12h	Avoid fluoroquinolones if possible in pregnancy, nursing mothers, or persons younger than 18 years old. Although highly effective, should be considered second-line treatment to preserve their usefulness for other infections. Moreover, in the United States, the FDA has stated that the risks of systemic fluoroquinolone antibacterial drugs outweigh their benefits for uncomplicated cystitis.
Ciprofloxacin extended release	500	q24h	
Levofloxacin	250	q24h	
Ofloxacin	200	q12h	

[a]Duration of therapy depends on the clinical setting (see text and Fig. 53.1).
FDA, U.S. Food and Drug Administration; TMP-SMX, trimethoprim-sulfamethoxazole.

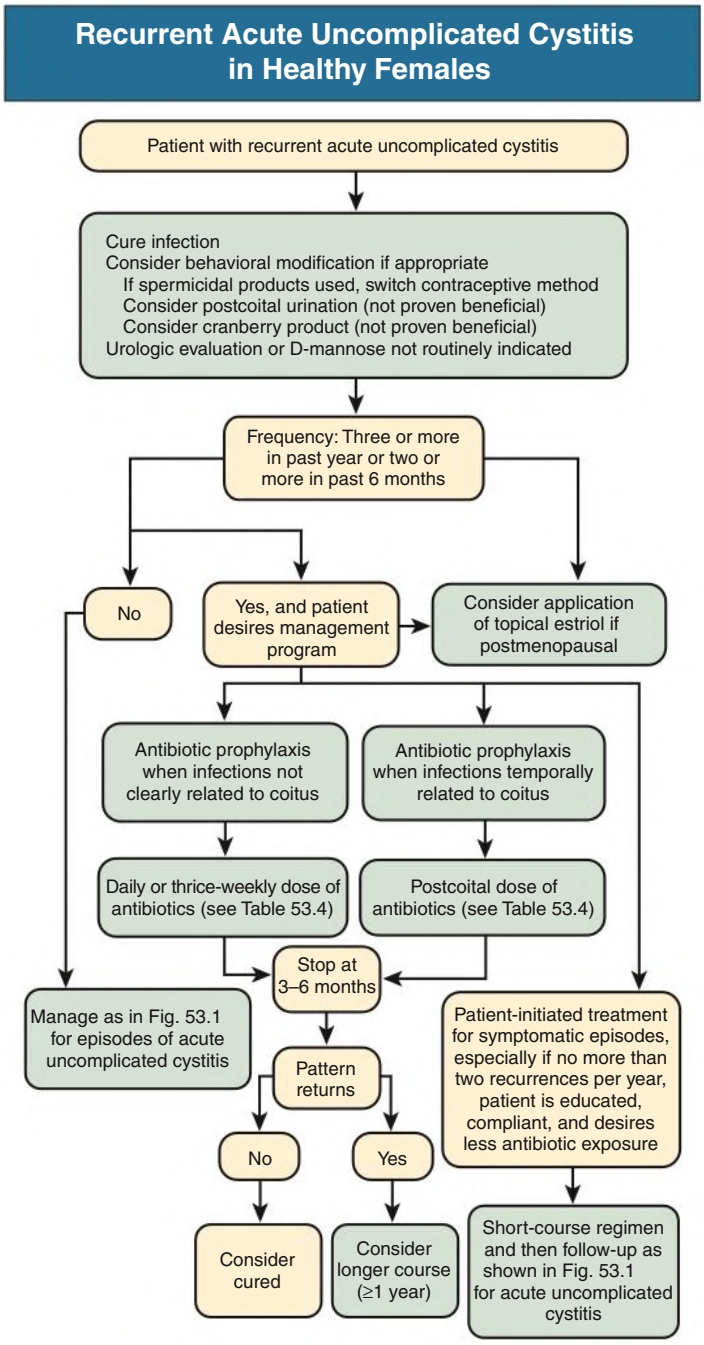

Fig. 53.2 Management strategies for recurrent acute uncomplicated cystitis.

Recurrent Acute Uncomplicated Cystitis in Females

Many cases of recurrent cystitis in healthy females are caused by persistence of the initially infecting strain in the fecal flora.[30] Studies in mice suggest that a latent reservoir of uropathogens in the bladder epithelium that persist after the initial UTI may be one cause of recurrence,[31] and indirect evidence indicates that this may occur in humans.[32] If the recurrence is within 1 or 2 weeks of treatment, an antimicrobial-resistant uropathogen should be considered, and a urine culture should be performed followed by treatment with an active antimicrobial. We treat later recurrences the same as the original infection, although if the recurrence is within 6 months, we consider a first-line drug other than the one used originally, especially if TMP-SMX was used, because of the likelihood of resistance.[33]

Long-term management of recurrent cystitis should be aimed to improve the quality of life while minimizing antimicrobial exposure.[13] Females with recurrent cystitis may benefit from behavioral modification (Fig. 53.2), such as avoiding spermicides, increasing fluid intake,[34] and ensuring postcoital micturition, although it is uncertain whether these practices are truly beneficial. Data on efficacy are sparse, but targeting the adherence mechanism of *Enterobacteriaceae* with D-mannose powder is another antimicrobial-sparing modality used by some females to prevent UTI.[35] Cranberry products are widely used to prevent recurrent UTI, but randomized, placebo-controlled trials (RCTs) have shown minimal benefits.[36] Females who do not want to try or who obtain no benefit from the preceding approaches should be offered

TABLE 53.4 Antimicrobial Prophylaxis Regimens for Females With Recurrent Acute Uncomplicated Cystitis

Drug	Dose (mg)	Frequency
Continuous Prophylaxis		
Nitrofurantoin	50 or 100	Daily
TMP-SMX	40/200	Daily
TMP-SMX	40/200	Three times weekly
Trimethoprim	100	Daily
Cefaclor	250	Daily
Cefalexin (cephalexin)	125 or 250	Daily
Postcoital Prophylaxis		
Nitrofurantoin	50 or 100	Single dose
TMP-SMX	40/200	Single dose
TMP-SMX	80/400	Single dose
Cephalexin	250	Single dose

See text and Fig. 53.2 for management strategy.

antimicrobial prophylaxis or have a course of antimicrobials on hand for intermittent self-treatment.

Antimicrobial prophylaxis reduces the risk for recurrent cystitis by approximately 95% (Table 53.4; see also Fig. 53.2).[37] Prophylaxis should be considered for females who experience three or more infections during a 12-month period or whenever the patient thinks their life is being adversely affected by frequent recurrences. Several approaches have been used, including continuous prophylaxis, postcoital prophylaxis (best for females who experience UTI only after intercourse), and intermittent self-treatment (which is really an early treatment method).[13] In postmenopausal females with recurrent UTI, intravaginal estradiol is effective, presumably by normalizing the vaginal flora, which reduces the risk for coliform colonization of the vagina.[38] This approach offers an alternative to antimicrobial strategies (see Fig. 53.2).

Promising antimicrobial-sparing approaches are being developed to specifically target virulence pathways, which might prevent uropathogens from causing disease, without altering the gut commensal microbiota. Antivirulence therapeutics target processes that are critical for UTI pathogenesis but are not required for the essential processes of growth and cell division (targets of conventional antimicrobials).

Acute Uncomplicated Pyelonephritis in Females and Males

Acute pyelonephritis is suggested by fever (temperature ≥ 38°C), chills, flank pain, nausea and vomiting, and costovertebral angle tenderness. Cystitis symptoms are variably present. Symptoms may vary from a mild illness to a sepsis syndrome with or without shock and kidney failure. Pyuria is almost always present, but leukocyte casts, specific for pyelonephritis, are infrequently seen. Gram stain of the urine sediment may aid in differentiating gram-positive and gram-negative infections, which can influence empiric therapy. A urine culture, which should be performed in all females with acute pyelonephritis, will have at least 10^4 cfu/mL of uropathogens in nearly all patients.[39]

Kidney biopsy shows focal inflammation with neutrophil and monocyte infiltrates, tubular damage, and interstitial edema (Fig. 53.3).

On imaging, the infected kidney is often enlarged, and contrast-enhanced computed tomography (CT) shows decreased opacification of the affected parenchyma, typically in patchy, wedge-shaped, or linear patterns (Fig. 53.4).

The availability of effective oral antimicrobials, especially fluoroquinolones, allows initial oral therapy in appropriate patients or, in those initially requiring parenteral therapy, the timely conversion from intravenous to oral therapy. Indications for hospital admission include inability to maintain oral hydration or to take medications; uncertain social situation or concern about compliance; uncertainty about the diagnosis; and severe illness with high fevers, severe pain, and marked debility. Outpatient therapy is safe and effective for select patients who can be stabilized with parenteral fluids and antibiotics in an urgent care facility and sent home with oral antibiotics under close supervision. In one population-based study of acute pyelonephritis in adult females, only 7% were hospitalized.[4]

The management strategy for acute uncomplicated pyelonephritis is shown in Fig. 53.5. Many effective parenteral (Table 53.5) and oral

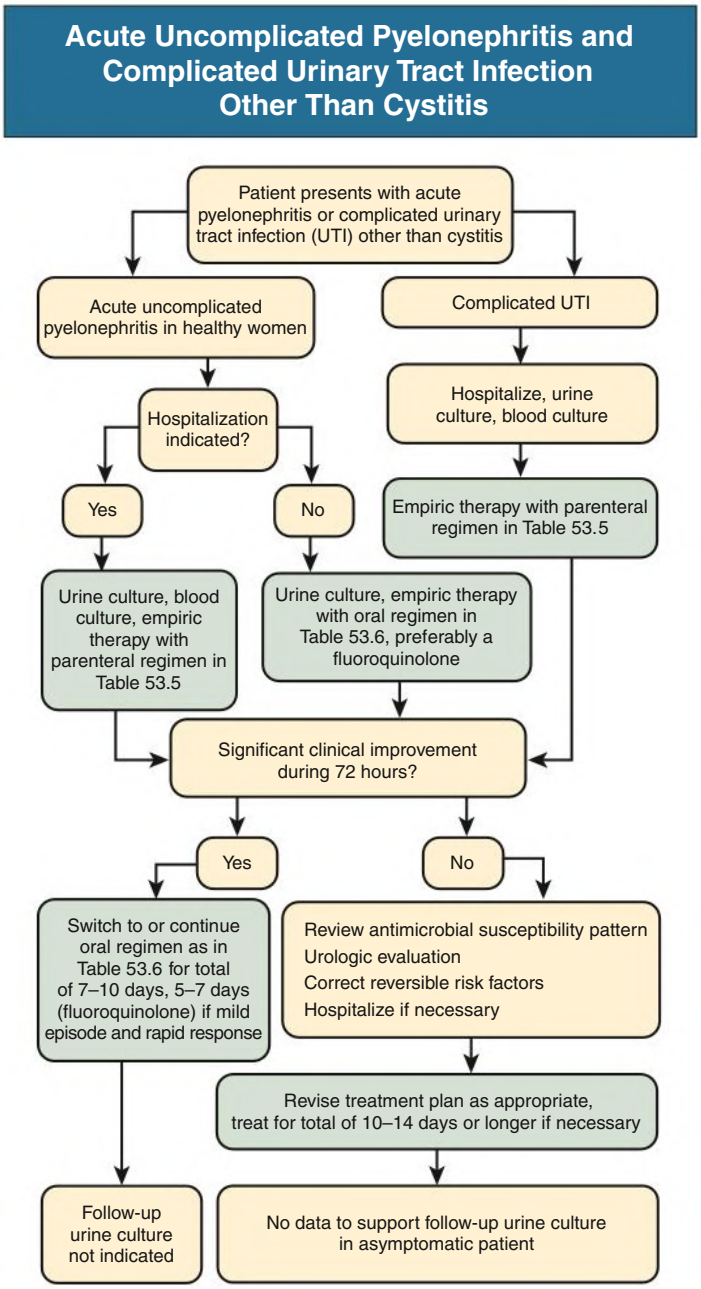

Fig. 53.5 Management algorithm for acute uncomplicated pyelonephritis and complicated urinary tract infection other than cystitis.

(Table 53.6) regimens are available for patients with acute uncomplicated pyelonephritis. For outpatients, an oral fluoroquinolone should be used for initial empiric treatment of infection caused by gram-negative bacilli.[21] TMP-SMX or other agents can be used if the infecting strain is known to be susceptible. If enterococci are suspected from the Gram stain, amoxicillin should be added to the treatment regimen until the causative organism is identified. Second- and third-generation cephalosporins also appear effective, although published data are sparse. Nitrofurantoin, fosfomycin, and pivmecillinam are not approved or recommended for the treatment of pyelonephritis because they only achieve therapeutic levels in the bladder. When antimicrobial resistance or intolerance of oral medications is a concern, one or more doses of a broad-spectrum parenteral antimicrobial is recommended until in vitro activity can be ensured.[21,39]

For hospitalized patients without evidence of gram-positive infection, ceftriaxone is effective and inexpensive. If enterococci are suspected based on the Gram stain, ampicillin plus gentamicin, ampicillin-sulbactam, or piperacillin-tazobactam are reasonable empiric choices. TMP-SMX should not be used as empiric monotherapy for pyelonephritis in areas with a high prevalence of resistance to this agent. Patients with acute uncomplicated pyelonephritis often can be switched to oral therapy after 24 to 48 hours, although longer durations of parenteral therapy are occasionally indicated in patients with continued high fever, severe flank pain, or persistent nausea and vomiting.

Treatment of acute uncomplicated pyelonephritis can be limited to 5 to 7 days for patients who have a rapid resolution of fever and

TABLE 53.5 Parenteral Regimens for Acute Uncomplicated Pyelonephritis and Complicated Urinary Tract Infection[a]

Drug	Dose (mg)	Interval
Ceftriaxone	1000–2000	q24h
Cefepime	1000–2000	q12h
Fluoroquinolones[b]		
Ciprofloxacin	200–400	q12h
Levofloxacin	250–750	q24h
Gentamicin[b] (± ampicillin)	3–5 mg/kg body weight	q24h
	1 mg/kg body weight	q8h
Ampicillin (+ gentamicin[b])	1000	q6h
Trimethoprim-sulfamethoxazole[b]	160/800	q12h
Aztreonam	1000	q8–12h
Piperacillin-tazobactam	3375	q6–8h
Imipenem-cilastatin[b,c]	250–500	q6–8h
Meropenem[c]	500	q8h
Ertapenem[c]	1000	q24h
Ceftolozane/tazobactam	1500	q8h
Ceftazidime/avibactam	2500	q8h
Vancomycin[d]	1000	q12h

[a]Duration depends on clinical setting (see text and Fig. 53.5).
[b]Avoid, if possible, in pregnancy.
[c]Recommended if ESBL Enterobacteriacea is suspected or known. Ertapenem is not indicated for suspected or known *Pseudomonas* infection.
[d]Recommended if methicillin-resistant *Staphylococcus aureus* is suspected or known.

TABLE 53.6 Oral Regimens for Acute Uncomplicated Pyelonephritis and Complicated Urinary Tract Infection[a,b]

Drug	Dose (mg)	Interval	Comment
Fluoroquinolones			Preferred for empiric treatment; avoid if possible in pregnancy, nursing mothers, or persons younger than 18 years of age.
Ciprofloxacin	500	q12h	
Ciprofloxacin extended release	1000	q24h	
Levofloxacin	250–750	q24h	
Trimethoprim-sulfamethoxazole	160/800	q12h	Use only when the causative pathogen is known to be susceptible. If used in pregnancy (not approved use), avoid in first trimester.
Cefpodoxime proxetil	200	q12h	Data are sparse; use only when the causative pathogen is known to be susceptible.
Amoxicillin-clavulanate	500/125–875/125	q12h	Use only when the causative pathogen is known to be susceptible or in addition to a broad-spectrum agent when empiric coverage against enterococci is desirable.

[a]A long-acting parenteral antibiotic should be given concomitantly if there are concerns about drug resistance.
[b]Duration depends on clinical setting (see text and Fig. 53.5).

symptoms soon after initiation of treatment. However, β-lactam regimens shorter than 14 days have been associated with unacceptably high failure rates.[40] One study demonstrated superiority of a 7-day ciprofloxacin regimen over a 14-day TMP-SMX regimen, with the difference accounted for entirely by the higher rate of resistance of the uropathogens to TMP-SMX.[33]

A U.S. study of patients with acute pyelonephritis presenting to emergency departments demonstrated that the prevalence of fluoroquinolone-resistant and ESBL-producing strains is increasing and that such patients are often treated with empiric antimicrobial drugs that are inactive against the causative strains.[41] The authors concluded that in areas with high fluoroquinolone resistance rates, where ESBL-producing *Enterobacteriaceae* infections have emerged, or among persons with antimicrobial drug resistance risk factors, clinicians should consider empiric treatment with a carbapenem or another agent with activity against these resistant strains.

Routine posttreatment urine cultures in asymptomatic patients are not useful, but cultures should be performed if symptoms persist or recur. Recurrent infections are treated with a 7- to 14-day course of an antibiotic to which the organism is susceptible. Symptomatic patients who have persistent infection with the same strain as the initial infecting strain warrant at least 10 to 14 days of therapy with a different antibiotic, and complicating factors should be sought and corrected if possible.

Males With Cystitis

Among premenopausal females, cystitis is more common than among similarly aged males. However, after the age of 50 to 60, rates of cystitis in males increase, although never reaching the rates of females of equivalent age.[42] Whereas cystitis in females is well studied, similar studies of male patients are lacking. Males with cystitis are often considered to be a category of complicated UTI, with male sex considered a factor that increase the risk of treatment failure or recurrence. Whether this classification is applicable to all males is unproven; many seem to respond to traditional cystitis treatment but may require a longer duration of treatment than females. Observational studies[43,44] and a recent trial[44a] suggest that shorter-duration therapy performs similarly well to longer-duration therapy, although even the shorter-duration therapy in these studies was longer than the 1- to 5-day regimens that are effective for females with cystitis. Whether males with cystitis who have additional complicating factors (e.g., urinary retention, renal calculi, indwelling catheters) need longer-duration therapy is unknown.

Another difference between males and females with cystitis is the relative lack of predictability regarding the causative organisms. Whereas the microbiology of cystitis among females is predictable, among males there is more variability. *E. coli* is still the most commonly isolated pathogen, but in some series is only a plurality versus the clear majority observed in females.[45,46] Because of this unpredictability, a urine culture should always be obtained to help guide therapy in male patients with cystitis.

Complicated Infections

Patients with UTI in the presence of complicating conditions may present with classic signs of cystitis and pyelonephritis but also may have vague or nonspecific symptoms, such as fatigue, irritability,

nausea, headache, and abdominal or back pain. Acute cystitis in healthy individuals other than young females is more likely to involve occult renal or prostatic infection and may respond poorly to short-course therapy. Noninvasive tools to localize infections to the kidney or prostate are lacking, so clinical estimation of risk in a given patient is imprecise. Some patients, such as those who are diabetic or pregnant, warrant special attention because of the serious complications that can occur if treatment is inadequate. Urethritis should be excluded in dysuric sexually active males by a urethral Gram stain or a urine nucleic acid amplification test for *Neisseria gonorrhoeae* and *Chlamydia trachomatis.* Complicated UTI, just as with uncomplicated infection, is generally associated with pyuria and bacteriuria, although these may be absent if the infection does not communicate with the collecting system.

Urine culture should always be performed in patients with suspected complicated UTI. Traditionally complicated UTI is at least 10^5 cfu/mL in the urine of females and at least 10^4 cfu/mL in males, but lower counts in symptomatic persons, as demonstrated in patients with uncomplicated UTI, may well represent significant bacteriuria. This is especially true when the specimen is collected from a urinary catheter. Thus, it is reasonable to use a colony count threshold of greater than 10^3 cfu/mL of uropathogens to diagnose complicated UTI.

The wide variety of underlying conditions (see Box 53.1), diverse bacterial agents (see Table 53.2), and paucity of RCTs make generalizations about antimicrobial therapy difficult. Figs. 53.1 and 53.5 outline the management strategy for complicated cystitis and other complicated UTIs, respectively.

Correction of any underlying anatomic, functional, or metabolic defect should be attempted because antibiotics alone may not be successful.[1] For empiric therapy in patients with mild to moderate illness who can be treated with oral medication, the fluoroquinolones provide the broadest spectrum of antimicrobial activity, cover most expected pathogens, and achieve high levels in the urine and urinary tract tissue. An exception is moxifloxacin, which may not achieve sufficient concentrations in urine to be effective for complicated UTI. If the infecting pathogen is known to be susceptible, TMP-SMX or other agents are reasonable therapeutic choices. Nitrofurantoin and fosfomycin should be avoided except for cystitis in pregnancy, in which duration of treatment is 5 days or single-dose, respectively.

For initial treatment in more seriously ill, hospitalized patients, several parenteral antimicrobial agents are available (see Table 53.5). The broader spectrum agents shown in Table 53.5 are preferable for health care–associated infections. *S. aureus* is more common in complicated UTIs, and, if suspected, the therapeutic regimen should have activity against *S. aureus.* Studies show that a high proportion of *S. aureus* isolates, even in the community, are methicillin resistant (MRSA), so vancomycin should be included in the empiric treatment regimen if *S. aureus* is suspected. Factors that must be considered in the management of complicated UTI include the increasing prevalence of resistance to fluoroquinolones in institutional settings and the frequency of enterococcal infections.

The antimicrobial regimen can be modified when the infecting strain has been identified and antimicrobial susceptibilities are known. Patients receiving parenteral therapy can be switched to oral treatment after clinical improvement. Few studies evaluate duration of treatment in populations with complicated UTIs. However, it is desirable to limit the duration of treatment, especially for milder infections, to reduce the selection pressure for drug-resistant flora. In one study, clinical and microbiologic success rates after treatment were almost identical in patients with acute pyelonephritis or complicated UTI treated with a 5-day course of levofloxacin or a 10-day course of ciprofloxacin.[47] These data suggest that a 5- to 10-day regimen is reasonable for most patients with complicated UTI, depending on their severity of illness and clinical response; shorter regimens, such as a 5-day regimen of a urinary fluoroquinolone, are likely to be sufficient in patients who are less severely ill, are infected with uropathogens susceptible to the antibiotic used, and have a rapid response to treatment. A recent large retrospective study of male veterans with UTI found no difference in recurrence rates with 7 days of treatment versus longer, with a trend toward more *Clostridium difficile* infections in those treated longer.[43] A clinical trial of V in veterans with UTI but without fever confirmed non-inferiority of 7 versus 14 days of antibiotics.[44a] At least 10 to 14 days of therapy is recommended in patients who have a delayed response.

Routine posttreatment cultures are not indicated unless the patient is symptomatic, except in pregnant patients (see Fig. 53.1). In males, early recurrence of UTI with the same species suggests a prostatic source of infection and warrants a 4- to 6-week regimen of either a fluoroquinolone (preferable) or TMP-SMX, depending on the antimicrobial susceptibility of the infecting strain.

Chronic Kidney Disease

Because of the wide variety of underlying diseases and comorbidities, prior instrumentation of the urinary tract, and differences in age and sex, the incidence of UTI in patients with CKD is not known.[48] Moreover, there are few data on urine concentrations of antimicrobials used for the treatment of UTI in patients with CKD.[49] Studies in animals suggest that (1) urine drug concentrations are necessary to sterilize urine, (2) effective tissue concentrations are necessary to treat pyelonephritis, and (3) serum concentrations of antimicrobials are correlated with the drug concentrations in kidney tissue. Thus, for patients with CKD who have a therapeutic serum drug level and adequate perfusion of the kidney parenchyma, the delivery of therapeutic concentrations of both the parenchyma and the urine should be adequate, but some oral agents for cystitis may not deliver adequate concentrations to the urine.[49] For patients with a low glomerular filtration rate (GFR) and pyelonephritis or cystitis, the agents listed in Tables 53.5 and 53.6 for pyelonephritis and complicated cystitis should be adequate to treat these infections if the organism is susceptible.[49]

As noted previously, β-lactams are not as effective as fluoroquinolones, even in patients with normal kidney function.[28,29] Doses of ciprofloxacin or levofloxacin should be adjusted for GFR; moxifloxacin is not recommended for UTI treatment. Nitrofurantoin and sulfamethoxazole are not recommended in patients with reduced GFR, although trimethoprim concentrations appear to be adequate.[48] Likewise reduced kidney function (such as CKD stage 3 or higher) significantly decreases the excretion of fosfomycin, which also should not be used in such patients.

Catheter-Associated Infections

Approximately 15% to 25% of patients in general hospitals have a urethral catheter inserted at some time during their stay, and approximately 5% to 10% of long-term care facility residents are managed with urethral catheterization, in some cases for years. The incidence of bacteriuria associated with indwelling catheters is 3% to 10% per day of catheterization, and the duration of catheterization is the most important risk factor for the development of catheter-associated bacteriuria.

Catheter-associated bacteriuria is the most common source of gram-negative bacteremia in hospitalized patients, often associated with catheter obstruction or trauma. Complications of long-term catheterization (≥30 days) include almost universal bacteriuria, often with multiple antibiotic-resistant flora, and (in addition to cystitis, pyelonephritis, and bacteremia, as seen with short-term catheterization) frequent febrile episodes, catheter obstruction, stone formation

associated with urease-producing uropathogens, and local genitourinary infections. Other rare complications include fistula formation and bladder cancer. An increase in mortality risk has been reported with catheter-associated bacteriuria, but it is difficult to distinguish the role of the catheter because most deaths occur in patients who have severe underlying disease.

Most episodes of catheter-associated bacteriuria are asymptomatic and do not require routine screening or treatment because treatment does not reduce the complications of bacteriuria and can lead to antimicrobial resistance.[7] Moreover, the presence or absence of pyuria does not differentiate symptomatic from asymptomatic urinary infection.[7] Symptomatic UTIs, often caused by many multidrug-resistant uropathogens, warrant broad-spectrum therapy, as described previously. In a symptomatic catheterized patient, a urine culture specimen should be obtained from a freshly placed catheter if the catheter has been in place for a few days because the catheter biofilm may result in spurious culture results. Moreover, clinical outcomes are improved if the catheter is replaced at the time of antimicrobial therapy.[50] The recommended duration of antimicrobial treatment for patients who have prompt resolution of symptoms is 7 days, and 10 to 14 days if response is delayed.[51]

Preventive measures are indicated to reduce the morbidity, mortality, and costs of catheter-associated infection. Effective strategies include avoidance of a catheter when possible and, when the catheter is necessary, sterile insertion, prompt removal, and strict adherence to a closed collecting system.[6,51] Bundling of preventive steps may be useful.[52,53] Meta-analyses have shown that rates of catheter-associated bacteriuria, at least in patients catheterized for less than 2 weeks, are higher in patients with an indwelling urethral catheter than in those with intermittent or suprapubic catheterization.[54] Likewise, condom catheterization is preferable to indwelling urethral catheterization in appropriately selected males.[54] Although highly effective in reducing catheter-associated bacteriuria rates, prophylactic systemic antimicrobial agents are generally not recommended for routine use because of concerns about selection for antimicrobial resistance. Antimicrobial-coated catheters appear to be effective in reducing catheter-associated bacteriuria in patients catheterized for less than 2 weeks, but these have not been shown to be effective in reducing symptomatic infection.

Spinal Cord Injury

Spinal cord injury alters the dynamics of voiding and often requires the use of bladder drainage with catheters. The diagnosis of UTI in patients with spinal cord injuries is based on the combination of symptoms and signs (which are often nonspecific), pyuria, and significant bacteriuria. Uropathogens are usually present in quantities of at least 10^5 cfu/mL. Fluoroquinolones are the empiric oral agents of choice in patients with mild to moderate infection, although many uropathogens, even in the outpatient setting, are resistant to this class of antibiotic, and parenteral antibiotics may be needed.

Treatment of asymptomatic bacteriuria in patients with spinal cord injuries is not of proven benefit and increases the risk for infection with antimicrobial-resistant uropathogens.[7,55] Likewise, antibiotic prophylaxis is generally not recommended, although it may be considered for select outpatients with frequent symptomatic UTIs for whom there are no correctible risk factors. Recent studies have shown that use of a hydrophilic-coated catheter for intermittent catheterization is associated with a reduction in the incidence of symptomatic UTI in patients with spinal cord injury.[56]

Prostatitis

Prostatitis occurs in up to 25% of males during their lifetime, but it is caused by acute or chronic bacterial infection in a minority.[57] The most common organisms causing bacterial prostatitis are gram-negative bacilli, including *E. coli, Proteus* spp., *Klebsiella* spp., *P. aeruginosa,* and, less frequently, enterococci and *S. aureus.* The pathogenesis of prostatitis is believed to be related to reflux of infected urine from the urethra into the prostatic ducts. Prostatic calculi, commonly found in adult males, may provide a nidus for bacteria and protection from antibacterial agents.

Acute bacterial prostatitis is rare. Patients present with dysuria, frequency, urgency, obstructive voiding symptoms, fever, chills, and myalgias. The prostate is tender and swollen, and the prostate exam should be limited to assessment of size and tenderness to avoid precipitating bacteremia. The patient will usually have pyuria and a positive urine culture. Patients who are severely ill require hospitalization and parenteral antibiotics, but many patients can be treated in the outpatient setting with oral fluoroquinolones. The recommended duration of treatment is 14 to 30 days.[57] Rarely, abscess formation may occur, which should be treated by source control with the assistance of a urologist.

Chronic bacterial prostatitis is characterized by recurrent UTIs with the same uropathogen with intervening asymptomatic periods. The prostate typically is normal to palpation during asymptomatic periods. Chronic bacterial prostatitis is characterized microscopically by the presence of at least 10 leukocytes per high-power field in expressed prostatic secretions or postmassage voided urine in the absence of significant pyuria in first-voided and midstream urine specimens, as well as a uropathogen colony count at least 10-fold higher in the expressed prostatic secretions or postmassage voided urine compared with the first-voided midstream urine. In addition, macrophage-laden fat droplets (oval fat bodies) are usually prominent in the prostatic secretions. These tests, however, are infrequently performed by urologists. Cure rates, which historically have been low, are 60% to 80% with the fluoroquinolones, which are the antibiotics of choice. The optimal duration of treatment is unknown, but 4 to 6 weeks is recommended by some authorities,[57] whereas others recommend up to 3 months. Some patients require long-term, low-dose suppressive therapy to prevent symptomatic UTIs. Surgical intervention is only rarely considered and is associated with high morbidity.

Kidney Abscess

Kidney cortical and corticomedullary abscesses and perirenal abscesses occur in 1 to 10 per 10,000 hospital admissions.[58] Patients usually present with fever, chills, back or abdominal pain, and costovertebral angle tenderness, but they may have no urinary symptoms or findings if the abscess does not communicate with the collecting system, as often occurs with a cortical abscess. Bacteremia may be primary (cortical abscess) or secondary (corticomedullary or perirenal). The clinical presentation may be insidious and nonspecific, especially with perirenal abscess, and the diagnosis may not be made until admission to a hospital or at autopsy. CT is recommended to establish the diagnosis and location of a renal or perirenal abscess (Fig. 53.6). Empiric antibiotic therapy should be broad and cover *S. aureus* and other uropathogens causing complicated UTI (see Fig. 53.5 and Table 53.5) and modified once urine culture results are known.

A *renal cortical abscess* (kidney carbuncle) is usually caused by *S. aureus,* which reaches the kidney by hematogenous spread. Treatment with antibiotics is usually effective, and drainage is not required unless the patient is slow to respond. A *renal corticomedullary abscess,* in contrast, usually results from ascending UTI in association with an underlying urinary tract abnormality, such as obstructive uropathy or VUR, and is usually caused by common uropathogenic species such as *E. coli* and other gram-negative bacilli. Such abscesses may extend deep into the renal parenchyma, perforate the renal capsule, and form

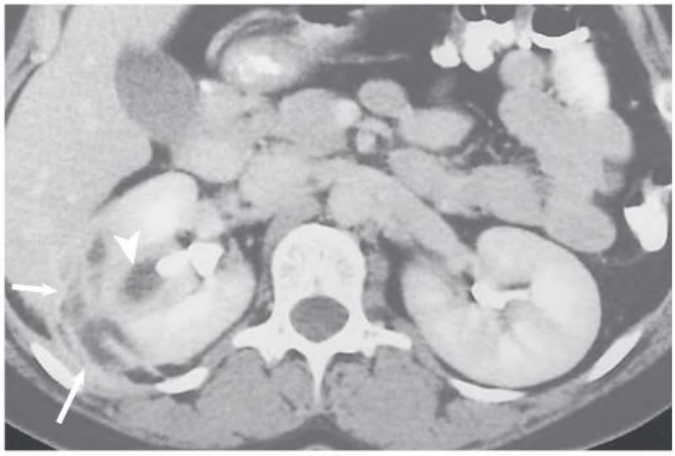

Fig. 53.6 Renal Abscess. Contrast-enhanced computed tomography scan shows an abscess in the medulla of the kidney *(arrowhead)* with penetration and extension into the perinephric space *(arrows)*. (Courtesy L. Towner.)

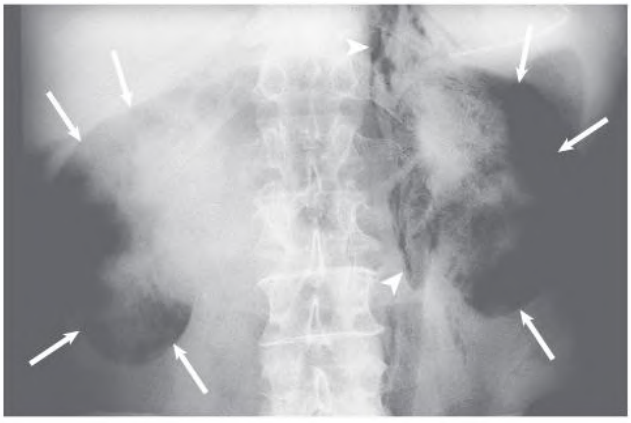

Fig. 53.7 Emphysematous Pyelonephritis. A plain radiograph in this febrile patient with diabetes reveals diffuse gas formation throughout both kidneys *(outlined by arrows)* and gas dissecting in the left retroperitoneal space *(arrowheads)*. (Courtesy W. Bush, University of Washington, Seattle.)

a perirenal abscess. Treatment with antimicrobial agents without drainage may be effective if the abscess is small and if the underlying urinary tract abnormality can be corrected. Aspiration of the abscess may be necessary in some patients, and nephrectomy may occasionally be required in patients with diffuse renal involvement or with severe sepsis. Perirenal abscesses usually occur in the setting of obstruction or other complicating factors (see Box 53.1) and result from ruptured intrarenal abscesses, hematogenous spread, or spread from a contiguous infection. Causative uropathogens are those usually found in complicated UTIs (see Table 53.2), including *S. aureus* and enterococci; polymicrobial infections are common. Anaerobes or *Mycobacterium tuberculosis* may be causative (see Chapter 54). A previously high mortality rate has been lowered with earlier diagnosis and therapy. In contrast to the other types of renal abscesses, drainage of pus is the cornerstone of therapy and nephrectomy may be indicated.

Papillary Necrosis

More than half of patients who develop papillary necrosis have diabetes, almost always in conjunction with a UTI, but the condition also complicates sickle cell disease, analgesic abuse, and obstruction. Kidney papillae are vulnerable to ischemia because of the sluggish blood flow in the vasa recta, and relatively modest ischemic insults may cause papillary necrosis. The clinical features are those typical of pyelonephritis. In addition, passage of sloughed papillae into the ureter may cause renal colic, renal impairment or failure, or obstruction with severe urosepsis. Papillary necrosis in the setting of pyelonephritis is associated with pyuria and a positive urine culture. Causative uropathogens are those typical of complicated UTI. CT is the preferred diagnostic procedure. Radiologic findings include an irregular papillary tip; dilated calyceal fornix; extension of contrast material into the parenchyma; and a separated crescent-shaped papilla surrounded by contrast called the *ring sign* (see Chapter 51, Fig. 51.8). Broad-spectrum antibiotics are indicated. Papillae obstructing the ureter may require removal with a cystoscopic ureteral basket or relief of obstruction by insertion of a ureteral stent.

Emphysematous Pyelonephritis

Emphysematous pyelonephritis is a fulminant, necrotizing, life-threatening variant of acute pyelonephritis caused by gas-forming organisms, including *E. coli, Klebsiella pneumoniae, P. aeruginosa,* and *Proteus mirabilis.*[59] Up to 90% of cases occur in diabetic patients, and obstruction may be present. Symptoms are suggestive of pyelonephritis, and there may be a flank mass. Dehydration and ketoacidosis are common. Pyuria and a positive urine culture are usually present. Gas is usually detected by a plain abdominal radiograph or ultrasound (Fig. 53.7). CT is the diagnostic modality of choice, however, because it can localize the gas better than ultrasound. Accurate localization of gas is important because gas also may form in an infected obstructed collecting system or renal abscess; although serious, these conditions do not carry the same poor prognosis and are managed differently. Parenteral broad-spectrum antibiotics and percutaneous catheter drainage with relief of obstruction may be adequate for less severely ill patients, but nephrectomy is warranted for those who are more severely ill and those less severely ill who do not respond to the preceding steps. Medical treatment is associated with mortality of 60% to 80%, which is lowered to 20% or less with surgical intervention (e.g., nephrectomy, percutaneous drainage).

Kidney Malacoplakia

Malacoplakia is a chronic granulomatous disorder of unknown etiology involving the genitourinary, gastrointestinal, skin, and pulmonary systems.[60] It is characterized by an unusual inflammatory reaction to a variety of infections and is manifested by the accumulation of macrophages containing calcified bacterial debris called *Michaelis-Gutmann bodies* (Fig. 53.8). The underlying disorder appears to be a monocyte-macrophage bactericidal defect. The diagnosis is made by histologic examination of involved tissue. Genitourinary malacoplakia, most often involving the bladder, is usually associated with gram-negative UTI. Patients with kidney malacoplakia generally have fever, flank pain, pyuria and hematuria, bacteriuria, and, if both kidneys are involved, impaired renal function. CT usually shows enlarged kidneys with areas of poor enhancement, and the condition may be indistinguishable from other infectious or neoplastic lesions. On occasion, the malacoplakia may extend through the kidney capsule into the perinephric space, simulating a renal carcinoma (see Fig. 53.8). Treatment consists of therapy with a broad-spectrum antimicrobial, attempted correction of any underlying complicating conditions, and improvement of renal function. Nephrectomy is recommended for advanced unilateral disease. When the disease is bilateral or occurs in a transplanted kidney, the patient's prognosis is very poor.

Xanthogranulomatous Pyelonephritis

Xanthogranulomatous pyelonephritis is a poorly understood, uncommon but severe chronic destructive granulomatous inflammation of

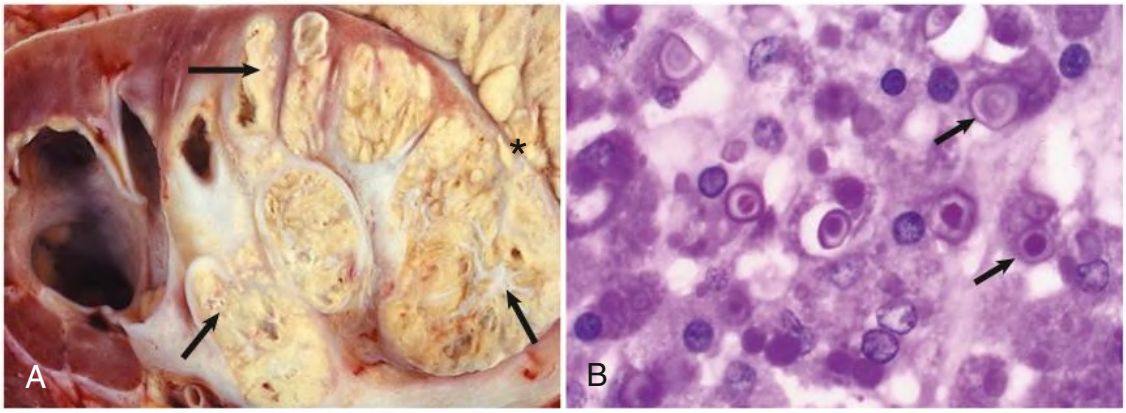

Fig. 53.8 Renal Malacoplakia. (A) Malacoplakia involving most of the kidney *(arrows)* with extension through the capsule *(asterisks).* A small portion of normal kidney is present associated with hydronephrosis secondary to obstruction by the malacoplakia. (B) The kidney tissue shows many macrophages containing intracytoplasmic inclusions (*arrows* identify two particularly well-demarcated macrophages with Michaelis-Gutmann bodies). (Courtesy L. Truong, Baylor College of Medicine, Houston, and N. Sheerin, Guy's Hospital, London.)

the kidney parenchyma associated with obstruction and infection of the urinary tract.[61] The renal parenchyma is replaced with a diffuse or segmental cellular infiltrate of foam cells, which are lipid-laden macrophages. The process also may extend beyond the kidney capsule to the retroperitoneum. Its pathogenesis appears to be multifactorial, with infection complicating obstruction and leading to ischemia, tissue destruction, and accumulation of lipid deposits. Patients with xanthogranulomatous pyelonephritis are characteristically middle-aged females and have chronic symptoms such as flank pain, fever, chills, and malaise. Flank tenderness, a palpable mass, and irritative voiding symptoms are common. The urine culture is usually positive with *E. coli,* other gram-negative bacilli, or *S. aureus.* CT generally shows an enlarged nonfunctioning kidney, often the presence of calculi and low-density masses (xanthomatous tissue), and, in some cases, involvement of adjacent structures (Fig. 53.9). It may be difficult to distinguish from neoplastic disease. Broad-spectrum antimicrobials are indicated, but total or partial nephrectomy is usually necessary for cure.

Asymptomatic Bacteriuria

Asymptomatic bacteriuria is common and generally benign.[7] Pyuria is almost universally present, especially in elderly people, and is a predictor for subsequent symptomatic UTI in some groups. Causative uropathogens are the same as those causing UTIs in the same population. Testing for and treatment of asymptomatic bacteriuria is generally not warranted.[7] In young females with recurrent UTI, asymptomatic bacteriuria may paradoxically be protective against symptomatic recurrence and treatment may increase the risk for such recurrences.[62] Two exceptions to this are pregnant patients and patients undergoing urologic surgery; in both these groups, screening for and treatment of asymptomatic bacteriuria is recommended to prevent subsequent complications.[7] Current management strategies in patients with a renal transplant, including long-term antimicrobial prophylaxis, help prevent both asymptomatic bacteriuria and symptomatic UTI. It is not clear, however, whether testing for or treatment of asymptomatic bacteriuria in such patients is worthwhile.[7] Some authorities advise treatment of asymptomatic bacteriuria found in patients with anatomic or functional abnormalities of the urinary tract, diabetic patients, and patients with urea-splitting bacteria (e.g., *P. mirabilis, Klebsiella* spp.). Evidence-based guidelines for evaluation and treatment of asymptomatic bacteriuria in these populations are needed.

Asymptomatic bacteriuria in catheterized patients in hospitals and long-term care facilities, although thought to be generally benign, represents a large reservoir of antimicrobial-resistant urinary pathogens that increases the risk for cross-infection among catheterized patients and results in frequent inappropriate antimicrobial use.[51]

IMAGING OF THE URINARY TRACT

Urologic consultation and evaluation of the urinary tract should be considered in patients who present with symptoms or signs of obstruction, urolithiasis, flank mass, or urosepsis. Similarly, such an evaluation should be considered for those patients with presumptive uncomplicated or complicated UTI who have *not* had a satisfactory clinical response after 72 hours of treatment, to exclude complicating factors. A kidney ultrasound can detect the size and contour of the kidneys and bladder, the presence of a renal mass or abscess, certain renal and ureteral calculi, hydronephrosis suggestive of obstructive uropathy, and elevated postvoid residual urine.[63] A plain abdominal radiograph (kidneys, ureters, bladder [KUB]) can identify radiopaque

calculi along the genitourinary tract, especially proximal and distal ureteral stones that can be missed on ultrasound. Kidney ultrasound and KUB are less sensitive than CT for detection of many conditions in patients with complicated UTI. Any finding suggesting mass or complex fluid collection should prompt follow-up imaging with CT. CT offers fine anatomic detail and is thus the superior study for evaluation of focal inflammation, renal or perirenal abscess and masses, and both radiopaque and radiolucent stones. However, CT also carries the greatest risk profile, exposing the patient to both intravenous contrast and ionizing radiation.[63] Non–contrast-enhanced spiral CT is a rapid, safe, and sensitive method for evaluating patients with suspected kidney stones. Radionuclide imaging procedures have no role in the evaluation of adults with UTI, although they are useful in children with pyelonephritis (see Chapter 62).

Excretory urography and cystoscopy in females with recurrent cystitis rarely demonstrate abnormalities or alter management[3] and therefore are not recommended. Likewise, imaging studies in young females with acute pyelonephritis are also generally not cost-effective and have a low diagnostic yield, although it is reasonable to obtain such studies after two episodes of pyelonephritis or if any complicating factor is present (see Box 53.1). Imaging studies and cystoscopy are unnecessary in a male who has had a single UTI with no obvious complicating factors and whose infection responds promptly to treatment.

SELF-ASSESSMENT QUESTIONS

1. Which of the following antimicrobials is *not* recommended for first-line use for uncomplicated cystitis by the Infectious Disease Society of America treatment guidelines?
   A. Fosfomycin
   B. Ciprofloxacin
   C. Trimethoprim-sulfamethoxazole
   D. Nitrofurantoin
2. What approach has not been shown to be effective in the management of recurrent cystitis in females?
   A. Postcoital antimicrobial prophylaxis
   B. Daily antimicrobial prophylaxis
   C. Intermittent self-treatment
   D. Periodic screening and treatment of asymptomatic bacteriuria
3. Which of the following antimicrobials should be *avoided* in the treatment of prostatitis?
   A. Ciprofloxacin
   B. Nitrofurantoin
   C. Levofloxacin
   D. Trimethoprim-sulfamethoxazole
4. In which of the following conditions is screening for and treatment of asymptomatic bacteriuria indicated?
   A. Elderly males and females
   B. Catheterized males and females
   C. Pregnant patients and patients undergoing urologic instrumentation
   D. After treatment for acute pyelonephritis

Tuberculosis of the Urinary Tract

R. Kasi Visweswaran, M. Sreelatha

DEFINITION

More than a century after *Mycobacterium tuberculosis* (MTB) was first described by Robert Koch, tuberculosis (TB) remains a global health problem and among the leading causes of death from infectious disease worldwide.[1] As per the World Health Organization (WHO) Global Tuberculosis Report in 2018, an estimated 10 million people developed TB, of whom 4 million people with TB remained undiagnosed and untreated.[2] Infection with MTB is responsible for nearly 1.3 million deaths each year. TB is the most common opportunistic infection in people with human immunodeficiency virus (HIV).[3] In HIV-endemic areas, as many as 75% of patients with urogenital TB (UG-TB) are coinfected with HIV. TB is also common in patients with chronic kidney disease (CKD). In some endemic areas, TB has been reported to occur in up to 8.7% of patients on hemodialysis, 12.3% of kidney allograft recipients,[4] and 9.3% of children with nephrotic syndrome.[5] Although the global incidence is estimated to be declining by 1.6% and mortality by 4.1% per year, few countries are likely to meet the United Nations (UN) Sustainable Development Goals target to end the epidemic by 2030.

Drug-resistant forms of tuberculosis are currently among the world's deadliest pathogens. Data from 2017 show that among nearly 0.55 million cases of rifampicin-resistant TB, 80% had multidrug-resistant (MDR) TB (defined as resistance to rifampicin and isoniazid) and 8.5% of patients with MDR-TB had extensively drug-resistant (XDR) TB (with XDR-TB defined as resistance to rifampicin, isoniazid, quinolones, and aminoglycosides).[6]

The common sites of extrapulmonary involvement by MTB are lymph nodes, urinary tract, genital tract, bone, adrenal glands, and the central nervous system. UG-TB may remain asymptomatic and undiagnosed in up to 20% of individuals with active pulmonary TB. Kidney involvement may also occur as part of miliary TB. Because UG-TB can easily be overlooked, a high index of suspicion is necessary for early diagnosis in endemic areas. Delayed diagnosis may result in irreversible organ damage and even end-stage kidney failure.[7]

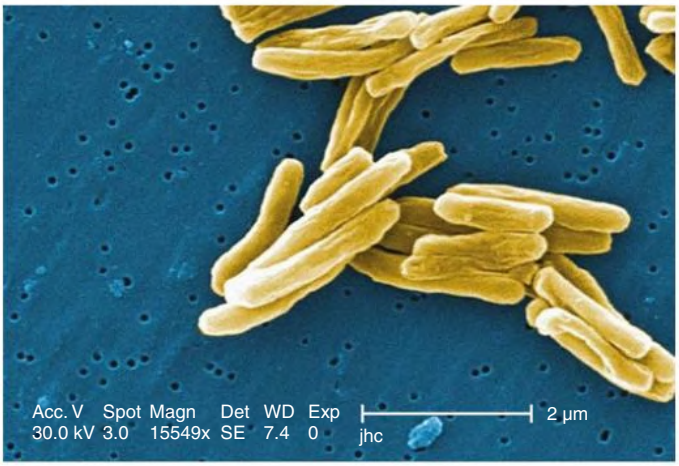

Fig. 54.1 Scanning Electron Microscopy of *Mycobacterium Tuberculosis.* The bacillus is a straight or slightly curved rod about 2 to 4 µm long and 0.3 to 0.5 µm wide. (High magnification × 15,549). (Courtesy Ray Butler MS, CDC. Division of Tuberculosis Elimination, National Center for HIV, STD, and TB Prevention. Atlanta, GA.)

ETIOLOGY

TB is caused by the *M. tuberculosis* complex (MTBC). *Mycobacterium tuberculosis* is a nonmotile, nonsporing, rod-shaped, slightly curved, obligate aerobe bacterium (Fig. 54.1). It is weakly gram-positive and acid- and alcohol-fast. The cell wall has a high content of mycolic acid that makes the organism resistant to acids, alkalis, antibiotics, osmotic agents, and intracellular events. Lipoarabinomannan (LAM) forms a part of the mycolic acid in the cell wall and its identification in urine is useful for diagnosis. The most superficial layer consists of glycolipids and polypeptide (Fig. 54.2). The polypeptides are isolated and purified to make the skin testing antigen, which is called purified protein derivative (PPD) (Table 54.1). Although most TB, including genitourinary TB, is caused by MTB, other mycobacteria, such as *M. avium-intracellulare, M. kansasii, M. bovis, M. fortuitum,* and *M. szulgai,* may cause clinical disease, especially in immune-compromised hosts. Among the atypical mycobacteria, *M. chelonei abscessus* belongs to the group of "rapid growers" and causes abscesses after injection or percutaneous procedures, especially in patients with diabetes.[8]

PATHOGENESIS

The most common routes of transmission are:

1. Inhalation of infected droplets from patients with active pulmonary TB (95%)
2. Ingestion of dairy products infected with *M. bovis* from cattle
3. After therapeutic intravesical bacillus Calmette-Guérin (BCG) instillation
4. Contiguous spread to nearby organs
5. Lymphatic or hematogenous spread
6. Congenital, sexual, or accidental inoculation (rare)

The clinical and pathologic manifestations of TB depend on the virulence of the organism and the effectiveness of the host response. In 95% of people, after primary infection, the bacilli multiply locally and evoke a local response to form a primary granuloma called the Ghon complex. The immune responses result in either eradication, containment as latent TB infection (LTBI), or active disease. The WHO has defined LTBI

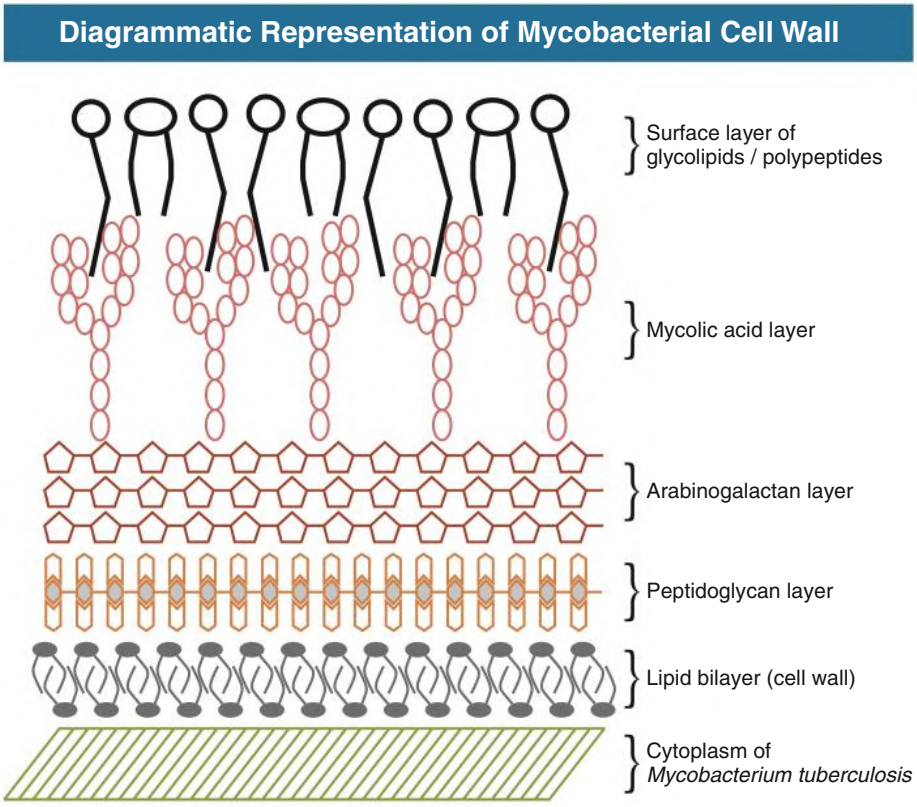

Fig. 54.2 Diagrammatic representation of mycobacterial cell wall.

TABLE 54.1 Cell Wall Characteristics Affecting Survival of *Mycobacterium tuberculosis*

Composition of Cell Wall	Factors for Survival
Mycolic acid	Resist proteolysis and uptake into phagolysosomes
Lipoarabinomannan	Detected by CD1 T cells that may assist the immune response
Muramyl dipeptide	Stimulate T cell responses (granuloma formation) that may assist clearance
Glycolipids	Inhibit macrophage function
Inert lipids and surface proteins	Dormant survival inside phagocytes

as a state of persistent immune response to stimulation by MTB antigens with no evidence of clinically manifest active TB. The Ghon complex may be found in the lungs, tonsils, gut, or any organ. The organisms from the primary focus drain to a regional lymph node or nodes, causing their enlargement. This triad of the primary Ghon focus, lymphangitis, and lymphadenitis is known as the primary complex and is self-limited in 90% to 95% of cases. Progression occurs in the remainder, leading to local or systemic dissemination of mycobacteria via lymphatics or the bloodstream.[9] Because of the slow replication rate, its intracellular location in macrophages, and acquired immune responses, it may take 1 to 2 years after primary infection for symptoms and signs to manifest. Reactivation of LTBI may occur in 5% to 15% of people and progress to active TB. Up to 10% of patients with UG TB have active pulmonary TB, and 50% have evidence of previous TB on chest radiographs.

Bacilli from the regional lymph node enter the bloodstream through the thoracic duct resulting in silent dissemination to various sites, including the kidney cortex (Fig. 54.3). Here, the bacilli elicit an inflammatory response, resulting in granuloma formation that may heal and form a microscopic scar, remain dormant for many years, or rupture into the proximal tubule of the nephron. The bacilli in the nephron are trapped at the level of the loop of Henle, where they multiply. The relatively poor blood flow, hypertonicity, and high ammonia concentration in the kidney medulla impair the immune response and favor the formation of medullary granulomas, leading to chronic tubulointerstitial nephritis, fibrosis, or papillary necrosis. The center of these granulomas (tuberculomas), which contains macrophages, may undergo coagulative necrosis and form ulcers or cavities filled with cheese-like caseous material (Fig. 54.4A). Extensive caseous destruction of the kidney parenchyma occurs with formation of lobules and cavities (see Fig. 54.4B). The dissemination of infection to the kidney pelvis can cause tuberculous pyelonephritis. This may burst into perirenal tissue to form perinephric abscess or into the calyx causing pyonephrosis. With progressive fibrosis and scarring of the uretero-pelvic junction, dilation of pelvis and calyces may occur. Extensive necrosis replaces the kidney parenchyma with caseous material. Various patterns of calcification may be seen in imaging (Fig. 54.5). Calcification commences intracellularly because of the accumulation of phosphate ions from the disintegration of nucleoproteins and entry of calcium ions from cell membrane damage. These dystrophic calcific lesions may harbor live or dormant mycobacteria and such dystrophic lesions are considered active disease and not signs of healing. Dystrophic calcification may result in a nonfunctioning kidney (autonephrectomy) with dystrophic calcification called *putty* or *cement* kidney. Kidney TB can be briefly classified as:

- Stage 1: nondestructive form (TB of parenchyma)
- Stage 2: small-destructive form (TB papillitis)
- Stage 3: destructive form with one or two caverns (cavernous kidney TB)
- Stage 4: widespread destructive form (polycavernous kidney TB)

Involvement of the ureter is common and frequently affects the lower third and ureteropelvic junction leading to obstructive uropathy.

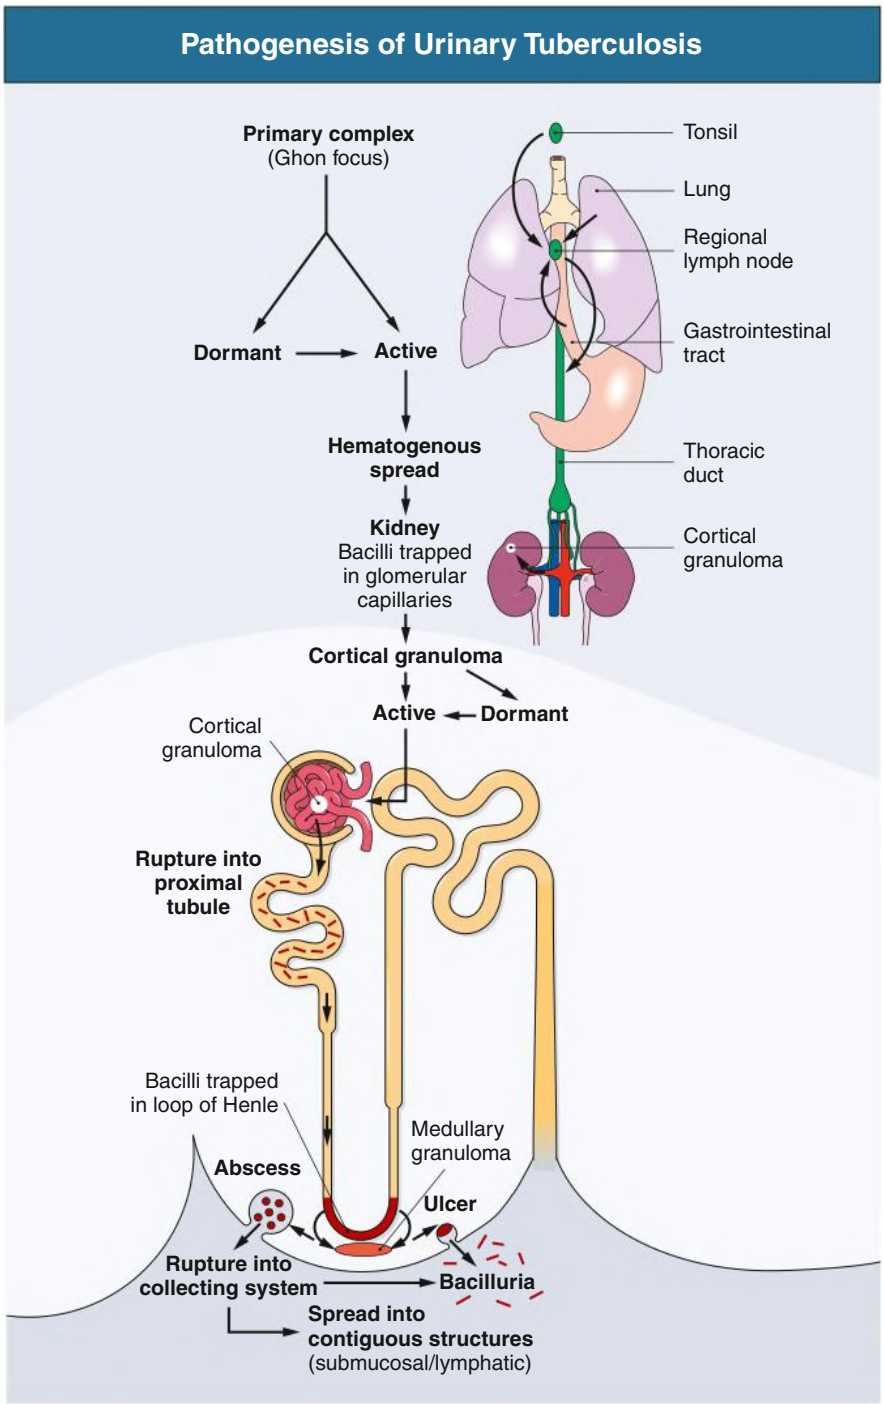

Fig. 54.3 Pathogenesis of urinary tuberculosis.

Ureteric involvement leads to inflammation, edema, granulomatous ulceration, and fibrosis, leading to irregular ureteric strictures (Fig. 54.6A), segmental dilation ("corkscrew" ureter), or fibrosis resulting in a shortened and rigid ureter ("pipe-stem" ureter).

The bladder may develop hyperemia near the ureteral orifice, followed by superficial ulcers and granulomatous changes involving all layers (pancystitis). Healing by fibrosis at the ureteral orifice results in a refluxing "golf-hole" ureter. Extensive fibrosis of the bladder wall results in a thick, small-capacity bladder called a "thimble" bladder (see Fig. 54.6B). Bladder infection also may rarely result from instillation of BCG in the bladder as part of treatment of superficial bladder carcinomas. Rare complications of bladder TB include vesicovaginal, vesicocolic, and enterovesical fistulae and bladder perforation. TB of the bladder can be classified into four stages[10]:

- Stage 1: infiltrative bladder TB (tubercles in bladder wall)
- Stage 2: ulcerous bladder TB (erosion of bladder mucosa)
- Stage 3: interstitial cystitis (painful bladder syndrome)
- Stage 4: contracted bladder (obliteration)

Involvement of the genital tract is also common. Men with TB of the urinary tract have epididymitis, prostatitis, seminal vesiculitis, orchitis, cold abscesses, or discharging scrotal sinuses. In women, genital tract involvement is less common, but, if present, usually presents as salpingitis, often diagnosed during investigation for infertility.

(A) Curvilinear pattern *(orange arrow),* amorphous and speckled pattern *(blue arrow),* ureteric calcification *(yellow arrow).* (B) Contrast-enhanced computed tomography image showing contracted densely calcified right kidney and normally functioning left side (density on right side was the same before and after contrast).

TB can be transmitted from the donor to recipient through kidney transplantation, and the risk can be minimized by thorough evaluation of the donor.[11]

CLINICAL MANIFESTATIONS

UG-TB can present at any age, but most patients are 20 to 40 years of age, with a male-to-female ratio of 2:1. It is relatively uncommon in children because of the long latency period. It may be asymptomatic and detected incidentally during investigations for other illnesses. Clinical presentation may include a range of manifestations (Table 54.2), but a high index of suspicion enables early diagnosis. Risk factors for TB include one or more of the following:

1. Close contact with sputum-positive individuals
2. Residence in an endemic area
3. Overcrowding/social deprivation/vagrancy
4. Immunosuppression (HIV/infection/diabetes mellitus)
5. CKD
6. Vitamin D deficiency
7. Malnutrition and other debilitating illnesses

Asymptomatic Presentation

In some countries, one-quarter of the population may have latent MTB.[11] Almost 25% of patients have no clinical or laboratory evidence of any abnormality, and the diagnosis of urinary TB is made on investigation for other diseases, during surgery, or at autopsy. Another 25% may have asymptomatic urinary abnormalities, particularly pyuria or hematuria. Nonspecific constitutional symptoms like fever, weight loss, and night sweats are uncommon. UG-TB should be suspected when conventional urine cultures are repeatedly negative in spite of empiric antibiotic therapy for suspected UTI. The urine pH may be acidic with persistent pyuria and negative routine bacterial cultures (acid-sterile pyuria). Genital involvement in males may be with chronic epididymitis or prostatitis that does not resolve with standard antibiotics.[11]

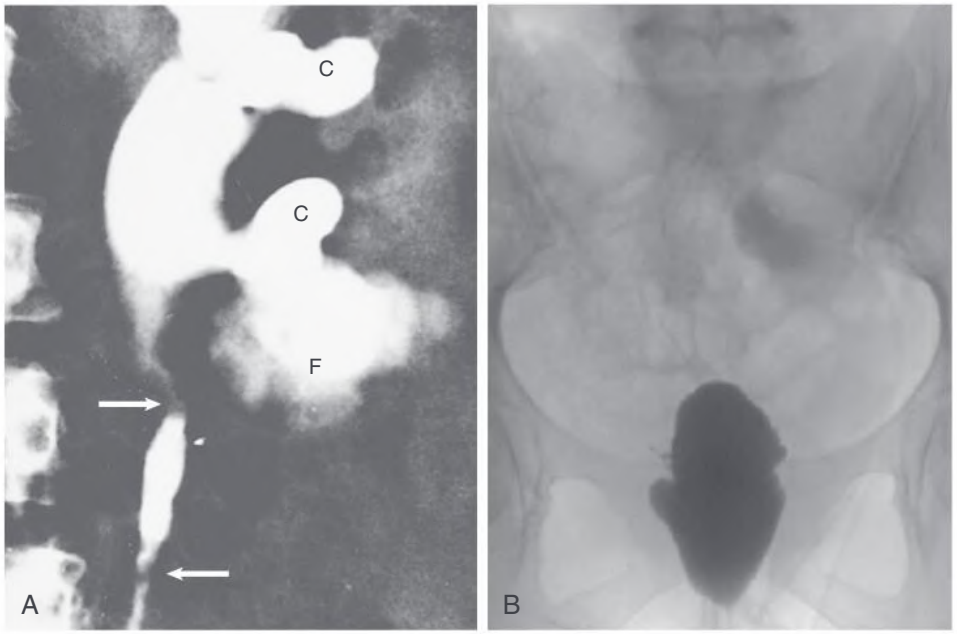

Fig. 54.6 Ureteric and Bladder Changes. (A) Multiple ureteric strictures *(arrows),* caliectasis *(C),* and fuzzy calyx *(F).* (B) Cystogram showing irregular, small capacity bladder or "thimble bladder."

TABLE 54.2 Clinical Features of Urinary Tuberculosis

Features	Frequency (%)	Symptoms
Asymptomatic	25	Detected during autopsy, surgery, or investigations for other diseases
Asymptomatic urinary abnormalities	25	Persistent pyuria, microscopic abnormalities, hematuria
Lower urinary tract symptoms (most common)	40	Frequency, urgency, dysuria, incontinence, nocturia, suprapubic pain, perineal pain
Male genital tract involvement	75	Epididymitis, hemospermia, infertility, reduced semen volume
Female genital tract involvement	<5	Amenorrhea, infertility, vaginal bleeding, pelvic pain
Constitutional symptoms	<20	Fever, reduced appetite, anorexia, weight loss, night sweats
Miscellaneous	—	Urolithiasis, hypertension, acute kidney injury, chronic kidney disease, abdominal colic, abdominal mass

Lower Urinary Tract Symptoms

Of the patients who are symptomatic, lower urinary tract symptoms, such as frequency, urgency, dysuria, nocturia, frank pyuria, or hematuria, occur in more than 75% of patients. Increased urinary frequency is the earliest and most common symptom. Recurrent bouts of painless gross macroscopic hematuria should alert the clinician to the possible diagnosis of urinary TB, although glomerular diseases such as immunoglobulin A (IgA) nephropathy also should be considered. Macroscopic hematuria in urinary TB is a result of bleeding from the ulcerating lesions, inflammation of the urothelium, or rupture of a blood vessel in the vicinity of a cavity. Episodes of frank pyuria also may be a manifestation of kidney TB and indicate either secondary bacterial infection or drainage of a caseous focus into the collecting system. In advanced disease, frequency and urgency of micturition related to reduced bladder capacity, incomplete emptying, increased susceptibility to infection, and secondary vesicoureteral reflux (VUR) may also occur.

Kidney Tuberculosis

Patients with kidney TB may be asymptomatic with only abnormal urinalysis. With advancing kidney TB, the clinical presentations are nonspecific symptoms and signs such as lower urinary symptoms, flank pain, colic, and hematuria. Long-standing kidney parenchymal involvement may result in tubular proteinuria, which is often in the subnephrotic range. The kidneys are of normal size and show diffuse interstitial nephritis, with noncaseating or caseating granulomas. MTB can be identified by molecular tests in nearly 75% of biopsy samples. The overall incidence of kidney failure reported in the literature is 24%. The mechanisms of kidney failure are[12]:

- Kidney parenchymal infection causing obliterative endarteritis
- Extensive dystrophic calcification
- Secondary kidney amyloidosis
- Multiple ureteric strictures with postobstructive atrophy
- Tubulointerstitial nephritis
- Destruction of kidney parenchyma by caseation

Nephrotic proteinuria occurs rarely, and it could be because of mesangioproliferative glomerulonephritis or serum amyloid A (SAA) protein–associated secondary amyloidosis. Chronic inflammation of the kidney pelvis can also lead to squamous metaplasia or carcinoma.

Ureteral Tuberculosis

Nonspecific manifestations like hematuria or abdominal colic occur because of ureteric obstruction associated with kidney stones, blood clots, or sloughed kidney papillae. Secondary infection with *Escherichia coli* is also common.

Genital Involvement

In males, the most common genital involvement is epididymitis, which manifests with scrotal discomfort, mass, or cold abscess or may be asymptomatic. When the cold abscess ruptures, a nonhealing posterior scrotal sinus discharging caseous material may form. Thickening of the vas deferens may result in a "beaded" texture. TB of the prostate may manifest with lower urinary tract symptoms and perineal pain. The prostate may be hard or boggy. Penile and urethral TB may manifest with strictures, fistulas, ulcers, or papulonecrotic skin lesions. Hemospermia, reduction of semen volume, and infertility are other manifestations of genital involvement. Direct spread of MTB to a sexual partner is also possible. Only 5% of females with kidney TB also have genital TB. The major manifestation of genital involvement in females is infertility resulting from adherent salpingitis. Secondary amenorrhea, vaginal bleeding, and pelvic pain caused by inflammation may occur.

Other Manifestations

Anemia is seen in less than 20% of patients with nonmiliary disease, but the frequency is higher in those with CKD stages 3 to 5. A few patients may develop nephrogenic diabetes insipidus or renal tubular acidosis. Hyporeninemic hypoaldosteronism may result from the tubulointerstitial injury secondary to obstructive uropathy.[13] Hypertension is unusual in kidney TB, but intimal proliferation of vessels near inflamed areas may lead to segmental ischemia and renin release and hypertension.[14] Relief of obstruction or removal of a nonfunctioning kidney causing hypertension may be necessary in rare instances.

Constitutional symptoms, such as fever, weight loss, night sweats, fatigue, and anorexia, occur in less than 20% of patients and indicate active infection in other organs or secondary bacterial infection of the urinary tract. All patients who present with constitutional symptoms must be carefully examined to identify pulmonary, lymph node, or skeletal TB. The chest radiograph may show evidence of active or healed tuberculous lesions in more than half of cases. Rarely, hypercalcemia may be present because of increased synthesis of calcitriol in the granulomas.

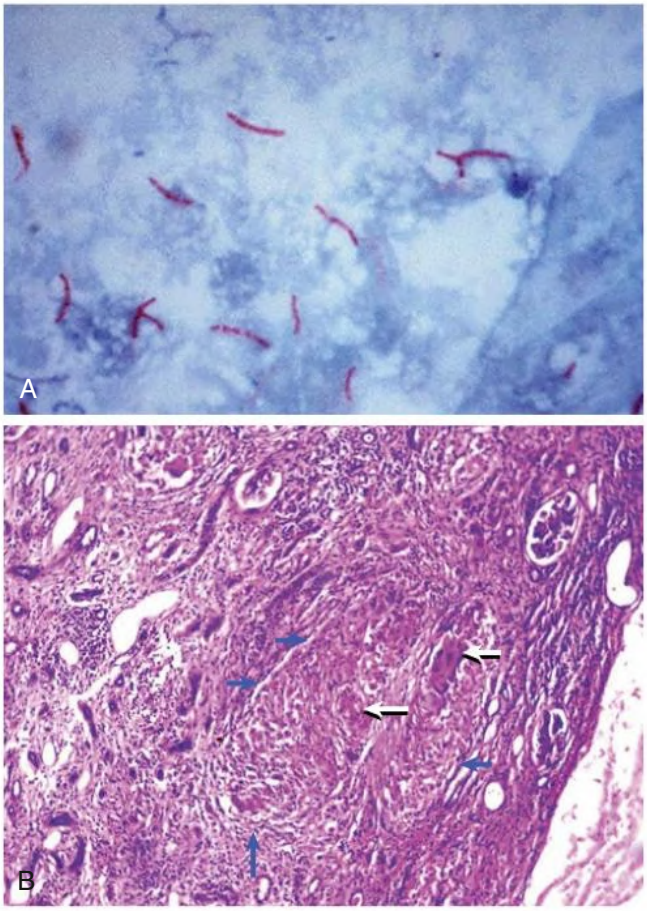

Fig. 54.7 Histologic Changes. (A) Acid fast bacilli in tissue (Ziehl Neelsen stain; ×1000 magnification). (B) Needle biopsy of kidney showing granuloma formation *(blue arrows)* and multinucleated Langhans giant cells *(white arrows)*. (A, Courtesy Dr. George Kubica, Centers for Disease Control and Prevention. B, Courtesy Department of Pathology, Medical College, Kottayam, India.)

PATHOLOGY

The pathologic process of urinary TB may take the form of a miliary, granulomatous, or ulcerocavernous lesion depending on the virulence of the organism and host response. In the miliary form, which is seen particularly in immunosuppressed individuals, the cortex is studded with yellowish white, hard, pinhead-sized nodules that on microscopy show several coalescent granulomas with central caseation.

In early disease and in those with effective cell-mediated response, granulomas are seen in the kidney parenchyma, characterized by macrophages with engulfed bacilli, surrounded by epithelioid cells and Langhans giant cells (Fig. 54.7). Surrounding this, a cuff of lymphocytes and plasma cells are seen.[15] Healing occurs by fibrosis and scarring.

In the more common ulcerocavernous form, yellow nodules consisting of pinhead-sized caseous foci are often seen on the outer surface. On cut section, granulomas and ulcers in the kidney pyramid or medullary cavities may be seen. Larger cavities filled with amorphous, soft, chalk-like eosinophilic material (caseous material) communicating with the collecting system also may be seen (see Fig. 54.2A). Other gross findings include multiple ulcers in the infundibular region of the calyces, calyceal stenosis, caliectasis (see Fig. 54.6A), ulcers, or strictures of the ureter with hydronephrosis, pyonephrosis, subcapsular collections, and perinephric abscesses. The bladder may show ulcers or be grossly fibrotic and contracted. In advanced cases, extensive caseating necrosis, replacing the normal kidney architecture, may be seen, which may undergo calcification. The presence of caseous necrosis or calcification suggests activity of the disease and is not to be taken as a sign of healing. Kidneys also may be enlarged from amyloidosis.

DIAGNOSIS

Early and accurate diagnosis of UG-TB is important for successful treatment outcomes, and a high index of suspicion is necessary. Elderly patients, as well as those exposed to or who have had infection in the past, immunocompromised individuals, and patients with TB elsewhere are at high risk. Although the gold standard for specific diagnosis of TB is by identifying MTB from a clinical sample, it may not be possible in all cases because of the paucibacillary nature of the disease. No single specific diagnostic test exists, and a range of microbiological, molecular, histopathologic, and imaging tests are available for the diagnosis.

Smear Microscopy

Microscopic examination of urine for acid-fast bacilli (AFB) using Ziehl-Neelsen (ZN) or auramine staining has been a first-line diagnostic test for UG-TB for the past 70 years. Bacterial load of 5000 organisms/mL is needed for positive smear and at least three early morning urine samples should be analyzed. Diagnostic yield from urine sample is only less than 40%. WHO recommends that conventional fluorescence

microscopy may be replaced by light-emitting diode (LED) microscopy.[16] Contamination of urine with environmental, nonpathogenic mycobacteria such as *M. smegmatis* may give false-positive results.

Urine Culture

Culture of specimens for *MTB* is the gold standard for the diagnosis of active TB with a sensitivity of 65% and specificity of 100%. Traditional culture requires about 6 to 12 weeks for a result. The WHO has recommended automated liquid mycobacteria growth indicator tube (MGIT) culture as the gold standard where positive results can be available within 2 weeks.[17] Because the organism is intermittently excreted, at least three, but preferably five, consecutive early morning specimens of urine should be cultured.

Tuberculin Skin Test

TST or Mantoux test is done by administering intradermally 0.1 mL of PPD of MTB, and the extent of induration caused by the injection is read after 48 to 72 hours. The test can be positive in active TB infection, LTBI, and those who have received BCG vaccination. This test is now rarely used.

Polymerase Chain Reaction

The sensitivities and specificities of polymerase chain reaction (PCR) on urinary samples are nearly 95% and 90%, respectively. A real-time quantitative PCR assay for amplifying MTB DNA and the gene for rifampicin resistance (GeneXpert MTB/RIF) is commercially available and is recommended by WHO. It is a rapid, affordable, near-point-of-care test for detecting *MTB* and rifampicin resistance simultaneously and can also be used for testing urine. An expanded new version called Xpert XDR allows for detection of resistance to isoniazid, injectable agents, and fluoroquinolones as well.[18] GeneXpert MTB/RIF assays may give false-positive test results in treated patients because the MTB DNA lingers in tissues even after eradication of live mycobacteria. Novel, battery-operated, portable, single-module, near-patient/point-of-care versions of the GeneXpert system (GeneXpert Omni, GeneXpert Edge) are also available.

Whole-Blood Interferon-γ Release Assays

The test is based on quantifying the interferon (IFN)-γ released from the white blood cells that have been exposed to the mycobacterial antigens. Available as the QuantiFERON TB Gold and T Spot test, these assays can identify latent or active TB, replacing the traditional tuberculin test, and are reported to have a sensitivity and specificity of more than 90%.[19,20] They can be performed in a single patient visit and are not altered by prior BCG vaccination.

Urine Tuberculosis Lipoarabinomannan Assay

Lipoarabinomannan forms part of the cell wall glycolipid of MTB bacterium and can be detected in the urine of patients with active or disseminated infection with kidney involvement. This immunochromatographic assay is recommended by the WHO for the diagnosis of HIV-associated TB in people with $CD4^+$ lymphocyte counts of less than 200 cells/μL. The usefulness of this assay for diagnosing UG-TB has not yet been evaluated.[21]

Histopathology

Conventional needle biopsies are usually not done for diagnosis of kidney TB. However, ultrasound-guided fine-needle aspiration/biopsy from the lesion is useful in defining the granulomatous nature of the lesion. Histologic diagnosis is made by identifying the pathologic triad of caseating necrosis, loose aggregates of epithelioid histiocytes, and Langhans giant cells. Endoscopic examination (cystourethroscopy, ureteroscopy, hysteroscopy, and laparoscopy) can be used for detecting anatomic abnormalities, localizing lesions, and obtaining biopsy tissue samples.

Imaging

All imaging findings may be normal in patients with early UG-TB, and findings are based on the presence of cavities, strictures, or calcifications. Imaging of the urinary tract helps to;

1. Localize the site of disease
2. Assess the extent of tissue destruction
3. Monitor response to treatment
4. Identify complications
5. Guide the needle to target sites for procuring samples for histologic, microbiological, and molecular analyses.

Plain Radiographs

Plain radiographs of the chest may show abnormal changes caused by active TB or healed TB in up to 50% of patients with UG-TB.[22] In a plain radiograph of the abdomen, various types of calcification can be identified:

1. Amorphous, granular, or curvilinear calcification, within the kidney parenchyma: indicates early stages
2. Diffuse granular opacification or "cumulus cloud calcification": often associated with active, granulomatous infection
3. Dense, punctate calcification: found in healed tuberculomas
4. Homogeneous, moderately dense, ground glass–like calcification: indicates calcified caseous tissue referred to as *putty kidney*
5. Triangular/ring-like calcifications: represents papillary necrosis
6. Lobar pattern with calcific rims outlining the periphery of distorted renal lobes: pathognomonic of TB.
7. Faint upper ureteral calcification along with any other kidney calcification: good marker of kidney TB.

Ultrasonography

In the early stages and in diffuse, infiltrative kidney TB, ultrasonography may appear normal. Granulomas are seen as small, hypoechoic intrarenal masses. In more extensive disease, changes similar to acute focal bacterial nephritis or chronic pyelonephritis may be seen. Large abscesses or tuberculomas distorting the kidney contour may be mistaken for tumors or cysts. Smaller parenchymal lesions, mucosal thickening, stenosis of the calyces, and ulcers can be identified by high-resolution ultrasonograms[23] (Fig. 54.8A–B). Various degrees of calcification, hydronephrosis, perinephric collections, bladder capacity, bladder emptying, and associated structural abnormalities in the genital tract can also be identified by ultrasonography.

Intravenous Urography

Intravenous urography (IVU) provides a simultaneous assessment of urinary tract anatomy and drainage. The important changes are:

1. Minimal calyceal dilation and loss of calyceal sharpness (early change) (see Fig. 54.6A)
2. Irregularity, fuzzy or feathery calyx ("moth-eaten" calyx)
3. Calyceal erosion and "phantom calyx"
4. Upward-pointing "hiked-up" pelvis
5. Kinking of the kidney pelvis (because of traction from a strictured infundibulum and parenchymal fibrosis): Kerr's kink sign
6. Irregular ureter and areas of stricture and dilation: corkscrew ureter
7. Diffusely thickened ureters: pipestem ureter
8. Distal ureteric narrowing at ureterovesical junction
9. Small-capacity, thick-walled bladder with an elevated bladder base: thimble bladder (see Fig. 54.6B)

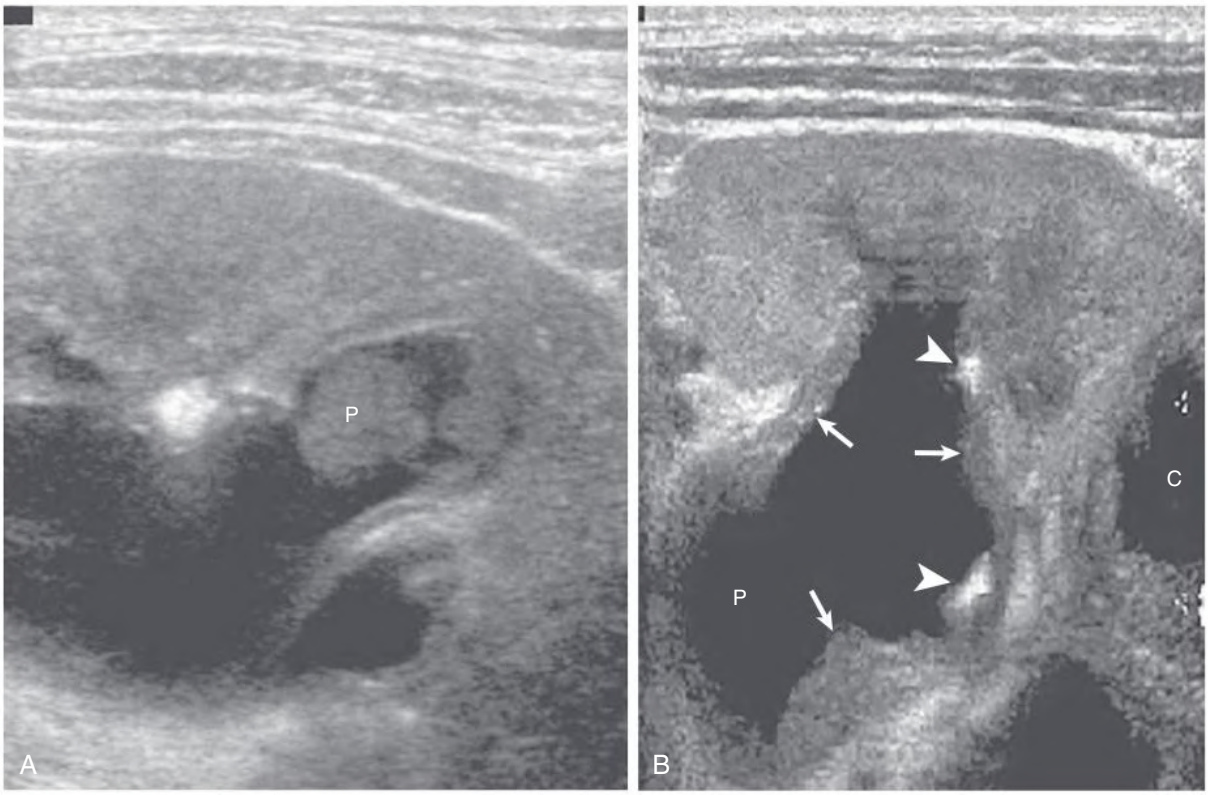

Fig. 54.8 High-Resolution Ultrasonography. (A) Sloughed, necrosed papilla *(P)* in the calyx. (B) Transverse ultrasound scan of kidney showing thickened mucosa *(arrows)* and calcification of calyces *(C)* and pelvis *(P).* There are calcifications of the wall of the calyx and pelvis *(arrowheads).* A parenchymal cavity (C) is also shown. (From Vijayaraghavan SB, Kandasamy SV, Arul M, et al. Spectrum of high resolution sonographic features of urinary tuberculosis. *J Ultrasound Med.* 2004;23[5]: 585–594.)

Computed Tomography Scan and Computed Tomography Urography

These imaging modalities are better than IVU and show abnormalities in greater detail. Computed tomography (CT) is a sensitive imaging modality to detect calcification, which is present in more than 50% of patients (see Fig. 54.5). Multidetector CT urography technology (MDCTU) using reformatted images such as multiplanar reconstruction and maximum intensity projection is replacing IVU for the assessment of kidney and urinary tract lesions.

Positron Emission Tomography–Computed Tomography Imaging

Positron emission tomography (PET) imaging using 2-deoxy-2-(fluorine-18)fluoro-d-glucose (^{18}F-FDG) provides functional information about sites with active inflammatory and immune cells that use glucose during metabolism. Anatomic and functional information is obtained by acquiring ^{18}F-FDG PET and CT data in a single scan. FDG PET-CT imaging does not help distinguish TB from cancer, thereby limiting its utility for specific diagnosis of UG-TB.

Magnetic Resonance Imaging

Magnetic resonance imaging (MRI) has a limited role because the sensitivity is low for detecting early lesions and abnormalities. For definitive diagnosis of tuberculosis, one major or two minor criteria are required.[24]

Major criteria include:

- Granulomatous lesion in biopsy specimen
- AFB in urine or tissue by smear or culture
- Positive PCR

Minor criteria include:

- IVU/CT findings suggestive of GU-TB
- Hematuria
- Raised erythrocyte sedimentation rate (ESR)
- Pulmonary changes of old tuberculosis

LTBI is common and can become reactivated even decades later. Currently, three tests are recommended by the WHO for detecting LTBI[25]:

1. Tuberculin skin test (TST)
2. QuantiFERON-TB Gold
3. T-SPOT TB

Differential Diagnosis

UG TB mimics numerous diseases. Chronic nonspecific urinary tract infections may be confused with kidney TB, especially because secondary bacterial infection may complicate 20% of cases of kidney TB. Absence of response to usual antibiotics should raise suspicion of urinary TB. Conditions causing recurrent painless hematuria, such as IgA nephropathy and schistosomiasis, are often misdiagnosed as TB in endemic areas. In interstitial cystitis, lower urinary tract symptoms similar to tuberculous cystitis may occur, but the urinalysis does not show gross pyuria, and cultures for AFB are negative. On radiologic examination, chronic pyelonephritis, kidney papillary necrosis, medullary sponge kidney, calyceal diverticulum, renal carcinoma, xanthogranulomatous pyelonephritis, and multiple small kidney calculi need to be differentiated from TB. In a few reported cases of pseudotuberculous pyelonephritis, caseating granulomas resembling TB were observed in the kidney parenchyma, but no mycobacteria or other microorganisms were detected in the kidney tissue or urine culture.

MANAGEMENT OF UROGENITAL TUBERCULOSIS

The aims of management are to eradicate the infection, treat complications, and manage comorbidities/risk factors. The general precautions to prevent toxicity and adverse reactions in patients with CKD and dialysis are appropriate dose modification and administering drugs after hemodialysis. Antituberculous drugs form the mainstay of treatment (Table 54.3).

The latest recommendation by the WHO for treatment of drug-sensitive organisms is a 2-month intensive phase of quadruple therapy with first-line drugs (such as rifampicin, isoniazid, pyrazinamide, and ethambutol) daily, followed by a 4-month continuation phase of two drugs (rifampicin and isoniazid). The response in terms of resolution/improvement of systemic urinary symptoms and kidney function is assessed at 8 weeks. In immunosuppressed individuals, the continuation phase is extended to a total of 9 months. As with pulmonary TB, this regimen gives a cure rate of 90%.

In the case of drug-resistant UG-TB, there are scarce data and no clinical trials. As recommended by WHO for MDR pulmonary tuberculosis, an intensive 4- to 6-month course of therapy monitored by an experienced TB physician is necessary. The drug combinations may include five to six drugs initially as follows: gatifloxacin/moxifloxacin, ethionamide/prothionamide, kanamycin/amikacin, high-dose clofazimine/isoniazid with ethambutol, and pyrazinamide. This is followed by a 5-month continuation phase of clofazimine, ethambutol, pyrazinamide, and gatifloxacin or moxifloxacin.[26]

In situations where the incidence of TB is high, LTBI is treated with isoniazid monotherapy for 6 months or rifampicin plus isoniazid daily for 3 months or rifapentine and isoniazid weekly for 3 months. In areas with lower incidence and for prevention, 6 to 9 months of isoniazid monotherapy or weekly rifapentine plus isoniazid for 3 months or rifampicin with or without isoniazid for 3 months is recommended. Newer drugs and repurposed drugs are used in MDR TB and XDR TB. Some drugs are still being examined in clinical trials (Table 54.4).

Surgical Treatment of Urogenital Tuberculosis

Surgical treatment as an adjunct to drugs is required in patients during or after TB drug therapy. Surgery is required for the following clinical settings:

1. Drainage for obstructed pelvicalyceal system
2. Drainage of abscesses
3. Reconstruction of ureters
   - Ureterocalicostomy
   - Reimplantation of ureters
   - Ileal replacement of ureter
4. Reconstructive surgery of the bladder (bladder augmentation)
5. Nephrectomy

Treatment Regimens in Special Situations

Women During Pregnancy and Lactation

Most antituberculous drugs are safe for use during pregnancy and lactation. However, streptomycin is ototoxic to the fetus and should be avoided. It is not necessary to isolate the baby from the mother unless the mother has active pulmonary tuberculosis. The baby should receive BCG immunization and isoniazid prophylaxis. Rifampin reduces the efficacy of oral contraceptives, and females should be advised to use alternative methods of contraception.

Patients With Liver Disease

In chronic liver disease, pyrazinamide is contraindicated. Isoniazid and two of the nonhepatotoxic drugs (streptomycin and ethambutol) can be used for 8 to 12 months. If rifampin is used, liver function should be closely monitored. In those with acute hepatitis unrelated to TB or its therapy, it would be safer to defer chemotherapy until the acute hepatitis has resolved. If immediate treatment of TB during acute hepatitis is mandatory, streptomycin plus ethambutol for 3 months followed by isoniazid and rifampin for 6 months is advised. Excessive alcohol consumption should be avoided.

Patients With Chronic Kidney Disease

Because streptomycin and ethambutol are excreted by the kidney, dosage modification of these drugs is necessary when GFR is less than 60 mL/min/1.73 m^2. For ethambutol, the full dose is administered every 24 to 36 hours if GFR is 10 to 50 mL/min/1.73 m^2 and every 48 hours if GFR is less than 10 mL/min/1.73 m^2. Monthly questioning for symptoms of visual dysfunction (alterations in visual fields, acuity, blue-green vision) and periodic ophthalmic examination may identify early ethambutol toxicity, at the stage of potential reversibility. Streptomycin is used only rarely now because of ototoxicity. It is avoided in older individuals, and the dose is 15 mg/kg every 48 to 72 hours if GFR is 10 to 50 mL/min/1.73 m^2 and every 72 to 96 hours if GFR is less than 10 mL/min/1.73 m^2. In patients with CKD, isoniazid, rifampin, and pyrazinamide, which are eliminated by the biliary route, can be given in normal dosages. In patients on dialysis, it is ideal to administer these drugs under supervision after each dialysis session.

Kidney Allograft Recipients

No clear-cut recommendations exist for GU-TB in native kidneys after transplantation. It is preferable to complete at least 6 weeks of therapy for all types of TB and reassessment before considering transplantation. Ideally, the patient could be considered for kidney transplantation after 6 months of treatment. Rifampin is avoided in patients receiving a calcineurin inhibitor (CNI) because enzyme induction may make maintenance of adequate CNI blood levels difficult. For patients with a kidney allograft, a suitable treatment regimen is with isoniazid and ethambutol for 18 months (with dose adjusted for GFR), combined with ofloxacin 200 mg twice daily for the first 9 months and pyrazinamide 750 mg twice daily for the first 3 months.[27] If rifampin is used in those receiving a non–CNI-based immunosuppressive regimen, the maintenance dose of prednisolone should be doubled.

Human Immunodeficiency Virus and Tuberculosis

In patients with HIV who are already on antiretroviral treatment (ART), conventional 6-month treatment with 4 drugs for the first 2 months followed by 2 drugs for the remaining 4 months is sufficient. In patients with HIV infection who are not on ART, antituberculous drugs are continued for 9 months. If HIV and TB are diagnosed simultaneously, antituberculous drugs are started first, followed by ART after 15 days if the CD4 count is less than 50 cells/μL and after 30 days if the CD4 cell count is less than 100 cells/μL.

Patients Who Do Not Respond to Treatment

Failure of clinical or radiologic improvement with treatment may signify poor compliance, inadequate regimen and/or dosage, incorrect diagnosis, delayed response, MDR TB, XDR TB, or the paradoxical reaction known as *immune reconstitution inflammatory syndrome.* This syndrome is characterized by unexpected worsening of symptoms or appearance of new lesions, including lymphadenopathy, serosal effusions, and pleural infiltrates. This syndrome is more common in those receiving ART for coexisting HIV and TB infections.[28]

Newer Therapies

The recent introduction of two new drugs, bedaquiline and delamanid, for rifampicin-resistant tuberculosis and ongoing studies on

TABLE 54.3 Antituberculous Drugs: Dosage, Actions, and Side Effects[a]

Drug	Dose Form	Dosage	Mode of Action	Dose Modification GFR (50–10 mL/min)	Dose Modification GFR (<10 mL/min)	Side Effects	Remarks
Isoniazid (INH)[b]	Tablet: 100, 300 mg	PO: 5 mg/kg/day (max 300 mg/day)	Bactericidal for groups I and II Interferes with mycolic acid synthesis	Nil	66%	Hypersensitivity Peripheral neuritis Hepatitis	Administer pyridoxine 50 mg/day
Rifampin (rifampicin)[b]	Tablet/capsule: 150, 300, 450 mg	PO: 10 mg/kg/day (max 600 mg/day)	Bactericidal for groups I, II, and III Interferes with protein synthesis by inhibiting RNA polymerase	Nil	Nil	Febrile reactions Acute interstitial nephritis Hepatitis	Dose adjustment when using calcineurin inhibitors or oral contraceptives May be used in pregnancy and lactation
Pyrazinamide[b]	Tablet: 400, 500 mg	PO: 25 mg/kg/day (max: 2 g/day)	Bactericidal for semidormant *Mycoplasma tuberculosis*	Nil	50%[c]	Hyperuricemia Hepatotoxicity Photosensitivity	Primary hepatic metabolism Monitor liver functions and uric acid
Ethambutol	Tablet: 100, 400 mg	PO: 15–25 mg/kg (max 2.5 g/day)	Bacteriostatic Bactericidal in high concentrations Inhibits cell wall synthesis	75%[c]	Avoid or 50%[c]	Optic neuritis (monitor for color vision)	Primarily renal excretion May be used during pregnancy and lactation
Streptomycin	Injection: 1, 0.75 g	IM: 15–25 mg/kg/day (max 1 g) Age >60 y: 75% dose	Bactericidal Inhibit protein synthesis	50%[c]	25%[c]	Ototoxicity Vestibulotoxicity Hypokalemia Hypomagnesemia	Therapeutic drug monitoring advised Peak level for efficacy Trough level for toxicity
Amikacin	IM/IV: ampoules, 500, 1000 mg	15 mg/kg/day (max 1 g/day)	Bactericidal Inhibit protein synthesis	50%[c]	25%[c]	Ototoxicity Vestibulotoxicity Hypokalemia Hypomagnesemia	Cleared by hemodialysis Supplement dose after HD or give regular full dose after dialysis Avoid coadministration of loop diuretics TDM recommended
Levofloxacin	PO: tablet, 250, 500, 750 mg IV: ampoules, 500–750 mg	750–1000 mg/day	Bactericidal Inhibit protein synthesis—DNA gyrase	50%[c] (500–750 mg q36h)	25%[c] (250–500 mg q48h)	Severe upper GI symptoms Prolonged QTc Arthralgia Tendon rupture	Hepatic and renal elimination Used in liver disease More effective than ciprofloxacin and ofloxacin
Moxifloxacin	PO: Tablet, 400 mg IV: infusion, 400 mg in 100 mL	400 mg/day	Bactericidal	Nil	Nil	Severe upper GI symptoms Prolonged QTc Arthralgia Tendon rupture	Not removed by HD
Capreomycin	IM/IV: 1-g vial	15 g/kg/day (max 1 g/day) on 5–7 days/wk	Strongly bactericidal Inhibits protein synthesis	75%	25%[c]	Nephrotoxicity Ototoxicity Hypokalemia Hypomagnesemia Hepatotoxicity when combined with other anti-TB drugs	Used only for MDR TB

TABLE 54.3 Antituberculous Drugs: Dosage, Actions, and Side Effects[a]—cont'd

Drug	Dose Form	Dosage	Mode of Action	Dose Modification GFR (50–10 mL/min)	Dose Modification GFR (<10 mL/min)	Side Effects	Remarks
Ethionamide	PO	15–25 mg/kg/day (max 1 g/day in 2 divided doses)	Weakly bactericidal Blocks mycolic acid synthesis	Nil	50%	Hepatotoxic Severe GI symptoms Hypothyroidism Gynecomastia	Not to be combined with cycloserine
Cycloserine	PO	15–25 mg/kg/day	Bacteriostatic	50%[c]	25%[c]	Neurotoxicity Seizures Peripheral neuropathy	Maintain peak level <35 μg/mL Cleared by dialysis Avoid in pregnancy and lactation

[a]The main drugs are listed with dosage form, dosage, mode of action, side effects, and dose modifications in those with low glomerular filtration rate. *M. tuberculosis* exists as three subpopulations. Group I is extracellular, occurs mainly in cavitating lesions, and responds to streptomycin, isoniazid, and rifampin. Group II resides intracellularly in macrophages, replicates slowly, and responds to pyrazinamide, isoniazid, or rifampin. Group III organisms exist within closed caseous lesions, survive better in neutral pH, replicate slowly, and respond best to rifampin.
[b]Prescribed dose to be given after hemodialysis.
[c]Dose reduction and/or increasing dosing intervals.
GFR, Glomerular filtration rate; *GI,* gastrointestinal; *HD,* hemodialysis; *IM,* intramuscular; *IV,* intravenous; *MDR TB,* multidrug-resistant TB; *PO,* orally, *QTc,* corrected QT interval on electrocardiogram; *TB,* tuberculosis; *TDM,* therapeutic drug monitoring.

TABLE 54.4 Newer Drugs: Clinical Pharmacology

Name of Drug	Class/Mechanism of Action	Dose/Route of Administration	Side Effects	Remarks
Bedaquiline	Diarylquinoline Inhibits mycobacterial ATP synthase Core drug in rifampicin resistant tuberculosis All-oral regimen Capable of killing both actively replicating and nonreplicating persistent mycobacteria in cells	Oral/400 mg once daily for 2 wk, followed by 200 mg three times/wk for 24 wk (total 26 wk)	QT prolongation Hepatitis GI toxicity	Recommended by WHO for treatment of MDR TB May be used in pregnancy
Delamanid	Nitrodihydroimidazooxazole Inhibits mycolic acid synthesis	Oral/100 mg twice daily for 24 wk	QT prolongation GI toxicity	Recommended by WHO Drug of choice for children <6 y with rifampicin-resistant tuberculosis Avoid in pregnancy
Pretomanid	Nitroimidazole	Oral 200 mg once daily	Peripheral neuropathy (81%) Headache (28%) Skin rash (21%)	Experimental No human trials yet
Clofazimine	Active against inactive nonreplicating mycobacterium	Oral 100–200 mg once daily	Red discoloration of skin, eyes, body fluids Photosensitivity GI toxicity	Avoid in pregnancy
Linezolid/sutezolid	Oxazolidinone/antibiotic	Oral or IV 600 mg once daily or 1200 mg once daily for 14 d	Myelosuppression GI toxicity Optic neuritis Peripheral neuropathy	Avoid in pregnancy
Telacebec	Imidazopyridine (IPA) compound Mycobacterial respiratory chain inhibitor Targets MTB cellular energy production by inhibiting (with high specificity) cytochrome bc1 complex	Oral	—	Completed phase II trial
Delpazolid	Oxazolidinone Inhibits protein synthesis Binding to domain V of rRNA			Ongoing phase II trials

rifapentine, clofazimine, and pretomanid may alter the treatment landscape in the future (see Table 54.4).[29] There is growing interest in the use of repurposed drugs such as linezolid and clofazimine. The second novel drug, delamanid, is recommended by WHO as the drug of choice for treating children younger than 6 years with rifampicin-resistant TB.[30]

A single interstitial injection of autologous bone marrow–derived mesenchymal stem cells (MSCs) into the bladder showed considerable reduction of inflammation as well as a reduction in the development of fibrosis and bladder wall deformity in animal models.[31]

SELF-ASSESSMENT QUESTIONS

1. All of the following are features of immune reconstitution inflammatory syndrome (IRIS) *except:*
   - **A.** Development of new lesions
   - **B.** Worsening of symptoms
   - **C.** Severity inversely proportional to the load of organisms
   - **D.** Common in MDR TB
   - **E.** Common in patients with simultaneous treatment of coexisting HIV infection
2. The following antituberculous drugs act as bactericidal agents when used in therapeutic does *except:*
   - **A.** Rifampicin
   - **B.** Isoniazid
   - **C.** Amikacin
   - **D.** Ethambutol
   - **E.** Pyrazinamide
3. The following symptoms point to suspicion of kidney tuberculosis *except:*
   - **A.** Recurrent painless macroscopic hematuria
   - **B.** Acid, sterile pyuria
   - **C.** Sterility in women/epididymitis in men
   - **D.** Lack of constitutional symptoms
   - **E.** Icterus
4. Which of the following antituberculous drug combinations require dose modifications in patients with kidney failure?
   - **A.** Isoniazid and rifampin
   - **B.** Streptomycin and ethambutol
   - **C.** Pyrazinamide and rifampin
   - **D.** Isoniazid and pyrazinamide
5. Which drug is uniformly effective against all three groups of *Mycobacterium tuberculosis*—group I (extracellular), group II (intracellular), and group III (closed caseous lesions)?
   - **A.** Isoniazid
   - **B.** Rifampicin
   - **C.** Pyrazinamide
   - **D.** Ethambutol
   - **E.** Streptomycin

Fungal Infections of the Urinary Tract

Carol A. Kauffman, Marisa H. Miceli

Funguria is a frequent finding in hospitalized patients. The organisms found in urine are almost always *Candida* spp., although several other yeasts and, less often, molds and endemic fungi, can be found (Table 55.1). Candiduria is not a symptom, a sign, or a disease, but frequently it is a perplexing phenomenon for the physician to address. Most patients with candiduria are asymptomatic and have colonization of the bladder or an indwelling urinary catheter. The most difficult diagnostic problem is determining when infection, rather than colonization, is present. Diagnostic tests to define colonization or infection have not been standardized, and neither have studies to localize the site of infection to either the bladder or the kidneys. In contrast to the situation with candiduria, growth in urine of organisms such as *Blastomyces dermatitidis, Aspergillus* spp., and *Cryptococcus neoformans* almost always reflects disseminated infection. This chapter outlines an approach to the diagnosis and treatment of candiduria and other less common fungal urinary tract infections (UTIs).

CANDIDA

Epidemiology

Candida spp. are common inhabitants of the perineum but are not found in urine in appreciable numbers in healthy hosts. A variety of predisposing factors allow these commensals microorganism to grow in the urine and in some cases to cause infection of the bladder or the upper urinary tract. These factors are frequently encountered in hospitalized patients, especially those in the intensive care unit (ICU).[1] In a cross-sectional survey of positive urine cultures obtained from hospitalized patients, *Candida* spp. were found in almost 10% of specimens and were the third most common microorganism isolated from urine.[2]

Risk factors for candiduria, but not specifically for *Candida* UTI, include increased age, female sex, antibiotic use, urinary drainage devices, prior surgical procedures, and diabetes mellitus[3,4] (Table 55.2). In a large surveillance study, urinary drainage devices, mostly indwelling urethral catheters, were present in 83% of 861 patients who had candiduria.[3] In a multicenter study of patients in an ICU, independent risk factors associated with candiduria were older than 65 years, female sex, diabetes mellitus, prior antibiotic use, mechanical ventilation, parenteral nutrition, and length of hospital stay before ICU admission.[4] Candiduria uncommonly leads to candidemia, confirming that most often candiduria reflects colonization, not infection.[3] When candiduria is found in patients with candidemia, the strains often have been shown to be unrelated by molecular techniques.[5] Prospective controlled studies assessing risk factors for well-documented *Candida* UTI have not been performed because firm diagnostic criteria specifically for infection have not been established. However, clinical experience suggests that UTI is more common in diabetic patients and in those with urinary tract obstruction.

Pathogenesis

Candida can cause urinary tract disease by either the hematogenous or the ascending route. The pathogenesis of hematogenous seeding of *Candida* to the kidney has been studied with animal models.[6] Multiple microabscesses develop throughout the cortex, with the yeasts penetrating through the glomeruli into the proximal tubules, where they are shed into the urine (Fig. 55.1). Healthy animals eventually clear the infection, but immunocompromised animals do not. Consistent with these studies, kidney microabscesses have been identified at autopsy in many patients with candidemia or invasive candidiasis. For ascending infection with *Candida,* obstruction is an important factor in many patients. Virulence factors that control adherence and biofilm formation are likely important.[6,7]

A unique syndrome seen early after kidney transplantation is graft site candidiasis, which appears to result from contamination of the donor kidney during the harvest procedure.[8] Arteritis with aneurysm formation and rupture can result from direct fungal invasion into the arterial wall. Most patients lose the graft, and mortality is high.

Microbiology

C. albicans accounts for 50% to 70% of all *Candida* urinary isolates, and *C. glabrata* for about 20% of isolates.[3] *Candida tropicalis* and *Candida parapsilosis* are less common, and other species are rarely isolated. Certain populations of patients have a predominance of *C. glabrata* isolated from cultures of urine; these include older adults, those who have diabetes, kidney transplant recipients, and persons who have had prior exposure to fluconazole. To prescribe appropriate treatment it is important to know the species causing candiduria. Resistance to fluconazole, the primary agent used for the treatment of *Candida* UTI, is common among isolates of *C. glabrata* and in all isolates of *Candida krusei.* In contrast, almost all isolates of *C. albicans, C. tropicalis,* and *C. parapsilosis* are susceptible to fluconazole.

Clinical Manifestations

Most patients with candiduria are asymptomatic, and, indeed, most do not have infection. A large prospective surveillance study of patients with candiduria noted that less than 5% of patients with candiduria had any symptoms suggesting UTI.[3] When patients have symptomatic cystitis or pyelonephritis, symptoms are indistinguishable from those noted with bacterial infections. Cystitis is manifested by dysuria, frequency, urgency, and suprapubic discomfort; patients with upper tract infection can present with fever, chills, and flank pain. Urinary tract obstruction can occur from formation of a bezoar or fungal ball in the bladder or the collecting system.

Patients who have had seeding of the kidney parenchyma during an episode of candidemia manifest the symptoms associated with invasive candidiasis, such as chills, fever, and hypotension, and not symptoms suggesting UTI.

TABLE 55.1 Fungal Genitourinary Tract Infections

Fungal Infection	Prostate	Bladder	Kidney
Candidiasis	++	++++	++++
Cryptococcosis	++	+/–	+++
Blastomycosis	+++	+	++
Histoplasmosis	+	+/–	++
Coccidioidomycosis	+	+/–	++
Aspergillosis	+/–	+/–	++
Mucormycosis	+/–	+/–	++

Shown is the relative frequency of the site of infection for various fungal organisms.

TABLE 55.2 Risk Factors for Candiduria

Type	Risk Factors
Kidney (hematogenous)	Neutropenia, recent surgery, central venous catheter, parenteral nutrition, antibiotics, dialysis
Lower urinary tract	Indwelling bladder catheter, older age, female, diabetes, obstruction, antibiotics, urinary tract instrumentation
Upper urinary tract	Older age, diabetes, antibiotics, obstruction, urinary tract instrumentation (e.g., nephrostomy tube, ureteral stent)

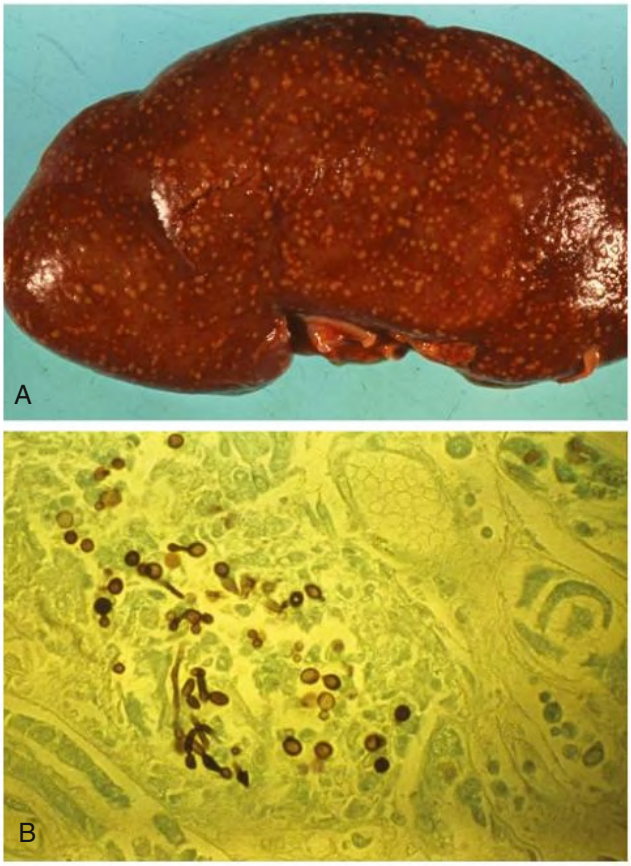

Fig. 55.1 Hematogenous Candidiasis Involving the Kidney. (A) Multiple small abscesses are seen throughout the kidney. (B) Histopathologic demonstration of a microabscess caused by *Candida albicans* in the cortex of the kidney (methenamine silver stain; yeast shown in *gray-brown*; magnification ×100).

Diagnosis

Major diagnostic difficulties are encountered in trying to differentiate contamination of a urine specimen from colonization of the bladder or an indwelling urethral catheter from invasive infection of the bladder or kidney. Contamination is most easily differentiated by simply repeating the urine culture a day later to determine whether candiduria persists. It may be necessary to obtain the second urine specimen by sterile bladder catheterization if the patient is unable to accomplish a clean-catch collection. In those patients who have an indwelling urethral catheter, the catheter should be replaced and a second urine specimen collected the next day. For either of these circumstances, if the repeated culture yields no yeasts, no further diagnostic studies or therapeutic interventions are needed.

Distinguishing colonization from infection is not straightforward. Compared with bacterial UTIs, in which the diagnosis is based on appropriate symptoms combined with the findings of pyuria and quantitative bacterial counts, no studies have established the importance of quantitative urine cultures or pyuria for the diagnosis of *Candida* UTI.

The role of quantitative urine cultures to differentiate upper tract infection from bladder colonization was assessed by investigators in the 1970s and unfortunately showed broad ranges of colony counts for both colonization and infection.[9] In patients who did not have indwelling catheters, documented kidney infection was found with colony counts as low as 10^4 yeast colony-forming units per milliliter (cfu/mL). For patients who had indwelling catheters, colony counts between 2×10^4 and 10^5 cfu/mL or more were noted and there was no correlation with biopsy-proven kidney infection.

The techniques routinely used in most clinical laboratories for the detection of bacteria will also detect *Candida* in urine. However, *C. glabrata* grows more slowly than other species, and colonies may not appear for 48 hours, which is often after routine cultures of urine have been discarded. Laboratories should be notified if *C. glabrata* is a likely pathogen.

Pyuria is often not a helpful diagnostic criterion for infection in patients with candiduria. Concomitant bacteriuria, frequently noted in patients with candiduria, may be responsible for pyuria, and when an indwelling bladder catheter is present, pyuria is routinely noted. In patients who do not have an indwelling bladder catheter or bacteriuria, the presence of pyuria is helpful.

Imaging procedures, including abdominal ultrasound and computed tomography (CT), are essential to document obstruction at any level in the urinary tract and to determine the presence of fungus balls in bladder or kidney (Fig. 55.2). In some patients, it is helpful to perform cystoscopy and biopsy of the bladder wall to determine whether inflammation is present and evaluate the extent of invasion (Fig. 55.3).

Treatment With Systemic Antifungal Agents

Most patients who have candiduria do not need treatment with an antifungal agent. For patients who are asymptomatic, treatment should be given only to those who are at high risk for development of candidemia or in whom the presence of candiduria, regardless of symptoms, is likely to represent disseminated infection. The guidelines for the management of candidiasis published by the Infectious Diseases Society of America recommend treatment for patients about to undergo urologic procedures, infants with very low birth weight, and neutropenic patients[10] (Table 55.3). Patients who have candiduria and who are to undergo a urologic procedure are at increased risk for development of candidemia and should be treated with an antifungal agent a few days before and after the procedure. Candiduria in

Fig. 55.2 Fungus Balls in the Pelvis of the Kidney. Several fungus balls (dark round "holes" in the contrast dye) are seen in the ureter and pelvis of the right kidney, causing hydronephrosis.

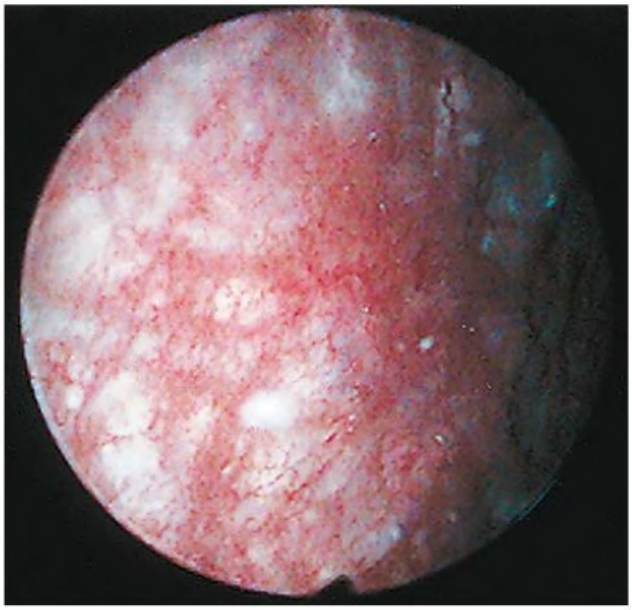

Fig. 55.3 Candida Cystitis. Cystoscopic appearance of extensive cystitis caused by *Candida krusei.*

neutropenic patients and in infants with very low birth weight has a high probability of representing disseminated candidiasis; thus these groups should be treated with an antifungal drug. Asymptomatic candiduria in the kidney transplant patient does not warrant systemic antifungal treatment unless obstruction is present; a urologic procedure, including stent removal, is planned; or symptoms suggestive of local or systemic infection develop.[10,11]

In non–high-risk patients who have asymptomatic candiduria, removal of an indwelling urinary catheter will eradicate candiduria in many patients.[3] If catheterization cannot be discontinued, the existing catheter should be removed and a new one inserted. This will often eradicate candiduria transiently, but it is highly likely that the organisms will return within a short time. It is not known if a suprapubic catheter is less likely to be colonized than an indwelling urethral catheter. Relief of obstruction, whether it is present in the upper or lower urinary tract, is essential for the long-term eradication of *Candida* from the urinary tract.

Patients who have symptoms suggestive of cystitis or pyelonephritis, and in whom bacteria and *Candida* are found in the urine culture specimen, should be treated initially with an antibacterial agent. If no bacteria are present, treatment with an antifungal drug is appropriate. Eradication of the organism with antifungal therapy is more likely if the indwelling catheter is removed.[12] Oral fluconazole, which is an azole antifungal agent and is excreted as active drug in the urine, is the agent of choice (see Table 55.3). A loading dose of 400 mg should be given, followed by 200 mg daily for 14 days.[10,13] Fluconazole does not effectively treat *C. krusei* infections, and many *C. glabrata* infections also do not respond to fluconazole.

The possibility of drug-drug interactions should be evaluated before fluconazole is prescribed. Phenytoin, warfarin, cyclosporine, tacrolimus, and sulfonylurea agents are a few of the drugs for which serum concentrations will increase and may reach toxic levels after the addition of fluconazole. Azoles should be used with caution in patients taking drugs that prolong the QTc interval.

The other available azole agents, itraconazole, voriconazole, posaconazole, and isavuconazole, are not excreted into the urine as active drug. Whether tissue concentrations might be high enough to treat invasive kidney or bladder infections is not known, but there is little clinical experience to suggest that they will be effective.

Intravenous (IV) amphotericin B deoxycholate is effective in treating *Candida* UTI but should be reserved for patients who have upper tract infection or for whom fluconazole therapy has failed, which will be predominantly those who have *C. glabrata* infection. Because of its inherent nephrotoxicity, IV amphotericin B deoxycholate must be used judiciously in patients who have kidney dysfunction. The recommended dosage is 0.3 to 0.6 mg/kg/day for 1 to 7 days, although this may be extended to 2 weeks for those who have complicated upper tract infection.[10] The dose used depends on kidney function and number of days infusions will be given; for example, some clinicians have had success with 0.3 mg/kg/day for 3 days, whereas others use a single dose of 0.6 mg/kg.[13] Infusion-related side effects are seen in some patients, even when low doses are used, and can include rigors, fever, nausea, vomiting, and headache.

TABLE 55.3 Treatment Recommendations for Candiduria and *Candida* Urinary Tract Infections

Infection	Treatment	Other/Alternative Therapy
Asymptomatic candiduria	Urologic surgery	Treat a few days before and after the procedure with fluconazole 200–400 mg/day PO *or* amphotericin B deoxycholate 0.3–0.6 mg/kg/day IV
	Low-birthweight infant	Treat as for disseminated candidiasis/candidemia with fluconazole 12 mg/kg/day
	Neutropenic patient	Treat as for disseminated candidiasis/candidemia with an echinocandin
Cystitis	Preferred: fluconazole 200 mg/day PO × 14 days[a]	Alternatives include amphotericin B deoxycholate 0.3–0.6 mg/kg/day IV × 1–7 days *or* flucytosine 25 mg/kg q6h PO × 7–10 days[b]
Pyelonephritis	Preferred: fluconazole 200–400 mg/day PO × 14 days	Alternatives include amphotericin B deoxycholate 0.3–0.6 mg/kg/day IV × 1–7 days with or without flucytosine 25 mg/kg q6h PO *or* flucytosine 25 mg/kg q6h PO × 14 days
Kidney (hematogenous)	Treat as for disseminated candidiasis/candidemia with an echinocandin or fluconazole	—
Fungus balls	Surgical removal *plus* fluconazole 200–400 mg/day PO until resolved	Alternatives include surgical removal *plus* amphotericin B deoxycholate 0.3–0.6 mg/kg/day IV with/without flucytosine 25 mg/kg q6h PO Irrigation through nephrostomy tube with amphotericin B deoxycholate 25–50 mg in 200–500 mL sterile water
Prostatitis Epididymo-orchitis	Surgical drainage *plus* fluconazole 400 mg/day PO until resolution noted on imaging studies	Alternatives include surgical drainage *plus* amphotericin B deoxycholate 0.3–0.6 mg/kg/day IV

[a]Fluconazole dosage in kidney failure: creatinine clearance (CrCl) 20 to 50 mL/min, reduce dose by 50%; CrCl <20 mL/min, reduce dose by 75%.
[b]Flucytosine dosage in kidney failure: CrCl 20 to 40 mL/min, reduce dose to 25 mg/kg q12h; CrCl <20 mL/min, reduce dose to 25 mg/kg q24h.
IV, Intravenous; *PO,* orally; *q6h,* every 6 hours.

Lipid formulations of amphotericin B are not recommended for treatment of fungal UTI. The decreased nephrotoxicity that results from the addition of the lipid component likely also precludes the drug's effectiveness by failing to achieve adequate levels in the urinary tract.[13]

One of the few uses of flucytosine is for the treatment of *Candida* UTI. Flucytosine is excreted into the urine in high concentrations but should be used only when fluconazole is not tolerated or the organism is fluconazole resistant. The usual dosage of flucytosine in patients who have normal creatinine clearance is 25 mg/kg orally every 6 hours for 7 to 10 days.[13] Most species of *Candida,* with the exception of *C. krusei,* are susceptible to flucytosine, but resistance emerges quickly when this agent is used alone. Serious adverse effects of flucytosine include bone marrow suppression and hepatotoxicity. These effects are dose related, and the risk increases greatly with kidney failure (see Table 55.3).

The echinocandins (caspofungin, micafungin, and anidulafungin) have minimal or no excretion into the urine as active drug. The tissue concentrations achieved with these agents may be adequate to treat invasive *Candida* infections of the bladder or kidney, but this is not clear. Both success and failure have been reported when echinocandins are used to treat *Candida* UTI.[14–16] Currently, echinocandins are not recommended for the treatment of *Candida* UTI but can be tried if all else fails in patient with *C. glabrata* UTI.

Local Antifungal Administration

Continuous bladder infusion of amphotericin B deoxycholate 50 mg in 1 L of sterile water through a triple-lumen catheter is sometimes used to treat *Candida* bladder infection. Bladder irrigation clears candiduria more quickly than systemic antifungal agents.[17] However, the effect is brief, and recolonization occurs within 1 to 2 weeks. Bladder irrigation is rarely ordered, but it is sometimes useful for patients who have recalcitrant bladder infection with azole-resistant *C. krusei* or *C. glabrata.*

In the patient with kidney obstruction caused by a fungus ball, irrigation through a percutaneous nephrostomy tube with amphotericin B deoxycholate is recommended, in addition to systemic antifungal therapy with fluconazole.[10] Absorption of amphotericin B does not occur, and direct infusion is not nephrotoxic. Surgical or endoscopic removal of the fungus ball is essential to eradicate the infection.

Localized Candida Infections

Prostatitis and prostatic abscess caused by *Candida* spp. manifest with symptoms that are similar to those of bacterial prostatic infection. The initial manifestation may be urinary retention; physical examination reveals a tender prostate, and imaging can show either discrete abscesses or diffuse inflammation. Treatment is drainage, if an abscess is present, and fluconazole, which achieves excellent concentrations in the prostate, for several months until the infection has resolved.[18] Epididymo-orchitis is less common and usually manifests as a tender scrotal mass. Surgical drainage or orchiectomy is required, along with fluconazole therapy until resolution has occurred.

OTHER YEASTS

Rarely, yeasts such as *Saccharomyces cerevisiae* and *Trichosporon asahii* cause UTI, but the most important non-*Candida* yeast that infects the genitourinary (GU) tract is *Cryptococcus neoformans.* Cryptococcosis occurs primarily in immunosuppressed hosts. In autopsy series, kidney involvement has been noted in 25% to 50% of patients who died of cryptococcosis, but GU tract symptoms were rare. The prostate is frequently infected and can be a reservoir for persistent *C. neoformans* infection. Isolated prostatitis and epididymo-orchitis have been reported in the absence of systemic cryptococcosis.[19] The diagnosis is usually made after biopsy of a mass or nodule; granulomatous inflammation is typically seen. Treatment of localized GU tract cryptococcal infection is fluconazole 400 mg/day for 6 to 12 months.

ASPERGILLUS AND OTHER MOLDS

The urinary tract is an uncommon site of infection with molds. However, individual case reports have noted GU infections caused by a variety of molds, including the Mucorales (e.g., *Rhizopus,*

Mucor) and *Aspergillus*.[20,21] The most common mold infection is aspergillosis. Hematogenous spread to the kidney with invasive disease in immunosuppressed patients results in numerous kidney microabscesses and infarcts. This may be an incidental finding at autopsy in patients with disseminated infection; in other patients, infection is localized to the GU tract.[21] Urinary tract obstruction from masses of fungal elements is not uncommon. Treatment is surgical removal of the obstructing mass, often nephrectomy, and systemic antifungal therapy for the specific mold. Mortality is extremely high when GU involvement is accompanied by disseminated infection.

ENDEMIC FUNGI

All of the major endemic mycoses have been reported to infect the GU tract. For all of these organisms, infection is by hematogenous spread to the GU tract. For upper tract infection, treatment is the same as that for disseminated infection. The treatment of focal infection, which is more likely to involve the lower GU tract, often requires surgical removal of the infected tissue and antifungal therapy.

B. dermatitidis has the greatest propensity to cause symptomatic infection. In patients with disseminated blastomycosis, involvement of the GU tract occurs in as many as a third of cases and usually manifests as prostate or epididymal infection.[22] In most patients, this involvement is discovered incidentally when urine cultures yield the organism or a biopsy is performed for a prostatic or epididymal mass.

Symptomatic GU tract involvement with histoplasmosis is uncommon. However, at autopsy, kidney lesions are often found in patients who have disseminated histoplasmosis.[23] Patients are usually asymptomatic in regard to urinary symptoms. Individual cases of testicular abscesses, epididymitis, and prostate nodules have been reported.

Coccidioidomycosis rarely causes symptomatic UTI. However, autopsy series of cases of disseminated coccidioidomycosis have noted kidney involvement in more than 50% of cases. and *Coccidioides* spp. can be grown in urine culture in patients with disseminated infection.[24] Localized infection, manifesting as abscesses or mass lesions of the epididymis or prostate, has also been reported caused by *Coccidioides* spp.

SELF-ASSESSMENT QUESTIONS

1. Which of the following *Candida* spp. is isolated *most* often in patients with candiduria?
   - **A.** *C. glabrata*
   - **B.** *C. parapsilosis*
   - **C.** *C. albicans*
   - **D.** *C. krusei*
   - **E.** *C. tropicalis*
2. The presence of pyuria is a helpful diagnostic test for *Candida* UTI when there is:
   - **A.** An indwelling bladder catheter in a symptomatic patient
   - **B.** An indwelling bladder catheter in an asymptomatic patient
   - **C.** Concomitant bacteriuria and candiduria in an asymptomatic patient
   - **D.** Concomitant bacteriuria and candiduria in a symptomatic patient
   - **E.** No indwelling bladder catheter and no bacteriuria
3. The dose of which of the following antifungal agents used to treat fungal UTI should be reduced in patients who have a creatinine clearance below 40 to 50 mL/min?
   - **A.** Amphotericin B
   - **B.** Flucytosine
   - **C.** Caspofungin
   - **D.** Liposomal amphotericin B
   - **E.** Voriconazole
4. The antifungal agent of choice for treating a *Candida albicans* UTI is:
   - **A.** Amphotericin B
   - **B.** Fluconazole
   - **C.** Flucytosine
   - **D.** Voriconazole
   - **E.** Caspofungin

The Kidney in Schistosomiasis

Rashad S. Barsoum, Tarek S. Fayad

INTRODUCTION

Schistosomiasis is a parasitic disease usually acquired by teenagers, often leading to complications that may extend into the fourth and fifth decades of life. It was known to the ancient Egyptians as "the bloody urine disease"[1] and is also known as *bilharziasis* in honor of its discoverer, Theodor Bilharz, the German physician who practiced in Egypt in the 1850s.

The life cycle of the parasite is shown in Fig. 56.1. Infection is acquired through contact with contaminated waters in ponds and slow-flowing canals. Cercariae enter through the skin or mucous membranes and migrate through the lymphatics and blood circulation into the portal or perivesical venous system, where they mature into sexually differentiated adult worms and live in almost continuous copulation. Females leave the males only to lay eggs, and, traveling against the blood flow, reach the rectal or bladder mucosa. The ova are driven out by visceral contraction during defecation or urination. Contact with fresh water within a couple of days allows the eggs to hatch, releasing miracidia, which infect specific snails. In this intermediate host, the organisms mature asexually into cercariae, which are eventually released to search for their definitive host, which is usually humans and occasionally apes and cattle. The snail demography defines the endemicity and frequency of schistosomiasis in different geographic regions and is influenced by temperature and humidity.[2]

About 230 million inhabitants (about 50% children) of 78 countries on five continents are infected, and an additional 700 million are at risk. Of the infected persons, 60% are symptomatic, 10% have serious sequelae, and 1% die of the disease each year, mainly in China, the Philippines, Brazil, northern Senegal, and Uganda. There has been a significant decline in prevalence during the second half of the past century, as a result of mass treatment with tartar emetic during the 1960s, the use of praziquantel during the 1980s, and the World Health Organization (WHO)-sponsored global mass praziquantel treatment program starting in the late 1990s. This has resulted in eradication of schistosomiasis from Japan and the Lesser Antilles islands; transmission was halted in Tunisia and significantly reduced in China, Egypt, Morocco, Saudi Arabia, Brazil, Venezuela, and Puerto Rico. However, certain schistosomal strains—up to 82% in Senegal—are resistant to praziquantel. Such strains are responsible for incremental prevalence in several countries and even spread to adjacent geographic regions in East and West Africa.

Of seven species that affect humans, three are responsible for almost all major morbidity from the disease: *Schistosoma haematobium* throughout Africa and adjacent regions; *Schistosoma mansoni* in Africa, South America, and the Caribbean; and *Schistosoma japonicum* in the Far East (Fig. 56.2).

S. haematobium affects the genitourinary (GU) tract, whereas *S. mansoni* and *S. japonicum* typically affect the colon and rectum and spread upstream through the portal venous system to the liver, leading to periportal fibrosis. All three species may cause "metastatic" lesions when ova are driven by the bloodstream to the lungs, brain, spinal cord, heart muscle, eyes, and other sites.[3] Overall morbidity is variable and depends on the virulence of the infective strains, host resistance, environmental factors, and standards of primary medical care. For example, chronic lower urinary tract disease among infected subjects was reported a few decades back to vary from 2% in Nigeria in the west of Africa to 52% in Tanzania in the east.[4] An even wider range (0.6%–67%) was reported among children in sub-Saharan Africa.[5]

The kidneys are secondary targets of both *S. hematobium* and *S. mansoni* infection. New cases of *S. mansoni*–associated nephropathy are reported mainly in South America[6,7] and of *S. hematobium*–associated urogenital disease in Africa.[8]

PATHOGENESIS

Schistosomes cause morbidity through two major mechanisms: (1) local reactions around the ova deposited in different tissues and (2) systemic effects attributed to the host's response to circulating antigens released from the worms or the ova (Fig. 56.3).[4,9]

The local reaction is a granulomatous cell–mediated immune response to soluble egg antigens diffusing out of trapped ova through micropores in the eggshell. The initial response is innate, being driven by tissue macrophages, and involves natural killer cells, neutrophils, and complement. This is followed by a specific immune response orchestrated by T helper (Th) lymphocytes. The schistosomal granuloma is composed of mononuclear cells, eosinophils, neutrophils, basophils, and fibroblasts, which are recruited and activated by a variety of Th lymphokines and by specific chemoattractants of parasitic origin (Fig. 56.4). These cells are involved in the elimination of the parasite by direct phagocytosis (monocytes), lymphocytotoxicity (T lymphocytes), antibody-dependent cytotoxicity (eosinophils), and antibody- and complement-dependent cytotoxicity (neutrophils). Later, the granuloma is modulated by gradual switching from Th1 to Th2 activation, largely mediated by a change in the monokine profile that favors release of modulatory cytokines, which are associated with a phenotypic change of the committed tissue macrophages. At this stage, the intensity of the inflammatory reaction is reduced, and progressive fibrosis is induced largely through the release of interleukin (IL)-5, IL-10, IL-13, somatostatin, and transforming growth factor (TGF)-β. Data from murine models incriminate additional T-cell subsets in promoting fibrosis, including Th9, Th17, and T-follicular helper cells (Tfh).[10] Further on, tolerance to the parasite is achieved by an established population of regulatory T (T-reg) cells, which develop under the combined influence of host- and ova-derived mediators. With the final extinction of the inflammatory reaction, granulomas in

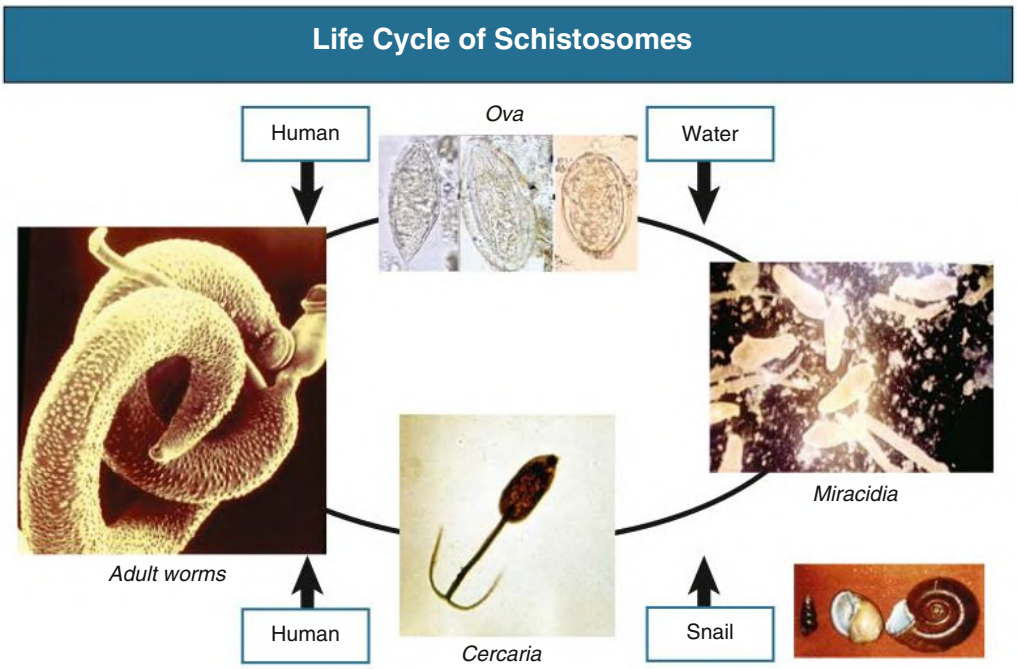

Fig. 56.1 Life cycle of schistosomes.

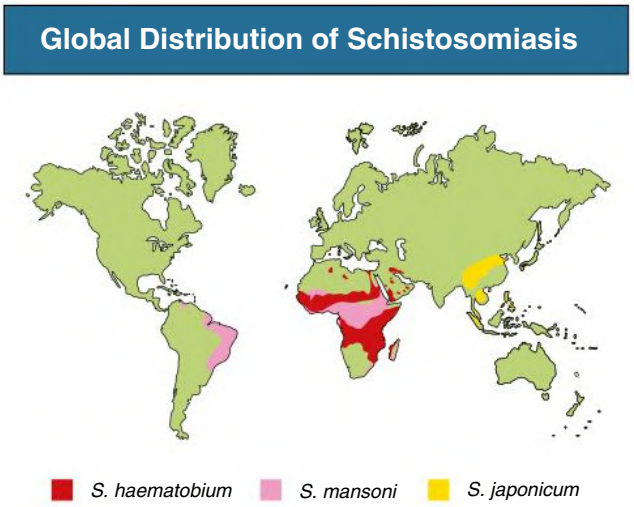

Fig. 56.2 World map showing the geographic distribution of the main pathogenic schistosomes.

the bladder, lower ureters, and seminal vessels heal with fibrosis and dystrophic calcification.[11,12]

The systemic immune response is primarily a humoral reaction to circulating schistosomal antigens, which originate mainly from the worm's digestive enzymes (gut antigens), with a less significant contribution of tegument and oval proteins. The gut antigens consist of a positively charged glycoprotein and a negatively charged proteoglycan (circulating cationic antigens and circulating anionic antigens, respectively). These antigens are present in most of the schistosomal immune complex–mediated lesions, particularly in glomeruli.[13] The antibody response is biphasic, driven by the successive Th1 and Th2 stages of lymphocyte activation. In the Th1 stage, B cells tend to produce immunoglobulin M (IgM), IgG1, and IgG3 under the influence of IL-2. During the Th2 phase, IgG2, IgG4, and IgA predominate; these have a limited ability to fix complement and may even block its deposition, hence their importance in modulating the granulomas.[14]

CLINICAL MANIFESTATIONS

Schistosomal lesions in the urinary system mirror the two major pathogenetic mechanisms. On one hand, there are local lesions, mostly affecting the lower urinary tract, caused by the local granulomatous response to *S. haematobium* ova.[15] One may also observe lesions caused by immune complex deposition in the glomeruli, usually associated with hepato-intestinal *S. mansoni* and, less commonly, urogenital *S. haematobium* infections.[15] Although glomerular lesions can be readily induced by *S. japonicum* in experimental animals,[16] this species does not seem to cause significant kidney disease in humans.

Lower Urinary Tract Schistosomiasis

The lower urinary tract and adjacent genital structures are the primary sites of *S. haematobium* infection. Clinical disease starts by the coalescence of multiple granulomas that form small pseudotubercles in the bladder mucosa (Fig. 56.5). These may consolidate to form sessile, occasionally pedunculated masses or ulcerate, leading to painful terminal hematuria, the most typical presenting symptom. Hematuria may vary from microscopic (40%–100% in different reports) to gross (0%–97%).[17] Ulcers eventually heal by fibrosis, with calcified granulomas under the atrophic and dirty mucosa, leading to the characteristic cystoscopic appearance of sandy patches and also the radiologic appearance of linear bladder calcifications in 2% to 62% of cases.[17] Similar lesions may occur in the lower ureters, bladder neck, seminal vesicles, and other organs in the vicinity (Fig. 56.6).

The bladder lesions predispose to secondary bacterial infection, particularly with *Pseudomonas* or *Proteus* spp., usually after diagnostic or therapeutic instrumentation. *Proteus* infection is notorious for favoring stone formation, which further complicates the scenario. The subsequent fibrotic process may involve the bladder neck, leading to outflow obstruction, or the vesicoureteral junction, leading to ureteral obstruction or vesicoureteral reflux. Involvement of the detrusor is late and may lead to an atonic or a hyperirritable bladder. Eventually, the bladder becomes a deformed, contracted, and calcified organ that accommodates a very small amount of urine that is difficult to void.

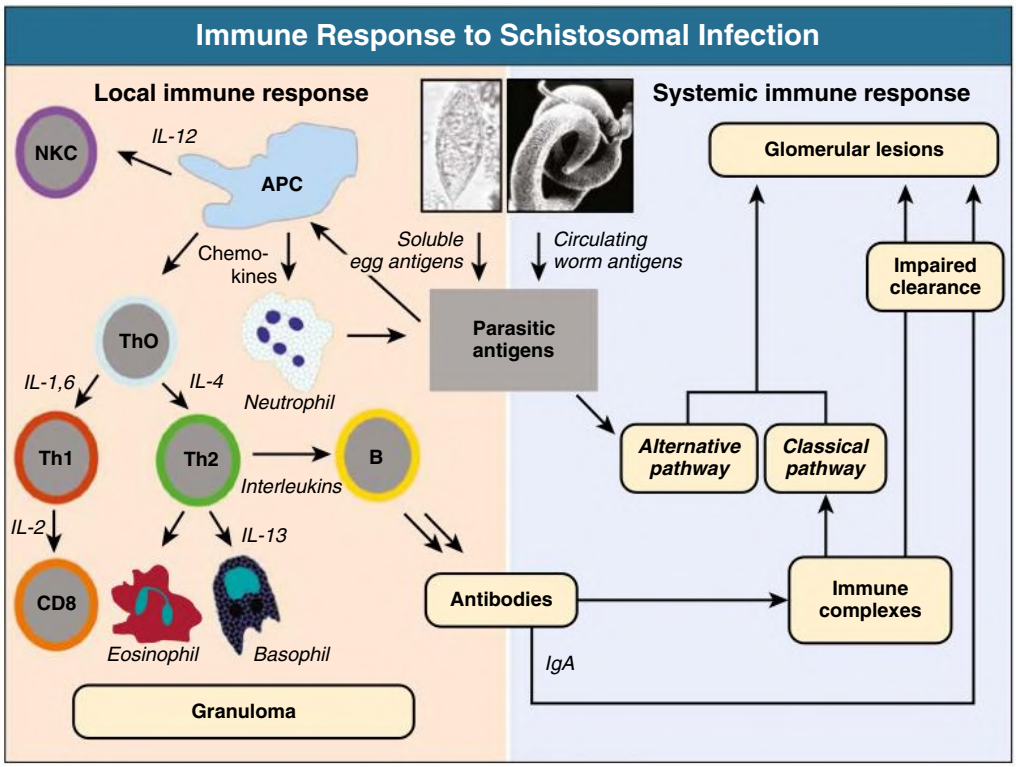

Fig. 56.3 Immune Response to Schistosomal Infection. The local immune response to deposited ova leading to granuloma formation is shown on the *left;* all cells shown in the diagram, in conjunction with antibodies or complement, participate in eventual parasite elimination (see text). The systemic immune response is shown on the *right;* note the important role of impaired clearance of schistosomal antigens and immunoglobulin A *(IgA)* in the development of glomerular lesions. *APC,* Antigen-presenting cell; *IL,* interleukin; *NKC,* natural killer cell.

Fig. 56.4 *Schistosoma haematobium* Granuloma. Note the egg's terminal spike *(arrow),* which identifies *S. haematobium,* and the distortion of shell by proteases and oxidants released by the local neutrophil infiltration. (Hematoxylin-eosin stain, ×500.)

Bladder Cancer

Chronic bilharzial cystitis is precancerous. The typical tumor is a squamous cell carcinoma,[18] although a time trend to predominance of transitional cell carcinoma was reported in a large series of close to 10,000 Egyptian patients with bladder cancer.[19] The tumor, particularly when of the squamous cell type, remains localized for a long time before spreading to the surrounding pelvic tissues or a distant site, thanks to the occlusion of lymphatics by the preceding fibrotic process.

Products of *S. hematobium* ova are directly incriminated in oncogenesis.[20,21] The major impact is on the *BCL2* gene, which leads to epithelial proliferation and inhibition of apoptosis. This is coupled by inhibition of the tumor suppressor genes *P27*, *TP53,* and others. Other oncogenic factors in schistosoma-associated bladder cancer include disturbance of the urinary microbiome and secondary bacterial infection.[21]

Development of malignancy is suspected when the symptoms of chronic cystitis worsen, along with recurrence of hematuria many years after the initial presentation and the passage of small pieces of necrotic tissue with urine (necroturia). A characteristic radiologic sign is the irregular "eating up" of the bladder calcification on a plain radiograph (Fig. 56.7). Cystoscopy shows the tumor and provides the means for a histologic diagnosis.

Upstream Consequences

Although ureteral strictures and calcifications are common, the hypertrophied upper ureteral musculature usually overcomes the lower obstruction, thereby limiting the upstream consequences. Nevertheless, hydronephrosis and progressive kidney failure may

develop when there is extensive ureteral scarring, in the presence of stones or secondary bacterial infection, or when the vesicoureteral junction is incompetent (Fig. 56.8). The frequency of upper urinary tract disease from *S. haematobium* is variably reported from different geographic regions—for example, from less than 10% in Niger to 48% in Cameroon.[4]

Interstitial Nephritis

Progressive kidney scarring is the eventual outcome of complicated *S. haematobium* infection, resulting from obstruction, reflux, and bacterial infection. Granulomas have occasionally been seen in the kidney interstitium but tend to be discrete and of no functional significance (Fig. 56.9).

The typical pathologic picture is that of a deformed kidney with calyceal dilation, distortion, and atrophic parenchyma. Dense interstitial infiltration, fibrosis, and periglomerular scarring are present. The glomeruli may show ischemic collapse or other schistosomal lesions, such as proliferative glomerulonephritis (GN) or amyloidosis.

The clinical picture is that of chronic tubulointerstitial nephritis (see Chapter 65), often associated with residual manifestations of lower urinary tract involvement. Hypertension is a late feature, being checked by concomitant tubular salt wasting. Anemia and osteodystrophy may be disproportionately severe because of the associated secondary distal tubular acidosis and nutritional deficiency in endemic areas.

Immune-mediated tubulointerstitial nephritis has been described with *S. mansoni* in humans.[22,23] Tubular dysfunction associated with hepatosplenic schistosomiasis includes salt wasting, impaired concentrating ability,[24] and Type I renal tubular acidosis.[24,25] Because these were also reported in chronic liver disease from other causes, their specificity to schistosomal etiology remains questionable.

Glomerulonephritis

Immune complex–mediated GN has been described in experimental[16] and human[15] infection, mainly with *S. japonicum* and *S. mansoni.* The latter species accounts for most clinically significant disease in humans. *S. haematobium* GN is rare, transient, and usually subclinical.[26]

Schistosomal gut antigens are present in circulating immune complexes and in the immune deposits in mesangial, subendothelial, and intramembranous locations. The presence of liver fibrosis is critical because it results in impaired hepatic clearance of schistosomal antigens and immune complexes. These are mostly generated within the portal venous system, which accommodates the adult worms.

Most patients are 20- to 40-year-old men with evidence of hepatosplenic schistosomiasis. This is often discovered accidently during a physical or ultrasonographic abdominal examination in an asymptomatic case. Less frequently, these patients may complain of abdominal distension, edema, upper gastrointestinal (GI) bleeding, or manifestations of chronic liver disease. Kidney involvement is asymptomatic in up to 40% of those, being identified by accidental or surveillance urinalysis, which may display various grades of proteinuria, or abnormal sediment. Some 15% of those with hepatosplenic schistosomiasis have overt GN, with proteinuria and microhematuria on presentation and with or without the nephrotic syndrome, hypertension, and impaired kidney function. Liver function test results are often normal. A polyclonal gammopathy is seen in most cases, whereas a monoclonal IgM response is seen in those with associated hepatitis C virus (HCV) infection and cryoglobulinemia. Rheumatoid factor activity and anti-DNA antibodies are detected in 5% to 10% of cases, particularly in association with *Salmonella* infection (see later discussion), but they do not correlate with clinical severity. Rheumatoid factor seropositivity is detected in much higher titers when HCV infection is associated.[27]

Six histologic classes of schistosomal GN are recognized (Table 56.1 and Fig. 56.10).[15,27] Class I (mesangial proliferative), class III (membranoproliferative), and class IV (focal segmental proliferative and sclerosing) result from the deposition of immune complexes representing different stages in the evolution of pure schistosomal hepatosplenic disease. The main deposits in class I are schistosomal antigens, IgM, and C3; and in class III and class IV, IgG and IgA, usually without schistosomal antigens. The IgA deposits parallel the severity of proteinuria and mesangial proliferation. Impaired hepatic clearance and increased mucosal synthesis of IgA have been documented in many of those patients.[28] Whereas class I lesions are seen in most asymptomatic cases, class III and class IV are usually symptomatic and progressive, even with eradication of the parasitic infection.

Class II (diffuse proliferative and exudative) is associated with urinary or biliary coinfection with *Salmonella* strains, usually *Salmonella paratyphi* A in Africa and *Salmonella typhimurium* in Brazil, which are attached to specific receptors in the tissues of adult schistosomes. C3 and *Salmonella* antigens have been detected in the glomerular capillary walls and the mesangium. In these patients the clinical presentation is typical of acute postinfectious GN, associated with manifestations of *Salmonella*-related toxemia (fever, exanthema, and severe anemia).

Serum amyloid A (AA) protein deposits are detected by special stains or electron microscopy in up to 15% of biopsy samples from patients with class III and class IV, whereas AA-amyloidosis may be

the predominant lesion (class V) in less than 5% of patients with clinically overt schistosomal GN. It occurs with heavy, often mixed infection regardless of the anatomic site. Minimal amyloid deposits do not seem to alter the clinical presentation or prognosis, but typical class V lesions are grossly nephrotic and relentlessly progressive.

Class VI lesion was described in patients with hepatosplenic schistosomiasis and HCV infection.[27] The lesion consists of a mixture of mesangial proliferation, amyloid deposition, fibrinoid necrosis, and cryoglobulinemic thrombi in the glomerular capillaries with tubular casts. Patients have chronic hepatitis, cirrhosis, nephrotic syndrome, cryoglobulinemic skin vasculitis, polyarthritis, and rapidly progressive kidney failure associated with severe protein-calorie malnutrition.

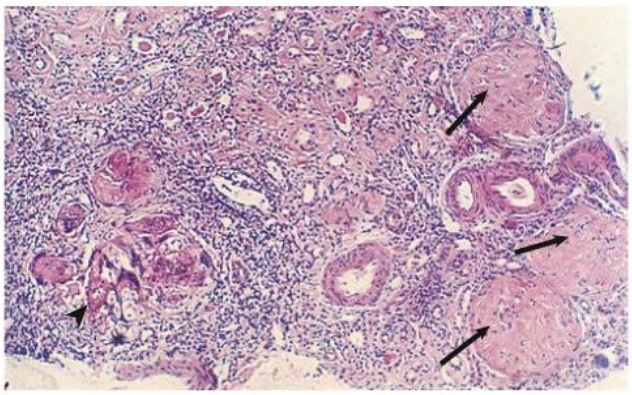

Fig. 56.9 Schistosomal Chronic Interstitial Nephritis. Note the dense cellular infiltration and fibrosis, atrophic dilated tubules, and thickened vessels. Three glomeruli heavily infiltrated with amyloid are seen on the right side *(arrows);* a schistosomal granuloma is seen in the lower left corner *(arrowhead).* (H&E stain; original magnification ×75.)

Other histologic lesions have described in chronic schistosomiasis, yet a cause-and-effect relationship has not been established. A frequently debated lesion is membranous nephropathy, which is believed to be a chance association of primary membranous nephropathy and schistosomiasis.[29] Collapsing glomerulopathy has been described in a patient with APOL1 genotype infected with *Schistosoma mansoni*,[30] which was blamed as a triggering factor in a predisposed patient.
