COINFECTION

Patients living in endemic areas may acquire one or more superimposed infections that can perturb schistosomal pathogenicity and modify its presentation. Mutually, schistosomiasis may modify the course of the confounding infection. The first reported coinfection is that of schistosomiasis and salmonellosis,[31] discussed earlier as class II schistosomal glomerulopathy. Likewise, class VI is attributed to coinfection with HCV.[27]

The list of other infections known to interact with schistosomiasis is expanding (Box 56.1). Some of the documented coinfections, namely those with plasmodium, filaria, tuberculosis, and staphylococci, are clinically significant. However, they were not reported to modify the known kidney lesions of schistosomiasis alone.

TABLE 56.1 Classification of Schistosomal Glomerulonephritis

Class	Histology	Immunofluorescence	Etiologic Agent	Prevalence	Clinical Findings	Treatment of Kidney Disease
I	Mesangial proliferative GN	IgM, C3, schistosomal antigens	*S. haematobium, S. mansoni, S. japonicum*	27%–60% of asymptomatic patients, 10%–40% of patients with kidney disease	Microhematuria, proteinuria	May respond to antiparasitic treatment
II	Diffuse proliferative exudative GN	C3, *Salmonella* antigens	*S. haematobium, S. mansoni, plus Salmonella* spp.	*Salmonella* infections	Acute nephritic syndrome, toxemia, reduced serum C3	May respond to treatment of *Salmonella* and schistosomal infections
III	Membranoproliferative GN	IgG, IgA, C3, schistosomal antigens	*S. mansoni* (*S. haematobium*?)	7%–20% of asymptomatic patients and in 80% of patients with overt kidney disease	Hepatosplenomegaly, nephrotic syndrome, hypertension, kidney failure	No
IV	Focal segmental glomerulosclerosis	IgM, IgG (occasionally IgA)	*S. mansoni*	11%–38%	Hepatosplenomegaly, nephrotic syndrome, hypertension, kidney failure	No
V	Amyloid	AA protein	*S. mansoni, S. haematobium*	16%–39%	Hepatosplenomegaly, nephrotic syndrome, hypertension, kidney failure	No
VI	Cryoglobulinemic GN	IgM, C3	*S. mansoni* + hepatitis C virus	Unknown	Hepatosplenomegaly, nephrotic syndrome, purpura, vasculitis, arthritis, hypertension, kidney failure	Interferon plus ribavirin, corticosteroids, immunosuppression, plasma exchange

AA, Amyloid A; *GN,* glomerulonephritis; *Ig,* immunoglobulin.

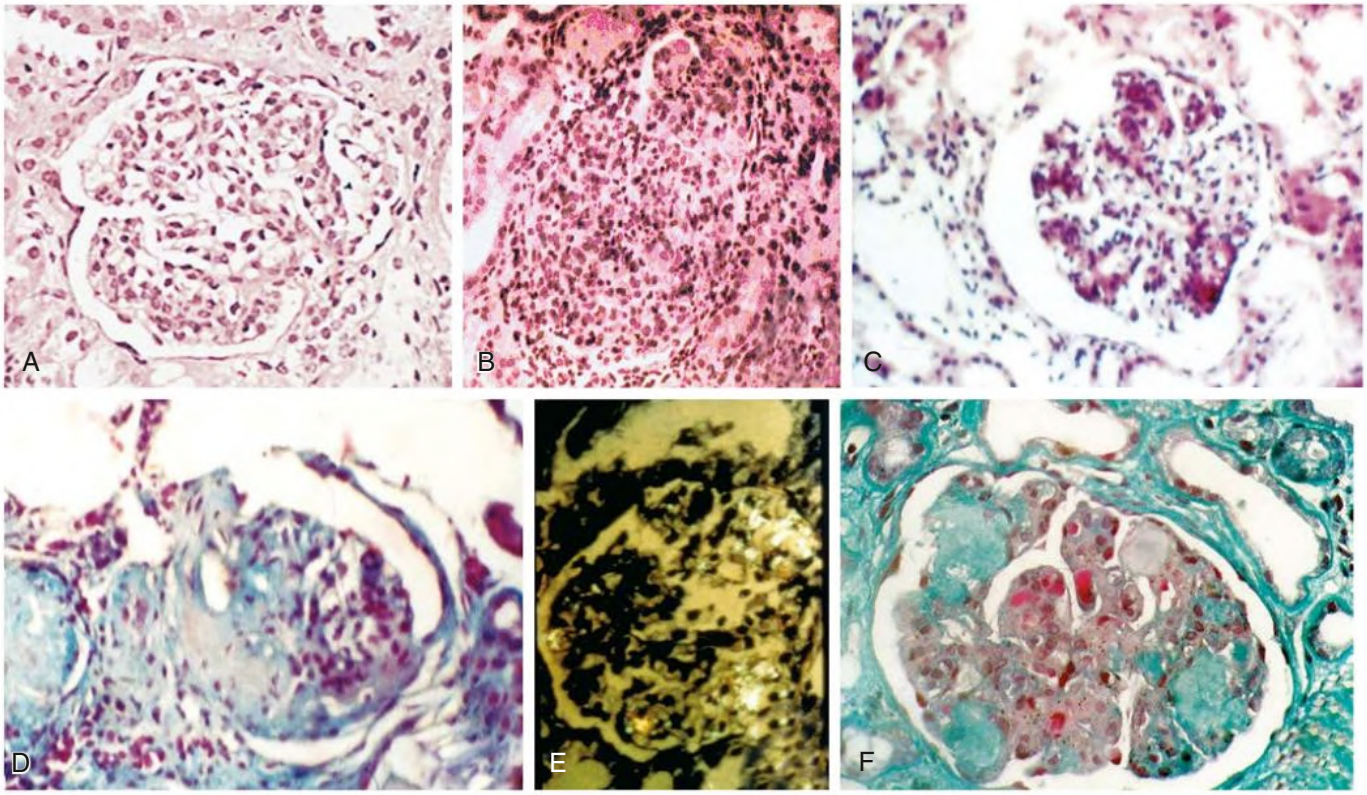

Fig. 56.10 Schistosomal Glomerulopathy. (A) Mesangial proliferative glomerulonephritis (GN), H&E stain (class I). (B) Schistosoma- and *Salmonella*-associated exudative GN, H&E stain (class II). (C) Membranoproliferative (mesangiocapillary) GN type I, H&E stain (class III). (D) Focal segmental glomerulosclerosis, Masson trichrome stain (class IV). (E) Green birefringence under polarized light in a glomerulus with mesangial proliferation in a patient with mixed *Schistosoma haematobium* and *Schistosoma mansoni* infection, Congo red stain (class V). (F) Amyloid deposits and cryoglobulin capillary thrombi *(red stain)* in a glomerulus displaying focal mesangial proliferation in a patient with schistosomal hepatic fibrosis and associated hepatitis C virus infection (class VI).

BOX 56.1 Clinically Relevant Coinfection with Schistosomiasis

Viral
Hepatitis B virus
Hepatitis C virus
Human immunodeficiency virus
Human papillomavirus

Bacterial
Tuberculosis
Staphylococci
Salmonella

Parasitic
Plasmodium
Filaria

On the other hand, there is evidence that coinfection with human immunodeficiency virus (HIV), hepatitis B virus (HBV), or human papilloma virus (HPV) may augment schistosomal morbidity:

Human Immunodeficiency Virus

Several studies have established an epidemiologic link between schistosomiasis and HIV infection. Females with lower urinary tract schistosomiasis are at significantly increased risk (odds ratio [OR], 2.9 in Zimbabwe[32] and 4.0 in Tanzania[33]) of acquiring and subsequently transmitting HIV to their sexual partners. Data on males with *S. hematobium* infection or either sex with *S. mansoni* infection are inconsistent. There are no published data on *S. japonicum* and HIV coinfection.

The immunologic perturbation induced by schistosomiasis seems to accelerate the progression and spread of HIV infection.[34] HIV coinfection impairs the immune response, resulting in alteration of the granulomatous process involving schistosomes, yet without known clinical sequelae. However, HIV-infected patients are more vulnerable to reinfection with schistosomes upon new exposure after successful eradication.[35]

There is some concern about the unexplained 3- to 16-fold increase of HIV viral load after treatment of schistosomiasis by praziquantel.[36] Fortunately, this effect is spontaneously reversible in a few weeks, and the benefit of eradicating the confounding parasitic infection on the clinical course and spread of HIV infection is unquestionable.[36]

Hepatitis B Virus

Vulnerability of patients with hepatosplenic schistosomiasis to coinfection with HBV is well documented in hospital-based,[37] but not in community-based,[38] studies, perhaps because of the selection of complicated cases in the former. Such coinfection augments the liver injury induced by schistosomiasis,[39] leading to increased incidence of abnormal liver function (46.6%), jaundice (23.3%), hepatocellular carcinoma (17.8%), and liver-related mortality (23.3%).[40] It is unknown

whether schistosoma and HBV coinfection influences the nature or severity of the kidney lesions associated with either.

Human Papilloma Virus

The association of HPV infection with nonschistosomal squamous cell carcinoma of the bladder was reported in 1994.[41] Three years later, an in-situ hybridization study in South Africa did not show evidence of such infection in 25 patients with bilharzial squamous cell bladder cancer.[42] However, because of the confirmed association of HPV with cervical carcinoma in patients with genital schistosomiasis,[43] debate continues whether it may also be a confounding risk factor for bilharzial bladder cancer.

Diagnosis

Schistosoma haematobium Urinary Tract Disease

The clinical diagnosis of lower urinary tract schistosomiasis is easily made, particularly in patients with the typical pattern of painful terminal hematuria after exposure to fresh river waters in an endemic area. Diagnosis is more difficult when the history of exposure is less convincing (e.g., swimming pools) or when the clinical presentation is atypical (e.g., bacterial pyelonephritis, typhoid, or amyloidosis).

The diagnosis is made by finding ova in a fresh urine sample, which is easy because of their abundance, large size, and typical appearance (see Fig. 56.4). Live ova, containing mobile miracidia, indicate active infection, whereas dead, calcified ova may continue to be shed from fibrotic lesions for many months or even years.

Serologic diagnosis is based on finding circulating schistosomal antigens or antibodies.[44] The circumoval precipitin test is most frequently used in clinical laboratories. Serologic diagnosis is useful for diagnosis in the absence of ova, which occurs with old infections when the worms are sterile but continue to release their antigens. Serologic tests are also useful in assessing the response to treatment because titers usually become negative within 3 to 6 months of complete eradication of infection.

A polymerase chain reaction (PCR) real-time assay is available for detection of the dra-1 *S. hematobium* antigen in the serum.[45] Because of its high cost, its clinical use is limited to early detection of infection in expatriates visiting endemic areas.

The radiologic appearances of bladder and seminal vesicle calcification are so typical that no further confirmatory tests are needed in an endemic area. Cystoscopic findings are equally pathognomonic although seldom required. Early pseudotubercles are easily distinguished from mycobacterial infection by their size and the surrounding mucosal pathologic changes. The presence of sandy patches with associated masses, polyps, and even neoplasms confirms the diagnosis. Tissue biopsy confirms the parasitic nature of the lesions. Different imaging techniques (e.g., ultrasound,[46] intravenous urography, voiding cystography) are useful in the diagnosis of upstream complications, including obstruction and reflux (see Chapters 61 and 62).

The main differential diagnosis for urinary schistosomiasis is tuberculosis, which also causes hematuria, strictures, back pressure, and chronic kidney disease (CKD). This differential can be resolved with appropriate parasitologic and bacteriologic techniques (see Chapter 54).

SCHISTOSOMA MANSONI GLOMERULONEPHRITIS

Overt glomerular disease in patients with hepatosplenic schistosomiasis is suspected in those who develop hypertension, nephrotic or nephritic syndrome, or CKD. Occult glomerular disease is indicated by the presence of abnormal urinary sediment or kidney function. Although kidney biopsy is essential for diagnosis and classification, no lesion is pathognomonic unless schistosomal antigens are detected, which is unusual in clinically overt cases when sought with conventional immunofluorescence.

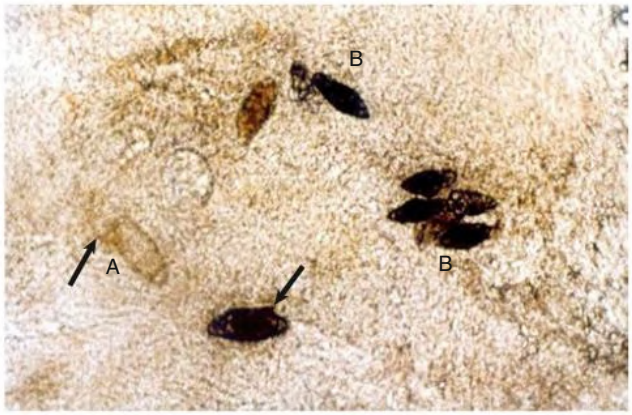

Fig. 56.11 Stool smears showing living *(A)* and dead *(B) Schistosoma mansoni* ova. Species are identified by the lateral spike *(arrows).*

Identification of *S. mansoni* eggs in the stools (Fig. 56.11) or submucosal rectal biopsy samples supports the diagnosis. Serologic tests for schistosomal gut antigens[47] and molecular tests for Sm1-7 encoding DNA[48] are usually positive. However, it is important to remember that these tests only indicate schistosomal infection and do not necessarily implicate schistosomes as causing the kidney disease.

Several biomarkers have been proposed for the detection of kidney injury in schistosomiasis. So far, none of these has reached a reliable, more specific, and noninvasive alternative to kidney biopsy.[49]

Concomitant *Salmonella* or HCV infection can be detected by appropriate microbiologic tests. The various serologic abnormalities described are of limited diagnostic value, except the high rheumatoid factor, monoclonal IgM expansion, and low C4 that are typical of class VI.

Other glomerular disorders associated with hepatic fibrosis, such as secondary IgA nephropathy and hepatic glomerulosclerosis, should be considered in the differential diagnosis. However, in both these conditions, the kidney disease is relatively milder, mainly with microhematuria at presentation but rarely with nephrotic-range proteinuria or impaired kidney function. The glomerular deposits are mostly mesangial, in contrast to those seen in schistosomiasis, in which subendothelial and intramembranous deposits may also be present.

TREATMENT

Schistosoma haematobium Urinary Tract Disease

S. haematobium is susceptible to antimony compounds, organophosphates (metrifonate), and niridazole. However, the standard drug of choice is praziquantel, with a cure rate greater than 85% and the least toxicity. It is administered as a single oral dose of 40 mg/kg body weight, which may be repeated 2 weeks later if there is evidence of active disease. The drug has a low toxicity profile, mainly a mild to moderate transient elevation of hepatic transaminases. In infections resistant to praziquantel, the antimalarial *Artemisia annua* may be used as an alternative with equal effectiveness.[50] Antiparasitic treatment cures the early bladder disease but has no effect on sandy patches or other fibrotic lesions. Ureteral distension with radiologic evidence of hydronephrosis may be reversed in a few weeks after successful treatment.

Antibacterial therapy usually controls acute episodes of cystitis and pyelonephritis. However, it must be combined with simultaneous eradication of parasitic infection if still active, especially when the urinary bacterial infection is because of typhoid *(Salmonella typhi).*

Chronic fibrotic lesions are difficult to treat. Surgery or the placement of stents may be necessary for the relief of an obstructive lesion. However, particular caution is required in dealing with the vesicoureteral junction to avoid induction of reflux. Several plastic procedures are available to restore the distorted ureteral, bladder, or urethral anatomy. Associated bacterial infections may require long-term low-dose antibiotics.

Chronic dialysis in such patients can be difficult because of the negative effects of the associated schistosomal lesions in the liver, lungs, and other organs and the comorbid impact of undernutrition, viral infection, or malignant disease. The same factors can compromise outcomes of kidney transplantation, with the additional risk for urinary leakage, which is many-fold higher than usual because of the presence of fibrotic granulomas and anatomic distortion in the bladder wall. Reinfection with *S. haematobium* also has been described.[51]

Schistosoma Mansoni Glomerulonephritis

S. mansoni is more resistant to treatment and may require higher doses of praziquantel (40–60 mg/kg body weight) or the use of oxamniquine (single dose of 15 mg/kg body weight in South America or two doses of 15 mg/kg body weight given 12 hours apart in Africa). Research is underway to overcome oxamniquine resistance, which is limiting its use in many geographic regions.[52] Nevertheless, eradication of the parasite can be curative only in classes I and II. In the latter, it must be combined with antibiotics for the control of *Salmonella* infection (usually quinolones, macrolides, or third-generation cephalosporins). Antischistosomal and immunosuppressive therapy are ineffective in all other classes of schistosomal GN.[15] These tend to progress to kidney failure in about 35% of cases 5 years after initial diagnosis.[6]

Chronic dialysis may be complicated by the risk for bleeding from esophageal or gastric varices after anticoagulation. Endoscopy is essential before the start of regular hemodialysis, with prophylactic sclerotherapy if necessary. Although peritoneal dialysis is viable for some, it is relatively contraindicated in those with significant ascites.

Kidney transplantation is a viable option in those who develop kidney failure, in the absence of major risk factors such as viral infection, undernutrition, or hepatic insufficiency. Uncomplicated residual hepatic fibrosis in the recipient does not seem to significantly modify the pharmacokinetics of immunosuppressive agents, but variations in cyclosporine blood levels can occur, perhaps secondary to altered GI absorption.[53] The severity of chronic liver disease may have a considerable impact on donor selection, choice of immunosuppression, and the eventual outcome.

Recurrence of schistosomal GN after transplantation has been described in a few patients,[53] suggesting the persistent release of antigens from living worms.[54] Although it is not an evidence-based practice, many authorities recommend the administration of a single dose of praziquantel before transplantation to recipients known to have been previously infected with the parasite.

SELF-ASSESSMENT QUESTIONS

1. A 45-year-old male recent Egyptian immigrant to Canada presents with a 4-week history of pyrexia, abdominal discomfort, asthenia, and increasing generalized edema. His medical history includes two treatment courses for intestinal schistosomiasis. Examination shows significant pallor, facial puffiness, a faint macular itchy eruption on the forearms and abdominal wall, and bilateral soft pedal edema. Temperature is 38.7°C (101.7°F), and blood pressure is 100/70 mm Hg. The liver edge is felt 2 cm below the right costal margin, firm and moderately tender. The spleen is felt 5 cm below the left costal margin and acutely tender. Urinary protein is 14 g/g creatinine, and the sediment shows 20 to 25 white blood cells, 8 to 10 red blood cells, and a few blood casts per high-power field. Peripheral blood hemoglobin is 8.6 g/dL; leukocyte count is 14,300/μL, of which 85% are neutrophils with left shift. Rheumatoid factor is positive at 48 IU/L, C-reactive protein is 128 units, and C3 is 54 mg/dL. Aspartate aminotransferase is 75 IU/mL, alanine aminotransferase is 62 IU/mL, and γ-glutamyl transferase is 123 IU/mL. Serum albumin is 1.8 g/dL, serum creatinine is 2.1 mg/dL, and blood urea nitrogen is 73 mg/dL. Which of the following is the *most* likely explanation for the patient's recent illness?
   A. Ascending pyelonephritis complicating neglected urinary schistosomiasis
   B. Schistosoma-associated *Salmonella* bacteremia
   C. Active hepatitis viral infection on top of hepatointestinal schistosomiasis
   D. Schistosoma-associated secondary immunoglobulin A nephropathy
   E. Cryoglobulinemic vasculitis
2. A 50-year-old male Nigerian patient presents with severe burning during micturition, with passage of blood and necrotic tissue with urine for 2 weeks. He received treatment for urinary schistosomiasis 30 years previously and for recurrent urinary bacterial infection many times after that. Examination shows an ill man, with bilateral edema of the left lower limb. The left kidney is palpable and slightly tender. Rectal examination reveals a mass indenting the anterior rectal wall. Midstream urine examination shows a protein/creatinine ratio of 4 g/g, and uncountable red blood and pus cells. Serum creatinine is 4.3 mg/dL, and blood urea nitrogen is 103 mg/dL. The *most* likely cause of his edema is:
   A. Schistosomal glomerulonephritis
   B. Schistosoma-associated chronic pyelonephritis
   C. End-stage postobstructive kidney disease
   D. Infiltrative bladder cancer
   E. Advanced prostatic cancer
3. A 38-year-old female Brazilian patient presents with painful swelling of the small joints of her hands, right knee, and left shoulder; bilateral soft lower limb swelling; and a raised brownish-purple macular skin eruption over the tibial shins. She has been under medical follow-up for compensated chronic hepatosplenic schistosomiasis. Urine examination shows a protein-to-creatinine ratio of 5.2 g/g, and the sediment shows many red blood cells, few leukocytes, and red blood cell and granular casts. Serum creatinine is 2.1 mg/dL; blood urea nitrogen is 26 mg/dL; serum albumin is 2.7 g/dL; serum C3 is 86 mg/dL; and C4 is 3.2 mg/dL. Rheumatoid factor is 256 IU/mL. Alanine aminotransferase is 128 IU/L, aspartate aminotransferase is 9 IU/L, and γ-glutamyl transferase is 396 IU/L. Which of the following is the *most* likely diagnosis?
   A. Acute schistosomiasis
   B. Autoimmune hepatitis
   C. Schistosomal glomerulonephritis
   D. Concomitant virus-induced cryoglobulinemia
   E. Superimposed rheumatoid arthritis

Glomerular Diseases Associated With Infection

Cynthia C. Nast, Bernardo Rodríguez-Iturbe

More than 250 years ago, dark, scanty urine was observed during convalescence from scarlatina infection. Richard Bright and others identified nephritis symptoms in patients with scarlet fever in the nineteenth century. In the early 1900s, von Pirquet proposed that nephritis occurring after scarlet fever resulted from antibodies that were pathogenic, an insight that unlocked the field of immune-mediated kidney disease. We now recognize that many infectious organisms can induce a spectrum of glomerular lesions via differing pathogenetic mechanisms, including immune complex deposition, direct kidney cell infection and injury, and sequelae of ongoing chronic inflammation (Table 57.1). Glomerular injury may occur secondary to resolved or ongoing infection; therefore, the preferred term is *infection-related glomerulonephritis* (GN).[1] As demographics, health care access, and public health conditions change, there are alterations in the epidemiology, clinical presentation, morphology, and therapeutic approaches to infection-related glomerulonephritides.[2] Table 57.2 shows the glomerular lesions associated with specific microorganisms.

BACTERIAL INFECTIONS

Poststreptococcal Glomerulonephritis

Etiology and Pathogenesis

Poststreptococcal GN (PSGN) is an immune complex–mediated lesion occurring after infection with a nephritogenic bacterial strain. Poststreptococcal GN traditionally was considered a complication of group A β-hemolytic streptococci infections of the skin (M types 49, 55, 57, 60) or upper respiratory tract (M types 1, 2, 4, 12), but PSGN can result from infections caused by other M type streptococci and other groups (particularly group C *Streptococcus zooepidemicus*). There are three immunologic mechanisms likely involved in streptococcal-associated GN: passive entrapment and deposition of circulating immune complexes, in situ immune complex formation associated with nephritogenic planted bacterial antigens or intrinsic antigens displaying molecular mimicry, and deposition of nephritogenic bacterial antigens that activate plasmin resulting in local complement activation.[3-6] Two nephritogenic streptococcal antigens are thought to be involved in PSGN immune complex formation: nephritis-associated plasmin receptor (NAPlr), characterized as glyceraldehyde-3-phosphate dehydrogenase, and the streptococcal pyrogenic exotoxin B (SPEB) together with its more immunogenic zymogen precursor (zSPEB).

Evidence for nephritogenicity includes demonstration of NAPlr and SPEB in kidney biopsies with acute PSGN, and elevation of antibody titers to both antigens in most convalescent sera.[5] In a Japanese study, 92% of PSGN convalescent sera and 60% of sera from patients with uncomplicated streptococcal infections contained anti-NAPlr antibodies.[7] Nephritis-associated plasmin receptor has been localized to glomerular areas with plasmin-like activity but not with complement or immunoglobulin, suggesting local binding to plasmin produces glomerular inflammation and enhances immune complex deposition.[3,7] Streptococcal pyrogenic exotoxin B also can bind plasmin, a possible common mechanism of action. However, unlike NAPlr, SPEB colocalizes with glomerular complement and immunoglobulin G (IgG), suggesting participation in immune-mediated glomerular damage.[4] Streptococcal pyrogenic exotoxin B is the only streptococcal nephritogenic antigen demonstrated in subepithelial "hump" deposits characteristic of PSGN, possibly because of its cationic charge. Studies from Latin America and Central Europe demonstrated only SPEB in PSGN kidney biopsy tissue. In contrast, the *S. zooepidemicus* strain responsible for a Brazilian epidemic lacked the SPEB-related gene, suggesting that different streptococcal antigens induce PSGN in different ethnic groups.[8] Thus, there likely are multiple nephritogenic antigens depending on the streptococcal species and genetic and other host factors.

Poststreptococcal GN is thought to occur when glomerular immune complexes or deposition of plasmin-activating nephritogenic bacterial antigens initiate an inflammatory cascade with local complement activation and recruitment of neutrophils and monocyte-macrophages. Subepithelial immune deposits develop associated with cationic antigens (e.g., SPEB) resulting from subendothelial immune complex dissociation, transit through, and reformation on the outer glomerular basement membrane, or in situ immune complex formation. Complement activation in PSGN has garnered renewed interest. In most patients with PSGN, serum C1q is normal while C3 is reduced, indicating predominantly alternative complement pathway activation. Because streptococcal antigens induce a robust antibody response, the classic complement pathway likely fails to be activated due to streptococcal produced "evasins" that bind C1q *(endopeptidase O)* and degrade IgG (*IdeS/Mac-1, Mac-2,* and *endopeptidase S*). Lectin complement pathway activation, characterized by early C4 level reduction, has been demonstrated in a significant number of patients with PSGN. One study identified mesangial deposits of mannose-binding lectin (MBL) and other lectin pathway components in 7 of 18 patients with PSGN.[9] However, lectin pathway activation is not required, as PSGN can develop in patients with MBL deficiency.

The demonstration of pathogenic autoantibodies in PSGN has renewed interest in other autoimmune aspects of this disease.[10] Rheumatoid factors (especially IgG) and cryoglobulins have been found in 35% of patient sera in the first week of disease. Rheumatoid factors were demonstrated in PSGN kidney tissue and kidney eluates from a fatal case. Loss of sialic acid from autologous IgG, due to streptococcal neuraminidase or from IgG Fc fragment binding to type II Fc receptors in the streptococcal wall, may induce anti-IgG reactivity. This anti-IgG antibody may play a role in deposition of IgG-containing complexes. Additional autoimmune manifestations include anti-C1q antibodies, particularly in severe cases, and rarely anti-DNA reactivity, antineutrophil cytoplasmic autoantibodies (ANCAs), and autoimmune hemolytic anemia.[10]

TABLE 57.1 Pathogenetic Mechanisms of Infection-Related Glomerular Injury

Mechanism	Representative Microorganism	Supportive Evidence
Circulating immune complexes	*Streptococcus*	Circulating antibodies against SPEB and NAPlr antigens
In situ immune complex formation	*Streptococcus*	Identification of SPEB in subepithelial deposits in PSGN
Nephritogenic antigen deposition with complement activation	*Streptococcus*	Glomerular deposition of NAPlr with plasmin activity
Superantigen binding to APCs activates T cells and polyclonal B cells, inducing immunoglobulin production	*Staphylococcus*	Selective peripheral blood activation of TCR V_β repertoire
Direct kidney cell infection	HIV, parvovirus	Virus identification in glomerular epithelial cells
Direct kidney cell injury	HBV	HBV induces mesangial cell proliferation and type IV collagen production in vitro
Cryoglobulin production	HCV	IgM rheumatoid factor against the HCV E2 envelope protein
Complement activation	*Streptococcus*	Low C3 levels, lectin deposits, serum antifactor B autoantibodies

APC, Antigen-presenting cell; *HBV,* hepatitis B virus; *HCV,* hepatitis C virus; *HIV,* human immunodeficiency virus; *IgM,* immunoglobulin M; *NAPlr,* nephritis-associated plasmin receptor; *PSGN,* poststreptococcal glomerulonephritis; *SPEB,* streptococcal pyrogenic exotoxin B.

TABLE 57.2 Infectious Organisms Causing Glomerular Injury

Microorganism	Associated Glomerular Lesions[a]
Bacteria	
Gram Positive	
Streptococci	DPGN, MPGN, DDD, IgA-dominant IRGN
Staphylococci	IgA-dominant IRGN, EPGN, DPGN, MesPGN, ICMGN, crescentic GN
Pneumococcus	EPGN, MPGN
Propionibacterium	MPGN, ICMGN (shunt nephritis)
Corynebacterium	MPGN, ICMGN (shunt nephritis)
Gram Negative	
Brucella	ICMGN
Campylobacter	DPGN, MesPGN
Escherichia coli	IgA-dominant IRGN
Haemophilus	IgAN
Klebsiella	DPGN, IgA-dominant IRGN
Legionella	Crescentic GN, EPGN, MesPGN
Meningococci	MesPGN, DPGN
Pseudomonas	MPGN, ICMGN (shunt nephritis)
Rickettsia	Crescentic GN
Salmonella	MesPGN, IgAN
Serratia	MPGN, ICMGN (shunt nephritis)
Yersinia	IgAN, EPGN
Other	
Bartonella	Crescentic GN (endocarditis)
Coxiella	Crescentic GN (endocarditis)
Leptospira	Segmental glomerular necrosis
Mycobacteria	MPGN, ICMGN, DPGN, amyloidosis
Mycoplasma	ICMGN
Treponema	MN, MPGN, DPGN, MesPGN
Viruses	
Hepatitis A	MPGN, IgAN, MesPGN
Hepatitis B	MN, MPGN + cryoglobins, DPGN with cryoglobulins, EPGN, MesPGN, IgAN, FSGS, amyloidosis
Hepatitis C	MPGN ± cryoglobulins, MN, fibrillary GN, immunotactoid GN, MesPGN, collapsing GP
HIV	Collapsing GP, FSGS, IgAN, ICMGN (including lupus-like), MCD
Parvovirus B19	Collapsing GP, ICMGN, EPGN, IgAN, FSGS
Adenovirus	EPGN, MesPGN
Coxsackie B virus	Proliferative GN
Cytomegalovirus	MPGN, MesPGN, collapsing GP, MN, crescentic GN
Dengue	MesPGN
Epstein-Barr	Collapsing GP, MN, crescentic GN, MPGN, EPGN, MesPGN
Hantavirus	MCD, MesPGN

TABLE 57.2 Infectious Organisms Causing Glomerular Injury—cont'd

Microorganism	Associated Glomerular Lesions[a]
Influenza	MesPGN, DPGN
Measles	DPGN
Mumps	MesPGN, DPGN
Rotavirus	MesPGN
Varicella	MesPGN, DPGN
Parasites and Protozoa (see Table 57.3 for more detail)	
Echinococcus	MN, MPGN
Filaria	MesPGN, MPGN, DPGN ± eosinophils, EPGN, MN, MCD, FSGS, collapsing GP, amyloidosis
Malaria	MPGN, MesPGN, MN, IgAN, MCD, FSGS, collapsing GP
Leishmania	MesPGN, MPGN, amyloidosis
Schistosoma	MPGN, FSGS, MesPGN, MN, amyloidosis
With Salmonella	PIGN
Toxoplasma	MPGN, FSGS, MesPGN
Trichinella	MesPGN, MPGN
Trypanosoma	MesPGN, MPGN

[a]These are glomerular lesions described in humans. More infection-associated glomerulopathies have been identified in animal models.
DDD, Dense deposit disease; *DPGN,* diffuse proliferative glomerulonephritis; *EPGN,* endocapillary proliferative glomerulonephritis; *FSGS,* focal segmental glomerulosclerosis; *GN,* glomerulonephritis; *GP,* glomerulopathy; *ICMGN,* immune complex–mediated glomerulonephritis; *IgA,* immunoglobulin A; *IgAN,* immunoglobulin A nephropathy; *IRGN,* infection-related glomerulonephritis; *MCD,* minimal change disease; *MesPGN,* mesangial proliferative glomerulonephritis; *MN,* membranous nephropathy; *MPGN,* membranoproliferative glomerulonephritis pattern; *PIGN,* immune complex–mediated postinfectious glomerulonephritis.

Epidemiology

The incidence of PSGN is decreasing worldwide; however, it remains high in low-income countries, with an incidence of 9.3 to 28.5 per 100,000 inhabitants.[2,11] Over the past several decades, likely because of early antibiotic administration, the incidence of PSGN has decreased to 0.2 to 0.6 cases per 100,000 person-years in wealthy countries.[12] Poststreptococcal GN now is more common in older adults with comorbid conditions such as diabetes, alcoholism, and malignancy.[2,6] The higher incidence in low-income countries and in alcoholics likely is associated with poor socioeconomic conditions, limited health care access, delayed antibiotic administration, and a tropical climate.

Poststreptococcal GN is the most common finding in children with acute nephritis in low-income countries occurring sporadically or in epidemics. It typically affects those 2 to 14 years old, with a 2:1 male predominance, and represents a major problem in indigenous populations as in Australia, where more than 95% of cases occur in aboriginal people residing in remote locations.[13] The risk for PSGN varies with infection site and nephritogenic bacterial strain, ranging from 5% in throat infections to 25% in skin infection with the M type 49 streptococcus, and is diminished with early antibiotic therapy. Epidemics have been associated with both skin and throat infection, as well as consumption of unpasteurized milk from cows with mastitis caused by *S. zooepidemicus.* There is also a genetic predisposition: PSGN is associated with human leukocyte antigen (HLA)-DR4 and HLA-DR1 expression, and siblings of sporadically affected patients have a 38% risk for developing clinical or subclinical glomerular disease.[6]

Clinical Manifestations

Poststreptococcal GN presents differently in children and older debilitated adults. Symptomatic children typically present with acute nephritic syndrome, microhematuria in 100%, macroscopic hematuria in 30%, hypertension in 80%, edema in 80% to 90% (chief complaint in 60%), and oliguria in 25% to 40%. Nephrotic syndrome occurs in 2%, and ascites is uncommon. In contrast, 20% of adults with PSGN have nephrotic syndrome, 80% to 86% have hypertension, 83% have kidney impairment, and 43% have congestive heart failure. Rapidly progressive kidney failure with glomerular crescents occurs in less than 1% of children and adults. Asymptomatic subclinical cases have microscopic hematuria, and transient hypocomplementemia is 4 times more frequent compared with symptomatic cases where hypocomplementemia typically is sustained. Serum CH50 is low and reduced C3 levels occur in more than 90% of patients in the first week of disease; these normalize within 2 months of disease resolution. Serum C1 levels are normal and C4 may be depressed early in disease. Eighty percent have elevated IgG and IgM with normal IgA in contrast to rheumatic fever, which has increased IgA levels in 80% of the patients. Cryoglobulins, rheumatoid factor, and anti-C1q antibodies occur in up to one-third of patients in the acute phase. Families may have various manifestations of PSGN; therefore, eliciting a family history for streptococcal infection and signs of glomerular disease is recommended.

Most patients give a history of streptococcal infection, although it often has resolved at presentation. *Streptococcus* cultures are positive in 10% to 70% of epidemic and in 20% to 25% of sporadic cases. The latent period between infection and nephritis symptoms is 2 to 4 weeks after skin infections and 7 to 10 days after throat infections. As cultures are often negative, antistreptococcal antibody levels are used to ascertain prior infection. The most widely used are antistreptolysin O (ASO) titers, increased in more than 65% of patients with PSGN following throat infections, and anti-DNAse B titers, elevated in 73% of postimpetigo cases. The more sensitive streptozyme panel measures anti-DNAse B, antihyaluronidase, antistreptolysin O, and antistreptokinase antibodies, and is positive in more than 80% of patients. Antibody titers to NAPlr and SPEB/zymogen are more sensitive and specific, but not available clinically.[5,11]

Pathology

Kidney biopsy is not routinely indicated in PSGN but may be required for confirmation when clinical features are atypical, such as nephrotic proteinuria, decreased C3 levels for more than a month (suggesting transformation to C3 glomerulopathy), worsening kidney dysfunction, or adult age. The most common appearance is diffuse endocapillary

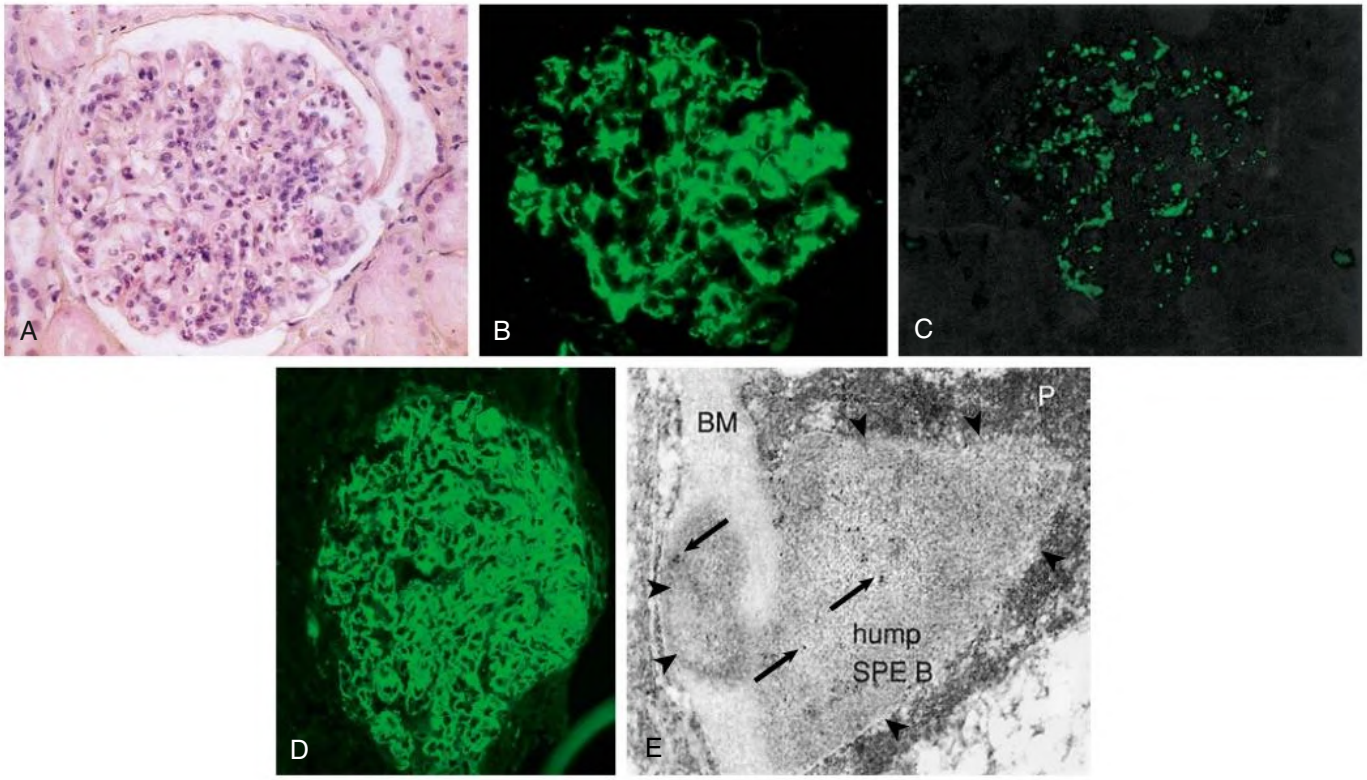

Fig. 57.1 Poststreptococcal Glomerulonephritis. (A) Light microscopic appearance of diffuse proliferative and exudative glomerulonephritis. (B–D) Immunofluorescence for C3 showing the mesangial (B), starry sky (C), and garland (D) patterns. (E) Immune electron microscopy showing the characteristic subepithelial electron dense deposit *(hump)* with intramembranous extension *(arrowheads),* inside which streptococcal pyrogenic exotoxin B *(SPE B)* is demonstrated *(arrows)* (immunogold staining). *BM,* Basement membrane; *P,* podocyte. (From Rodríguez-Iturbe B, Batsford S. Pathogenesis of poststreptococcal glomerulonephritis a century after Clemens von Pirquet. *Kidney Int.* 2007;71[11]:1094–1104.)

GN characterized by endocapillary neutrophils with fewer monocytes and variable mesangial hypercellularity (Fig. 57.1). Less often or during resolution, there may be diffuse proliferative GN with more mesangial and variable endocapillary hypercellularity, focal endocapillary GN, or mesangial proliferative GN (mesPGN). A membranoproliferative GN (MPGN) pattern is infrequent; however, NAPlr antigen has been identified in biopsy samples with an MPGN pattern, suggesting PSGN may have varied histology. Small numbers of necrotizing and crescentic lesions occur in up to 50% of cases, whereas extensive crescent formation is unusual.[14]

Immunofluorescence shows dominant C3 staining, and the pattern varies with the phase of disease.[15] In acute and subacute disease the immune deposits are in glomerular capillary walls and mesangial regions in a "starry sky" pattern containing strong C3 with less frequent and intense IgG, and IgM in up to 50% of cases; IgA and C1q are minimal or absent. The "garland" pattern is associated with numerous subepithelial hump deposits and heavy proteinuria corresponding to active disease, although also has been described in later disease. As deposits are cleared in subacute to chronic injury, mesangial deposits may persist resulting in a mesangial pattern with predominant C3, loss of immunoglobulins, and fewer infiltrating leukocytes (see Fig. 57.1). Although not routinely assessed, properdin and the terminal membrane attack complex C5b-C9 have been identified in capillary wall and mesangial deposits.[16]

Electron microscopy (EM) demonstrates subepithelial individual hump-shaped deposits, which are typical, although not pathognomonic, of PSGN. These deposits may be infrequent or abundant and are preferentially located where the capillary basement membrane reflects over the mesangium. Glomerulonephritis resolves with deposit clearing and cell apoptosis. However, deposit fragments may remain for years, appearing as weak, irregular, granular glomerular C3 staining with electron-lucent areas or an appearance of striated membranous structures indicative of remote immune complex deposition.[17]

Differential Diagnosis

In a patient with typical symptoms and serologic findings, the diagnosis is straightforward. However, when oliguria lasts more than a week, acute decrease in kidney function lasts 2 weeks, hypocomplementemia lasts more than 1 month, or without a preceding infection history, kidney biopsy is indicated. The differential diagnosis encompasses the spectrum of C3 glomerulopathies and crescentic GN (see Chapter 23). C3 GN may appear morphologically indistinct from PSGN, including subepithelial humps, diffuse endocapillary GN, and weak immunoglobulin deposition. Dense deposit disease demonstrates diagnostic electron-dense transformation of glomerular and tubular basement membranes. Correlating clinical findings, the patient course and C3 levels may be required for a correct diagnosis. Recently, Chauvet and colleagues[18] found that transient antifactor B antibodies, which activate C3 convertase activity, were present in 31 of 34 patients with PSGN and correlated with serum C3 levels. These antifactor B autoantibodies differed from C3 nephritic factor and permitted discrimination between PSGN and C3 glomerulopathy with a sensitivity of 95% and a specificity of 82%. When glomerular crescents on light microscopy occur together with a positive ANCA assay, the differential diagnosis is pauci-immune (ANCA-associated) crescentic GN; the diagnosis of PSGN depends on identifying C3-containing electron-dense deposits in a subepithelial pattern.

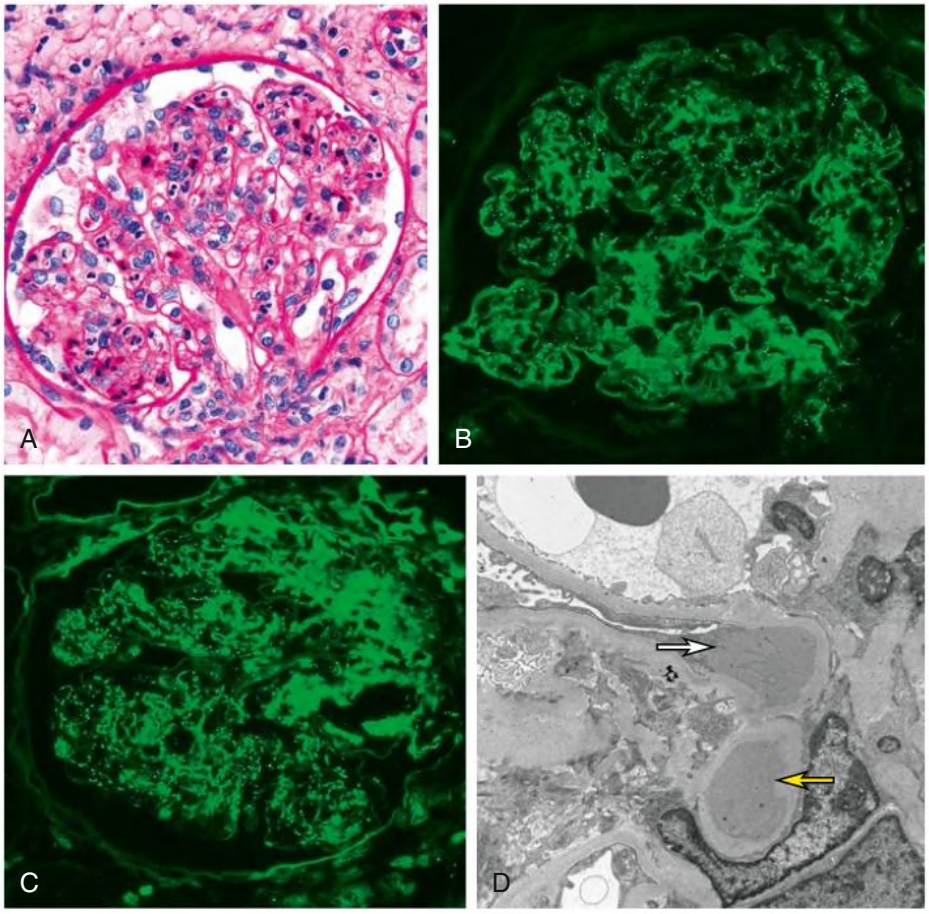

Fig. 57.2 Immunoglobulin A (IgA)-Dominant Glomerulonephritis (GN) in a Diabetic Patient With Methicillin-Sensitive *Staphylococcus aureus* Infection. (A) A diffuse exudative GN is present with neutrophil infiltration. (B) Immunofluorescence shows IgA irregular granular mesangial and capillary wall deposits. (C) Immunofluorescence shows C3 in a pattern similar to that of IgA. (D) Electron microscopy shows dome-shaped subepithelial deposit *(white arrow)* and mesangial deposit *(yellow arrow)*.

Natural History

Most children with PSGN recover with increased urine output and clinical symptom resolution in 7 to 10 days, and normalization of serologic tests within 1 month. End-stage kidney disease (ESKD) occurs in less than 1% of children observed for one to two decades after the acute attack.[11] Following recovery, mild proteinuria (<500 mg/day) and microscopic hematuria may persist for up to 1 year without affecting the long-term prognosis. However, older patients with comorbidities are more likely to experience acute complications, including kidney impairment in 30% to 77%, congestive heart failure in 40%, nephrotic proteinuria in 20%, and mortality in up to 30%.[11,19] A nephrotic presentation and persisting proteinuria are associated with worse long-term prognosis. Underlying alternative complement pathway dysregulation may increase risk for progressive kidney disease leading to C3 GN, which is now thought to encompass most cases of "atypical" postinfectious GN. Certain epidemics also have reported a high incidence of chronicity, perhaps related to more affected adults, who tend to have worse outcomes.[20] Studies in Australian aboriginal communities have shown that PSGN in infancy increases risk for subsequent albuminuria, hematuria, and chronic kidney disease (CKD).[19] The latter is attributed to a two-hit injury resulting from imposition of diabetes, metabolic syndrome, or low birth weight on early PSGN.

Treatment

Management includes culture and treatment of any persistent streptococcal infection. Early antibiotic treatment likely prevents PSGN, and prophylactic treatment of family members in high-risk communities or epidemic circumstances may be indicated. Treatment is with oral penicillin, intramuscular penicillin (a single intramuscular injection of 1.2 million units of benzathine penicillin in adults, or half this dose in small children), erythromycin (in patients allergic to penicillin), or cephalosporins. Oral treatments are given in doses every 6 hours for 7 to 10 days.[21] Treatment of acute nephritic syndrome includes fluid and sodium intake restriction and loop diuretic administration. An oral long-acting calcium antagonist is usually sufficient to control hypertension. Intravenous medications may be indicated in exceptional cases with hypertensive emergency. Dialysis (hemodialysis or peritoneal dialysis) is required in 25% to 30% of adults but seldom in children. Poststreptococcal GN complicated with crescents may benefit from pulse methylprednisolone. The prognosis of crescentic PSGN is significantly better than for crescentic GN from other causes, but residual impairment of kidney function occurs in more than half the cases.

Immunoglobulin A–Dominant Infection-Related Glomerulonephritis

Etiology and Pathogenesis

Immunoglobulin A–dominant infection-related GN (IRGN) is an immune complex–mediated lesion typically associated with *Staphylococcus aureus* infections in adult patients with underlying comorbidities.[22] Koyama and colleagues[23] suggested that the pathogenesis involves staphylococcal enterotoxins functioning as superantigens

that bind directly to the major histocompatibility complex (MHC) class II molecules on antigen-presenting cells. This enterotoxin–MHC class II complex engages the V_β T cell–receptor region, resulting in T cell activation and a cytokine burst, initiating a B cell polyclonal IgG and IgA response putatively against a *S. aureus* cell envelope antigen.[23] This antigen colocalizes with glomerular IgA deposits and induces mesangial deposits in an experimental model.

Epidemiology

Immunoglobulin A–dominant IRGN usually occurs in the setting of ongoing (rather than resolved) infection in adults, with an average age of 58 and up to 41% over 65 years.[24,25] There is a male predominance, and most patients have comorbidities, including diabetes in up to 65% of patients, malignancy, heart disease, or alcohol or substance abuse.[6] The incidence is unknown, but IgA-dominant IRGN occurred in 1.6% of kidney biopsies in adults in one institution and appears to be increasing.[26,27] In developed countries, it has a 300% increased prevalence compared with PSGN, and many cases of IgA-dominant IRGN likely are asymptomatic and undiagnosed. Approximately 65% of patients are infected with methicillin-resistant *S. aureus* (MRSA), and 25% have methicillin-sensitive *S. aureus* (MSSA).[24] The most frequent sites of infection are the skin and viscera, including pneumonia, endocarditis, and osteomyelitis. Although less common, other pathogens such as *S. epidermidis, Streptococcus, Klebsiella,* and *Escherichia coli* have been associated with IgA-dominant IRGN.[6,22,25]

Clinical Manifestations and Pathology

Active disease often presents with acute or rapidly progressive kidney failure or nephrotic range proteinuria in 50%. Hematuria is universal with gross hematuria in 25%.[24] However, a mild clinical course is not uncommon, with subacute or chronic disease and delayed diagnosis due to underlying chronic disease in elderly patients. Low C3 levels are found in 55% to 70% of patients, and serum IgA levels may be mildly increased.

Kidney biopsy reveals diffuse endocapillary or proliferative GN in 40% to 80% of cases, MesPGN in 20% to 60%, and crescentic GN (≥ 50% crescents) in less than 5%.[24-26] A smaller number of crescents occurs in up to 35% and positive ANCA in 22%.[27] The deposits contain weak to intense IgA with codominant C3 staining in the same pattern and kappa light chain similar to or greater than lambda.[22,27] Electron microscopy shows mesangial deposits in most cases, with up to 83% having variable numbers of subepithelial hump deposits and half with small and less frequent subendothelial deposits[2] (Fig. 57.2). A subset of patients with cirrhosis and staphylococcus, or few other bacterial infections, develop large confluent mesangial and subendothelial (wire loop-like) deposits with fewer subepithelial and intramembranous deposits, typically IgA dominant or codominant.[28]

Differential Diagnosis, Natural History, and Treatment

Differentiation from IgA nephropathy is important for treatment and outcome. Immunoglobulin A–dominant IRGN is favored in the presence of staphylococcal infection, hypocomplementemia, severe proteinuria, and kidney biopsy demonstrating immune staining and electron-dense deposits as detailed earlier and absent IgA in globally sclerotic glomeruli. Recently, differences in kidney tissue protein abundance in IgA nephropathy versus IgA-dominant IRGN were identified by mass spectrometry and confirmed by immunohistochemistry.[29] There is a worse outcome compared with IgA nephropathy, likely because of underlying comorbid conditions. Mesangial IgA deposits may persist despite recovery from infection, possibly related to an underlying risk for IgA immune complex disease.

Active infection should be treated with appropriate antibiotics, and recovery of kidney function may result despite ongoing infection. Corticosteroid treatment is contraindicated, at least during active infection, highlighting the importance of differentiation from IgA nephropathy, in which corticosteroids may be indicated in severe cases (see Chapter 24).

Staphylococcus-Associated Glomerulonephritis

Etiology, Pathogenesis, and Epidemiology

Infection with MRSA, MSSA, and methicillin-resistant and methicillin-sensitive *Staphylococcus epidermidis* can cause GN, usually IgA-dominant IRGN, endocarditis-associated GN, or shunt nephritis. However, a minority of patients with staphylococcal infection will develop GN that does not fit into these categories.[12,24] As described earlier, the infection results in immune complex deposition in most cases. In addition, an *S. aureus* plasmid-encoded peptide homologous to the myeloperoxidase (MPO) T cell epitope has been shown to induce MPO-ANCA, possibly inducing crescents and vasculitis in some patients.[12] Staphylococcal infection–related GN has increased over the past three to four decades, although the incidence and prevalence are unknown. Most patients with staphylococcal-associated GN are adults and have comorbidities.

Clinical Manifestations and Pathology

There is no latent infection-free period, although the presence or source of infection may not be obvious. Low C3 is found in 30% to 50%, C4 levels are normal, and ANCA may be positive.

Hematuria, proteinuria, often in the nephrotic range, and acute kidney injury (AKI) variably occur. Glomerular lesions other than those previously indicated include MesPGN, diffuse endocapillary or proliferative GN, and necrosis and crescents. Immunofluorescence reveals moderate to strong glomerular C3 staining in most biopsies, weak IgA staining in 10%, no IgA or IgG in 15%, and a pauci-immune pattern in 13%.[27] Electron microscopy shows mesangial and few subendothelial deposits, and subepithelial humps in less than one-third of cases.

Differential Diagnosis and Treatment

The differential diagnosis for the manifestations of staphylococcal-associated GNs includes PSGN, IgA nephropathy, IgA vasculitis, C3 GN, ANCA-associated crescentic GN, and rarely cryoglobulinemia. Clinical pathologic correlation and a search for infection, including endocarditis, are necessary. Treatment involves eliminating the infection and supportive care. Immunosuppression is contraindicated during active infection and has not been shown to improve outcome in this setting.

Endocarditis-Associated Glomerulonephritis

Etiology and Pathogenesis

Endocarditis may be an acute or subacute infection. Approximately one-third of patients with endocarditis develop AKI secondary to GN, kidney emboli (infarcts and cortical necrosis), or treatment (drug-induced interstitial nephritis). The pathogenesis of endocarditis-associated GN involves deposition of immune complexes containing bacterial antigens similar to that proposed for PSGN. Less virulent organisms with longer undiagnosed endocarditis may predispose to immune complex formation and development of GN.[30] Polyclonal type III cryoglobulins occur in 50% of patients but rarely deposit in glomeruli. Some bacteria, classically MRSA, express superantigens that can activate T cells directly leading to a polyclonal gammopathy and immune complex GN.

Epidemiology

Historically, infective endocarditis (IE) affected young adults with rheumatic heart disease; however, it now occurs in older and at-risk patients, including drug users, prosthetic valve and implantable device recipients, and those with human immunodeficiency virus (HIV) and hepatitis C infection, diabetes, and health care–associated bacteremia.[30,31] *S. aureus* and *S. epidermidis* cause more than half of the endocarditis-associated

GN[31] and are the most common pathogens in hospital-acquired IE. *Streptococcus* infections are more frequent in community-acquired and native valve endocarditis, although MRSA-associated community-acquired IE is increasing.[32] Gram-negative bacteria (*Enterococcus faecalis, E. coli, Brucella,* and *Proteus*) and HACEK microorganisms (*Haemophilus, Aggregatibacter, Cardiobacterium, Eikenella,* and *Kingella*) less frequently cause IE. Culture-negative IE is usually caused by *Coxiella burnetii, Bartonella* spp., and *Tropheryma whipplei* in untreated patients and by streptococcal species in those with prior antibiotic administration.[33] The HACEK organisms require special laboratory procedures; if these are not used, infected patients will be culture negative. *Bartonella henselae* endocarditis is frequently associated with congenital valvular disease and exposure to cats. Polybacterial infections are usually associated with drug abuse.

Clinical Manifestations

Patients often have fever, arthralgias, anemia, and purpura. Rarely, IE may present as primary kidney disease without systemic symptoms. Classic findings such as Osler nodes, Janeway lesions, and splinter hemorrhages are rare, and the diagnosis may be missed until autopsy in 38% of patients.[30] The most common kidney presentation is AKI, and microhematuria and proteinuria are almost universally present, whereas nephrotic syndrome and rapidly progressive glomerulonephritis (RPGN) are infrequent. Risk factors include intravenous drug in 29% of patients and cardiac valvular disease in 30%.[31] Decreased C3 and C4 levels, elevated rheumatoid factor, circulating immune complexes, and type III cryoglobulins are found in 50%, whereas ANCAs occur in 22% of patients. In those who develop GN, hypocomplementemia, particularly C3, is more frequent, suggesting alternative complement pathway activation. However, complement levels may be normal in superantigen-mediated GN.[31]

Pathology

Autopsy studies have demonstrated glomerular lesions in 7% to 17% of those with IE, including crescentic GN, MPGN, and focal and diffuse proliferative GN patterns, although morphologic details are not uniformly provided.[30] Kidney biopsy findings also are variable, with up to 45% of biopsies demonstrating GN, including 55% crescentic GN, 35% diffuse or focal endocapillary GN, 10% MesPGN, and infrequently MPGN[31] (Fig. 57.3). Immunofluorescence discloses pauci-immune GN in 44%. All proliferative GN cases have C3 staining with IgG or IgA in mesangial regions in more than half and less often in capillary walls. Electron-dense deposits occur in 90% of all GNs, mesangial in 85%, subepithelial humps in 49%, and subendothelial in 45% of the cases.[31,34]

Differential Diagnosis, Natural History, and Treatment

In crescentic GN with or without positive ANCA titers, hypocomplementemia should raise suspicion for underlying IE. Antibiotic treatment usually eradicates the endocarditis and corrects the serologic abnormalities. However, microhematuria, proteinuria, and decreased kidney function may persist for months after successful therapy. The overall mortality of IE is 20% and increases to 36% in patients who develop kidney failure; only 32% of the surviving patients have complete recovery of kidney function.[31] Early diagnosis, risk stratification, and prompt antibiotic therapy are critical for successful resolution, with diminution of circulating immune complex levels correlating with better outcomes.[35] In patients with crescentic GN, pulse plasma exchange with and without steroids has been used in addition to appropriate antibiotic therapy, but the value is unconfirmed. Immunosuppression currently is considered contraindicated in IE-associated crescentic GN.[12]

Shunt Nephritis

Etiology, Pathogenesis, and Epidemiology

Shunt nephritis is an immune complex GN that may develop in association with central nervous system shunt infections. It is rare in ventriculoperitoneal or ventriculovascular shunts presently used, but approximately 6% of previously used ventriculoatrial shunts became infected. Glomerulonephritis develops in 0.7% to 2% with infected shunts 2 months to many years after insertion, and is decreasing due to improved shunt infection rates. The microorganisms are usually *S. epidermidis, S. aureus,* or *Propionibacterium acnes,* and less often diphtheroids, *Pseudomonas, Serratia,* or *Corynebacterium.*

Clinical Manifestations and Pathology

Children are most frequently affected, typically within 6 months of surgery, with recurrent low-grade fever, arthralgias, weight loss, anemia, rash, hepatosplenomegaly, hypertension, and signs of increased intracranial pressure.[12] There may be no signs of systemic infection. Microscopic hematuria occurs in 90%, often with nephrotic range proteinuria. Serologic findings include elevated rheumatoid factor, cryoglobulinemia, decreased serum C3, less often reduced C4, and occasionally positive PR3-ANCA titers. Cerebrospinal fluid may demonstrate eosinophils. Kidney histology shows an MPGN pattern or MesPGN with variable crescent formation, and IgM, IgG, and C3 containing electron-dense deposits in subendothelial and mesangial regions. Cerebrospinal fluid cultures obtained by tapping the shunt are positive for the pathogen, but repeated cultures may be required due to the low numbers of bacteria.

Natural History and Treatment

Treatment requires antibiotic therapy and prompt removal of the infected shunt, usually replaced by a ventriculoperitoneal shunt. Delay in diagnosis and shunt removal worsens the kidney prognosis. If dialysis is required, hemodialysis is preferred because peritonitis carries the risk for meningitis in patients with a ventriculoperitoneal shunt. Complete recovery occurs in more than half of the patients, whereas 22% have persistent urinary abnormalities and 6% develop ESKD.

Glomerulonephritis Associated With Other Bacterial Infections

Osteomyelitis and intraabdominal, pelvic, pleural, and dental abscesses can be associated with GN, typically when infection persists for several months. Kidney disease encompasses mild urinary abnormalities to RPGN, with nephrotic syndrome the most frequent presentation, usually with normal complement levels. Kidney biopsy reveals an MPGN pattern, diffuse endocapillary or proliferative GN, MesPGN, or IgA-dominant IRGN, with or without crescents. If started early, antibiotic treatment may result in recovery of kidney function.

Congenital, secondary, or early latent syphilis may be associated with GN. In congenital syphilis, nephrotic syndrome may be the primary clinical manifestation, with anasarca occurring 4 to 12 weeks after birth. Kidney involvement is uncommon in acquired syphilis, and usually occurs with secondary syphilis. The presentation is nephrotic syndrome or occasionally acute nephritis. Membranous nephropathy (MN) is the most common glomerular finding, but diffuse proliferative GN with or without crescents, an MPGN pattern, MesPGN, and rarely minimal change disease (MCD) have been observed. Treponemal antigens may be identified in the immune deposits. Syphilitic GN responds to antibiotic treatment, often with rapid resolution of nephrotic syndrome in MN, although remission may not occur for 4 to 18 months, particularly with other glomerular manifestations.

Acute typhoid fever from *Salmonella typhi* is characterized by fever, splenomegaly, and gastrointestinal symptoms. In severe cases, disseminated intravascular coagulation or thrombotic microangiopathy

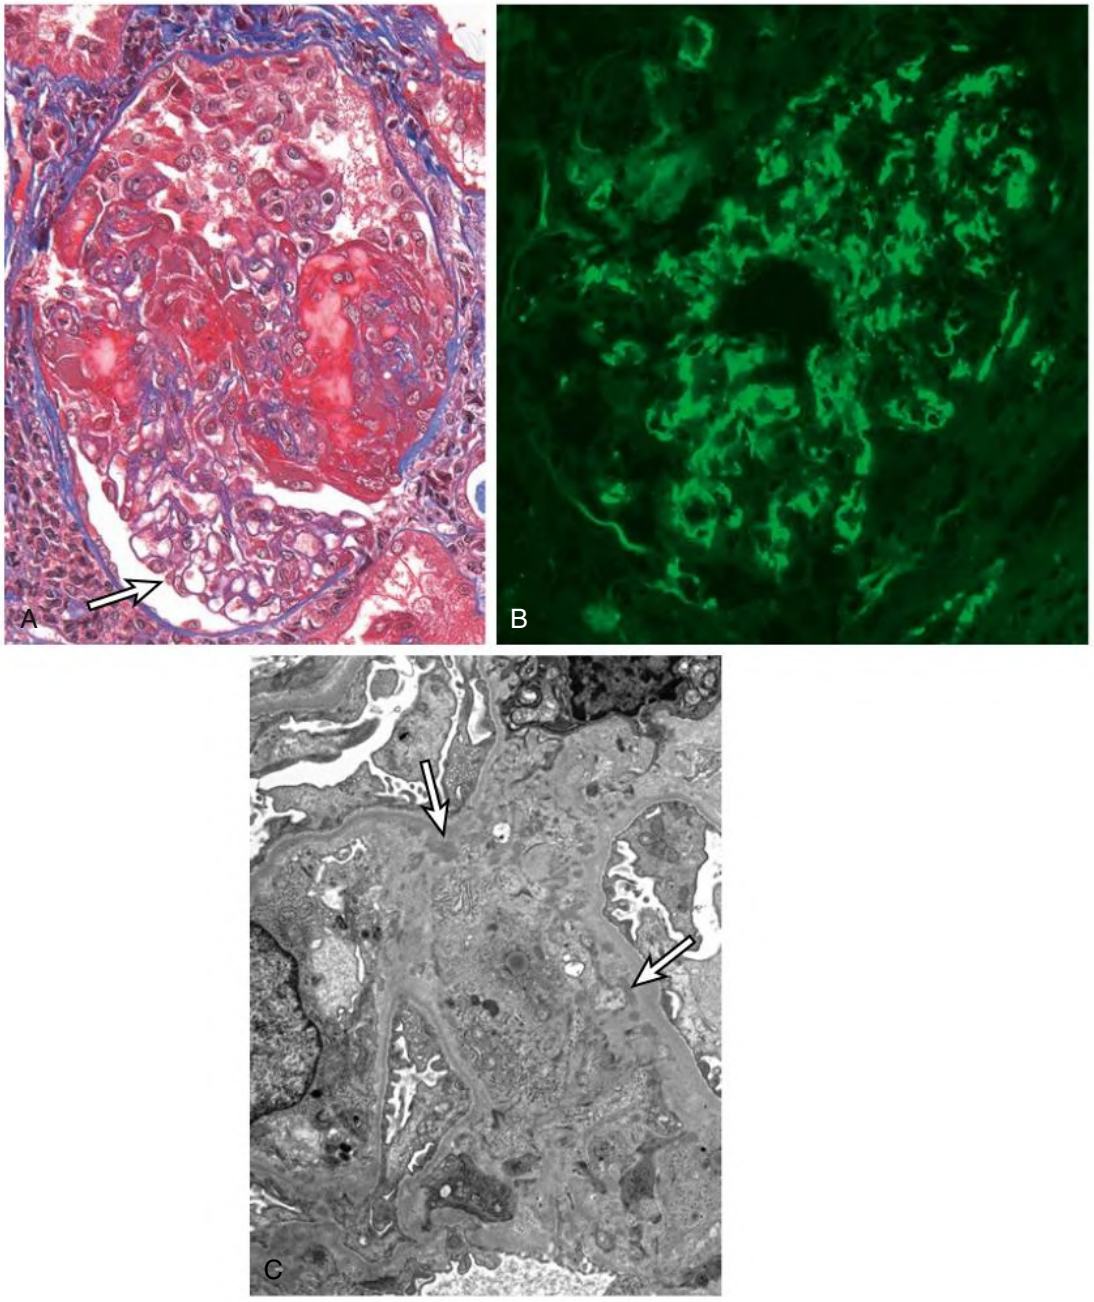

Fig. 57.3 Crescentic Glomerulonephritis Associated With Infective Endocarditis. (A) Glomerulus with a necrotizing and cellular crescent. Note the uninvolved tufts have no inflammation or hypercellularity *(arrow)*. (B) Immunofluorescence for C3 with mesangial staining pattern. (C) Small electron dense deposits *(arrows)* are in mesangial regions without subepithelial hump deposits.

occur rarely. Microhematuria and mild proteinuria appear in 25% of patients with MesPGN.[36]

Leprosy (*Mycobacterium leprae* infection) affects 10 to 15 million patients worldwide, with up to 45% having glomerular disease. Glomerulonephritis is immune complex mediated with frequent hypocomplementemia. Nonnephrotic to nephrotic range proteinuria occurs in 2% to 68%, and kidney dysfunction occurs in 4% of patients.[37,38] Nephrotic syndrome is rare and is usually associated with amyloidosis, often with erythema nodosum.[38] Prospective studies demonstrate increased serum creatinine in 35% of patients at some time during their course, and hypertension is common. Kidney biopsy shows proliferative GN and MN with similar frequencies, whereas in autopsy studies, 4% to 31% have amyloidosis, and 5% to 14% demonstrate MPGN or diffuse proliferative GN with IgG, C3, and less frequently IgM, IgA, and fibrin deposition.[36] The incidence of reduced kidney function decreases to 9% after 8 months of multidrug therapy.

Pneumococcal pneumonia is rarely associated with microhematuria and proteinuria, seen with delayed treatment. Diffuse endocapillary GN with crescents and MPGN have been reported, with pneumococcal antigen in the immune deposits. *Streptococcus pneumoniae* is rarely associated with hemolytic uremic syndrome due to unmasking of the glomerular and erythrocyte Thomsen-Friedenreich antigen by pneumococcal neuraminidase A, allowing preformed antibodies to bind and elicit an immune response.

Gastroenteritis caused by *Campylobacter jejuni* may be associated with MesPGN or diffuse proliferative GN. Other bacteria, including *E. coli, Yersinia,* meningococcus, and *Mycoplasma* pneumonia, may induce GN in this setting (see Table 57.2).

VIRAL INFECTIONS

Glomerular injury can occur in several viral infections, primarily hepatitis B virus (HBV), hepatitis C virus (HCV) (see Chapter 22), and HIV (see Chapter 58). These may coincide with acute or chronic infection, depending on the virus and host response, including genetic risk factors such as *APOL1*. The advent of better antiviral therapeutic agents has modified associated glomerulopathies and improved prognoses for patients with virus-associated GN.

Hepatitis A–Associated Glomerulonephritis

Hepatitis A virus (HAV) infection has increased in the last few years in the United States with an epidemiologic shift from contaminated foods to drug abuse and person-to-person transmission leading to updates in vaccination strategies; associated kidney involvement is uncommon.[39] Immunoglobulin A nephropathy has been temporally associated with HAV, with simultaneous resolution of the viral infection and GN suggesting a causal relationship. There are case reports of MesPGN and MPGN, including with dominant IgA. There is experimental evidence for HAV-associated mesangial proliferation and immune complex GN, further supporting causation in humans. Patients present with microscopic hematuria and nonnephrotic proteinuria or may be nephrotic, particularly in association with MPGN. Glomerulonephritis resolution usually coincides with recovery from the viral infection.

Hepatitis B–Associated Glomerular Lesions

Etiology and Pathogenesis

Hepatitis B virus is a DNA virus of the Hepadnaviridae family and contains the hepatitis B surface antigen (HBsAg), hepatitis B core antigen (HBcAg), and hepatitis B e antigen (HBeAg), which is a splice variant of the core antigen. The virus causes immune complex–mediated glomerular injury predominantly through deposition of circulating immune complexes that have been identified in the serum of infected patients with GN. Immune complexes contain the three major hepatitis B antigens, which differ in specific glomerular locations likely related to their size and charge.[1] Hepatitis B e antigen is in smaller cationic subepithelial immune complexes in MN. The larger HBcAg and HBsAg typically deposit in subendothelial and mesangial regions.[1,40] In situ immune complex formation may occur associated with locally expressed HBcAg, evidenced by identification of glomerular HBcAg and its corresponding RNA. Hepatitis B virus may directly injure glomerular cells, as it induces mesangial cell proliferation and increased type IV collagen production in vitro. There likely are contributing host factors, including MHC class II risk alleles.

Epidemiology

Chronic HBV infection is defined as persistence of HBsAg-positive serology without IgM antibodies to HBcAg. Persistent infection occurs in 0.1% to 15% of those with HBV infection and afflicts approximately 350 million people worldwide, who often are asymptomatic. Infection with HBV becomes chronic in more than 90% of infants, 25% to 50% of children infected between 1 and 5 years of age, and 6% to 10% of older children and adults. Vertical transmission (maternal-infant) often occurs in endemic areas, such as China and Southeast Asia. Horizontal transmission follows blood contamination or direct mucous membrane contact. The prevalence of HBV infection is lower in Europe and the United States, with most carriers becoming infected as adolescents or adults by horizontal transmission because of drug abuse, blood transfusions, or sexual relations.

Clinical Manifestations and Pathology

Acute HBV infection may cause nausea, vomiting, fever, hepatomegaly, and a short-lived serum sickness–like syndrome with urticaria, maculopapular rash, neuropathy, arthralgias, arthritis, microscopic hematuria, and nonnephrotic proteinuria. There are no published kidney biopsy studies in acute infection, and kidney disease associated with acute infection resolves in 1 to 2 months associated with viral illness recovery. In chronic HBV infection, 3% to 5% of patients develop kidney disease; additionally, 10% to 30% of patients with chronic HBV are coinfected with HCV and 5% to 10% with HIV.[1,40]

Hepatitis B Virus–Associated Membranous Nephropathy

Membranous nephropathy is the most common glomerular disease in chronic HBV carriers. Children usually present between 6 and 12 years of age and show a strong male predominance, asymptomatic proteinuria or nephrotic syndrome, microhematuria, normal kidney function, and minimal liver disease.[40] The prognosis is usually good with frequent spontaneous remission associated with anti-HBeAg antibody production. Adults develop proteinuria or nephrotic syndrome, often with impaired kidney function and liver disease; approximately 30% will progress to CKD and 10% to ESKD. Hypocomplementemia occurs in less than half the patients.

Kidney biopsy shows MN with active to clearing deposits depending on lesion chronicity. In contrast to primary MN, there often is mesangial hypercellularity with mesangial and/or subendothelial deposits indicative of a form of secondary MN. Endocapillary hypercellularity and endothelial cell tubuloreticular inclusions may occur. Circulating antiphospholipase A2 receptor (PLA2R) antibodies and PLA2R in subepithelial deposits typically are associated with primary MN. However, in HBV-endemic areas in Asia, PLA2R has been reported to colocalize with HBV antigens in glomerular deposits in HBV-associated MN; the significance of this is uncertain.[1] Immunoglobulin G subclass staining of deposits may be helpful, as IgG4 usually dominates in primary MN but is nondominant in secondary MN.[40] Both HBeAg and HBsAg may be identified in glomerular deposits, and HBeAg has been found in eluted proteins (Fig. 57.4).

Hepatitis B Virus–Associated Glomerulonephritis With a Membranoproliferative Pattern

An MPGN pattern is the second most frequent HBV-associated glomerular lesion, typically found in adults. Patients present with nephrotic or less frequently nonnephrotic proteinuria and microhematuria; half are hypertensive, and 20% have reduced kidney function.[1] This pattern is associated with serum HBsAg and HBcAg and reduced serum C3 and C4 levels. Cryoglobulinemia, type II or more often type III, occasionally occurs in HBV-infected patients, whereas type II is more prevalent with concurrent HCV infection.[1,40] Kidney biopsy shows an MPGN pattern with additional subepithelial deposits if there is concomitant MN, and HBsAg may be identified in mesangial and subendothelial deposits (see Fig. 57.5).

Other Hepatitis B Virus–Associated Glomerular Lesions

There are several reports of IgA nephropathy associated with HBV infection, including some that have entered a sustained remission of kidney disease following successful HBV treatment with pegylated interferon. Other studies have shown similar outcomes for patients with IgA nephropathy with and without HBV infection, possibly due to a coincidental association rather than a causal relationship. Immunoglobulin A nephropathy is highly prevalent in HBV-endemic areas in Asia, and mesangial IgA deposits occur in chronic liver disease secondary to impaired clearance of IgA circulating immune complexes (see Chapter 24). There is a report of 10 patients with chronic HBV infection and all three HBV antigens in the serum, showing diffuse endocapillary GN with uncommon subepithelial humps and glomerular HBsAg and HBV DNA.[41] Amyloid A amyloidosis is associated with chronic inflammatory diseases, has been identified in adults and children with chronic HBV infection, and presents with proteinuria

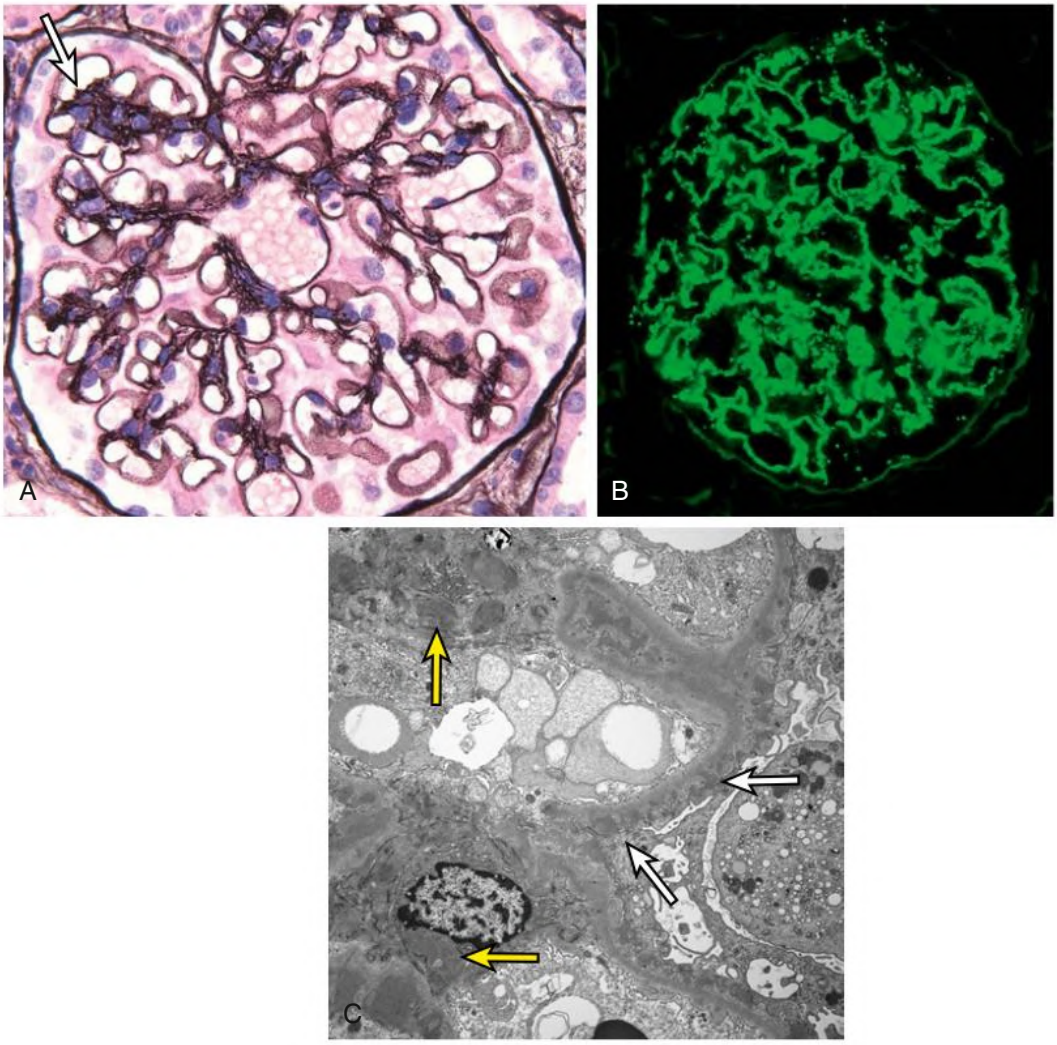

Fig. 57.4 Hepatitis B–associated membranous nephropathy. (A) Irregular glomerular capillary due to small subepithelial spikes with segmental mesangial hypercellularity *(arrow)*. (B) Immunofluorescence shows granular immunoglobulin G along capillary walls and segmentally in mesangial regions. (C) Electron microscopy shows subepithelial *(white arrows)* and mesangial *(yellow arrows)* electron-dense deposits.

or nephrotic syndrome. There are rare reports of MCD and collapsing glomerulopathy associated with HBV infection, with HBV DNA in shed urinary podocytes in the latter, suggesting direct HBV infection. Clinical remission occurred after successful HBV infection treatment.[40]

Polyarteritis Nodosa

This vasculitis has been associated with HBV infection and is discussed in Chapter 26.

Treatment

This section addresses only the treatment of patients with GN related to HBV infection (positive HBe antigen or HBV DNA more than 2000 units in HBeAg negative patients). Antiviral treatment is indicated in this setting, as there is consistent evidence that treatment response is associated with reduction in proteinuria. Interferon or nucleoside/nucleotide monotherapy induces seroconversion of positive HBeAg to anti-HBe, and the decrease in HBV DNA levels is associated with significant reduction of proteinuria in 30% to 80% of patients.[42,43]

Interferon therapy has a high rate of seroconversion and sustained remission, although side effects can be frequent and severe.[44] Pegylated interferon may be used in young patients with mild hepatitis and low viral load if not contraindicated (advanced liver disease, leukopenia, thrombocytopenia, depression, pregnancy) but should not be used to treat patients with replicative HBV infection and glomerulonephritis.

In most patients, nucleoside/nucleotide therapy may be chosen, including lamivudine, adefovir, telbivudine, entecavir, or tenofovir, which are all given orally. Nucleoside/nucleotide analog administration should be maintained until HBe antigenemia disappears, usually 4 to 5 years or longer. Early therapy discontinuation increases the risk of virus-related liver failure. All nucleoside/nucleotide drugs are excreted by the kidney in unchanged form, and some have dose-related nephrotoxicity,[44] which is increased with comorbidities including diabetes, hypertension, and CKD.[45]

Entecavir and tenofovir are preferred initial therapies due to higher antiviral activity and lower resistance rates compared with other nucleoside/nucleotide agents. *Entecavir* is generally safe and is used for treatment and prophylaxis of HBV infection in kidney transplant patients. The dose of entecavir is 0.5 mg/day when CrCl is 50 mL/min or more, 0.25 mg/day or 0.5 mg every 48 hours if CrCl is 30 to 50 mL/min, 0.15 mg/day or 0.5 mg every 72 hours if CrCl is 10 to 29 mL/min, and 0.5 mg weekly if CrCl is less than 10 mL/min or the patient is on hemodialysis. Entecavir treatment can be complicated by lactic

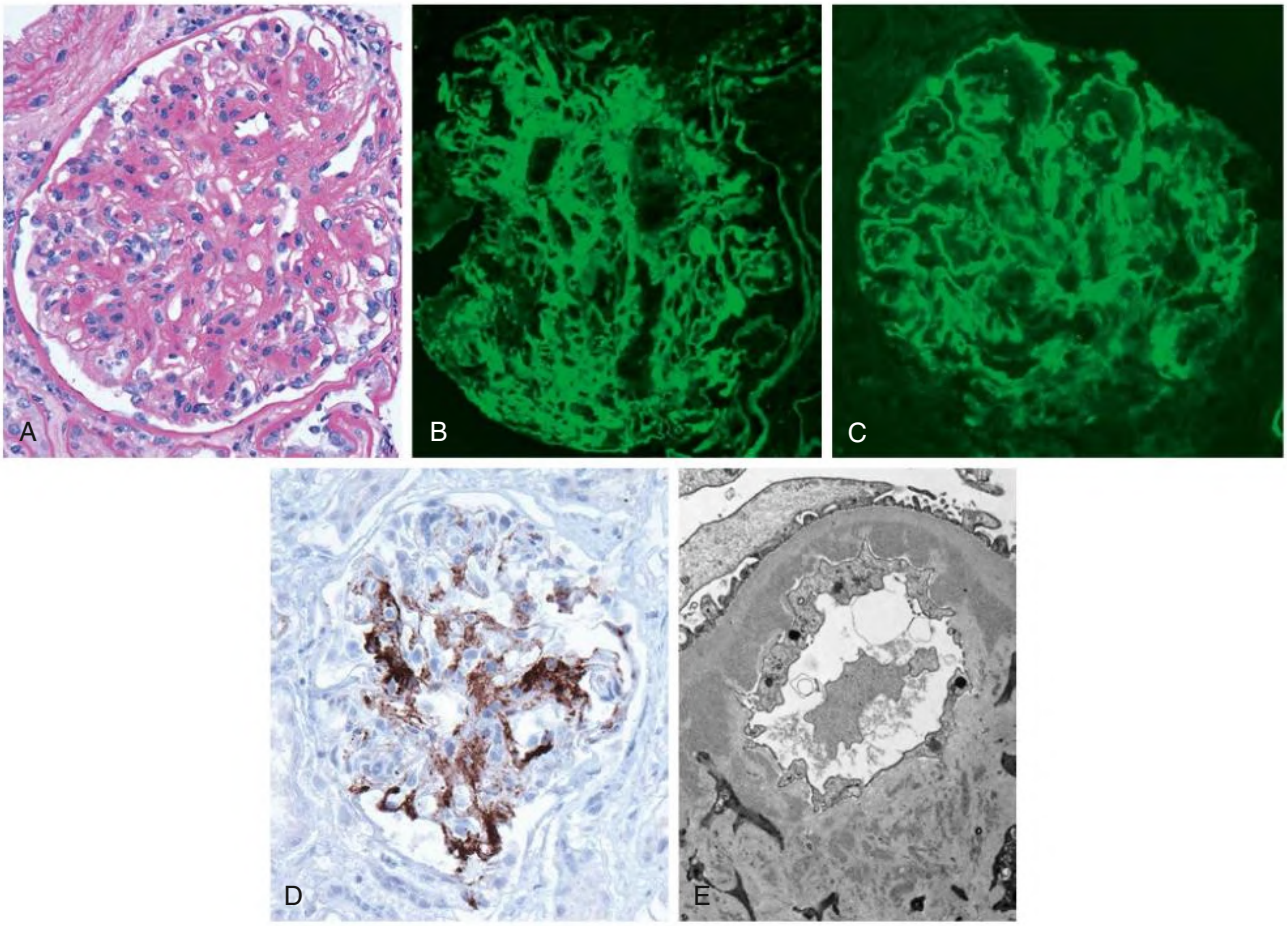

Fig. 57.5 Hepatitis B–Associated Membranoproliferative Glomerulonephritis (MPGN). (A) MPGN pattern of injury with a lobular hypercellular glomerulus. (B) Predominantly mesangial staining for C3 by immunofluorescence. (C) Capillary wall and lesser mesangial staining by immunofluorescence for immunoglobulin M. (D) Hepatitis B surface antigen staining most prominent in mesangial regions. (E) Subendothelial and mesangial electron dense deposits.

acidosis in patients with impaired liver function. *Tenofovir* is used as initial therapy or in patients with resistance to other drugs. The main adverse effects are reduced bone density (osteomalacia) and nephrotoxicity with proximal tubular mitochondriopathy and Fanconi syndrome. Formulations include tenofovir disoproxil fumarate (TDF) and tenofovir alafenamide (TAF), the latter a newer formulation with better stability and more hepatic uptake, requiring substantially lower doses for comparable antiviral activity. A dose of 25 mg of TAF induces similar reduction of HBV DNA levels as low as 300 mg of TDF without adverse effects.[46] Patients switched from TDF to TAF demonstrate improvements in bone density and urinary biomarkers. The dose of TDF is 300 mg/day if CrCl is 50 mL/min or higher, 300 mg every 48 hours if CrCl is 30 to 49 mL/min, 300 mg every 72 to 96 hours if CrCl is 10 to 39 mL/min, and 300 mg once a week if the patient is on hemodialysis. The dose of TAF is 25 mg/day if CrCl is 15 mL/min or more, and in those with CrCl less than 15 mL/min and on hemodialysis, the dose is 25 mg after dialysis on hemodialysis days. Insufficient data are available to recommend doses of TDF or TAF in patients with CrCl less than 10 to 15 mL/min who are not receiving hemodialysis or who are receiving peritoneal dialysis.

Other nucleoside/nucleotide drugs are less effective with a higher incidence of resistance. *Lamivudine* is a second-line therapy with a 20% annual rate of resistance. Lamivudine dosage (100 mg/day) is reduced to 50 mg/day after the first dose if CrCl is 30 to 49 mL/min, to 25 mg/day if CrCl is 15 to 29 mL/min, to 15 mg/day if CrCl is 5 to 14 mL/min, and to 10 mg/day in those on hemodialysis or peritoneal dialysis. Serious adverse effects are rare and include liver failure and rhabdomyolysis. *Telbivudine* has a 25% annual resistance rate, and serious adverse effects include myopathy (cumulative incidence of creatine kinase elevation is 84%), peripheral neuropathy (particularly combined with peg-interferon), hepatoxicity, and lactic acidosis. *Adefovir* is rarely used today due to high resistance rate and dose-dependent nephrotoxicity and Fanconi syndrome that may persist for months after drug withdrawal. Antiviral drug combinations have been used with variable success, but there is no convincing evidence that initial combination therapy with two nucleoside analogs is better than monotherapy.

Patients with concomitant HBV and HCV infections and GN should have HBV DNA and HCV RNA assessed to determine which virus is more likely responsible for the kidney disease. Direct-acting antivirals used to treat HCV infections may activate HBsAg without affecting HBV-associated GN; therefore, patients with combined infections should be treated with interferon that is active against both viruses or have concurrent administration of direct-acting antivirals and nucleoside/nucleotide drugs.

Treatment of HBV-related GN should be limited to antiviral therapy in most patients because seroconversion from HBeAg positive to anti-HBe and reduced HBV DNA levels usually induce proteinuria remission, whereas immunosuppression may stimulate viral replication.

To be noted, a retrospective analysis of 317 patients with HBV-related GN (12 clinical trials) who received combined antiviral and immunosuppressive therapy showed the majority of patients had reduced proteinuria without increase in HBV-DNA viral replication or alterations in liver function.[47] However, immunosuppressive agents are best avoided in patients with replicative HBV infection. In patients with simultaneous HBV infection and anti-PLA2R antibody-mediated MN, treatment with rituximab and cyclophosphamide should be postponed until a sustained virologic remission has been obtained by nucleoside or nucleotide analog therapy.

In specific settings, such as RPGN or severe polyarteritis nodosa (PAN), combination therapy appears to be useful (see Chapter 26). Whenever combined antiviral and immunosuppressive therapy is used, it is important to monitor HBV DNA levels for at least 6 months after immunosuppressive therapy is discontinued.

Other Virus-Associated Kidney Disease

Cytomegalovirus (CMV) infection rarely causes diffuse proliferative GN with immune deposits containing CMV antigens in native kidneys. Cytomegalovirus also has been linked to collapsing glomerulopathy and ESKD in patients without HIV infection. In kidney allograft patients with CMV infection, immunosuppression is reduced (see Chapter 110). Depending on infection severity, oral valganciclovir 900 mg twice daily or ganciclovir 5 mg/kg intravenously every 12 hours is administered until clinical recovery and two blood samples negative for CMV by polymerase chain reaction are obtained, followed by 3 months of oral valganciclovir 900 mg/day or oral ganciclovir 1 g three times daily. Toxic effects of these drugs include neutropenia, central nervous system dysfunction, and carcinogenicity and teratogenicity in experimental studies.

Parvovirus B19 is a single-stranded DNA virus with marked tropism for erythroid precursor cells. Its receptors include the erythrocyte P antigen and glycosphingolipid globoside (Gb4). Infection with a viral prodrome may be followed by nephritic or nephrotic syndrome; nephrotic syndrome may precede an aplastic crisis in patients with sickle cell disease. In transplanted patients, parvovirus infection should be suspected when there is severe anemia resistant to erythropoietin treatment with inappropriate reticulocyte response. Diffuse endocapillary and proliferative GN and MPGN have been reported with subendothelial and fewer mesangial IgG and C3 deposits.[48] Collapsing glomerulopathy has been attributed to parvovirus B19 infection; some, but not all, studies have detected viral DNA in kidney biopsy tissue, and there appears to be an association with *APOL1* risk alleles. There is no specific antiviral therapy, and treatment is intravenous immunoglobulin administration 2 g/kg given over a period of 5 days.

Dengue hemorrhagic fever is currently the most prevalent mosquito-borne urban viral infection worldwide, and is caused by four serotypes of the Flaviviridae virus family. The most common kidney complication is AKI (see Chapter 71). Glomerular involvement may be secondary to direct glomerular cell injury or immune complex deposition. Infected patients may present with hematuria, proteinuria, and kidney failure associated with diffuse endocapillary or proliferative GN with IgG, IgM, and C3, transient IgA deposits, or MPGN.[49] There are no specific treatments, and management is supportive.

Mild kidney abnormalities occur in acute Epstein-Barr virus (EBV) infection, with microhematuria and proteinuria in 10% to 15% of cases associated with diffuse endocapillary GN, MesPGN, MPGN pattern, and collapsing glomerulopathy. Many viral infections, including varicella, mumps, adenovirus, coxsackievirus, and influenza, can be associated with transient microscopic hematuria, nonnephrotic proteinuria, and a mesangial or diffuse proliferative GN in which viral antigens can be identified in the mesangium. Measles may cause diffuse proliferative GN but is better known for its unique ability to induce remission in patients with MCD and nephrotic syndrome as infection abates, due to increased production of Treg cells.

PARASITIC INFECTIONS

Kidney involvement is common in various parasitic infections and includes a range of kidney lesions (Table 57.3). With the exception of malaria, leishmaniasis, filariasis, and schistosomiasis, glomerular involvement is usually mild and transient.[50,51]

Malaria

Etiology and Pathogenesis

There are four major species of *Plasmodium,* two of which typically are associated with GNs in humans: *Plasmodium falciparum* and *Plasmodium malariae.*[52] Malarial antigens activate the immune system by interaction with monocytes, secretion of chemokines and cytokines, polyclonal B cell activation, and circulating immune complex formation. Infected erythrocytes may participate in immune activation through preferential expression of surface antigens and endothelial activation. Malarial antigens have been identified in 25% of glomerular immune complexes and in glomeruli without immune complex deposition, suggesting in situ immune complex formation. Additionally, the alternative complement pathway may be directly activated.[36,52] Concomitant infection with other parasites (schistosomiasis) or viruses (EBV, HIV), or genetic factors such as *APOL1* risk alleles may participate in the pathogenesis of kidney injury and influence geographic disease variations.

Epidemiology, Clinical Manifestations, and Pathology

Malaria is the most prevalent endemic global infectious disease, with 200 million cases predominantly occurring in Africa, India, Southeast Asia, and Latin America causing 600,000 deaths each year (Fig. 57.6).[53] It is acquired by the bite of infected *Anopheles* mosquitoes or infected vectors from blood transfusion or infected organ transplants. *P. falciparum* invades erythrocytes of any age and may cause AKI and multiple organ failure (see Chapter 71). Transient mild proteinuria and microhematuria occur in 25% to 50% of patients, more often children, with infrequent nephritic syndrome and impaired kidney function. Patients develop MesPGN with deposits of IgG, IgM, and C3 and rarely IgAN (Fig. 57.7). Patients present with nephrotic syndrome due to focal segmental glomerulosclerosis (FSGS), infrequently MCD, and most often collapsing glomerulopathy with and without concomitant HIV infection, and associated with African descent and *APOL1* risk alleles.[54] In contrast, *P. malariae* (quartan malaria) infects aging erythrocytes and is less severe. Patients present with steroid-resistant nephrotic syndrome (tropical nephritis or nephrotic syndrome) primarily in children 4 to 8 years old. Adult GN often manifests with hypertension and reduced kidney function. Kidney biopsy shows an MPGN pattern with granular IgG, IgM, and C3 deposition and subendothelial and mesangial electron-dense deposits, and infrequently MN or MCD[52,55] (Fig. 57.8). Despite treating the infection, with or without corticosteroids, there is progression to ESKD, which is attributed to continuing autoimmune mechanisms. *Plasmodium vivax* causes AKI and rarely thrombotic microangiopathy (see Chapter 71), but GN has not been reported. For severe malaria the treatment is artesunate intravenously 2.4 mg/kg per dose at hours 0, 12, and 24, then artemisinin-based combination therapy orally for 3 days. In uncomplicated malaria, recommended treatment options include Artemether-lumefantrine (1.4–4.4/10–16 mg/kg) by mouth twice daily for 3 days or artesunate (4 mg/kg) plus amodiaquine (10 mg/kg) orally daily for 3 days or artesunate (2 mg/kg) orally daily plus tetracycline (4 mg/kg) orally every 6 hours for 7 days. Immunosuppressive treatment is not indicated for malarial nephropathy.

TABLE 57.3 Kidney Lesions in Parasitic Infections

Parasite	Glomerular Lesions	Tubulointerstitial Lesions	Amyloidosis	Tissue Reaction, Symptoms	Acute Kidney Injury	Posttransplant Disease
Schistosomiasis

[a]Parasitic antigens or specific antibodies detected in the glomeruli.
All conditions documented in humans unless otherwise indicated.
DPGN, Diffuse proliferative glomerulonephritis; *EPGN,* endocapillary proliferative glomerulonephritis; *FSGS,* focal segmental glomerulosclerosis; *GP,* glomerulopathy; *IgAN,* immunoglobulin A nephropathy; *MCD,* minimal change disease; *MesPGN,* mesangial proliferative glomerulonephritis; *MN,* membranous nephropathy; *MPGN,* membranoproliferative glomerulonephritis pattern.

Malaria-associated kidney disease in low-income countries has declined due to malarial control and overall improved health care.

Filariasis

Filariae are nematodes, of which only eight of the hundreds of species affect humans and only three are associated with kidney disease. *Wuchereria bancrofti* is responsible for several clinical syndromes, including tropical eosinophilic pneumonia, elephantiasis, and chyluria, and induces proteinuria, hypoproteinemia, and hematuria in infected patients. The dominant glomerular lesion is MesPGN; less frequently an MPGN pattern or acute endocapillary GN with eosinophilic predominance can be seen; and rarely amyloidosis or collapsing glomerulopathy are found. Immune complex deposits containing worm antigens have been demonstrated in glomeruli.[52,56]

Bancroftiasis is often associated with bacterial infection, usually staphylococci and certain streptococci; it is uncertain if this contributes to the development of GN. Even less understood is a potential role of the rickettsia-like bacteria *Wolbachia,* discovered within filarial nematodes and blamed for activation of innate immune pathways. Ivermectin, diethylcarbamazine, and albendazole are approved treatments for filariasis.

Onchocerca volvulus is less common and causes scrotal lymph node obstruction ("hanging scrotum"). Onchocercosis is associated with immune-mediated manifestations, including keratitis, anterior uveitis, and optic atrophy leading to "river blindness." GN induces proteinuria, including steroid-resistant nephrotic syndrome with progressive kidney impairment, usually an MPGN pattern with IgM, IgG, and C3 in subendothelial and mesangial deposits, with less frequent MCD and sclerosing glomerular lesions.[52,56] Glomeruli may contain onchocercal antigens, and GN recurs in transplanted kidneys. When *W. bancrofti* or *O. volvulus* is treated, the proteinuria and hematuria may worsen due to parasitic disintegration and increase in circulating immune complex formation. After successful parasite eradication, the kidney disease typically resolves.

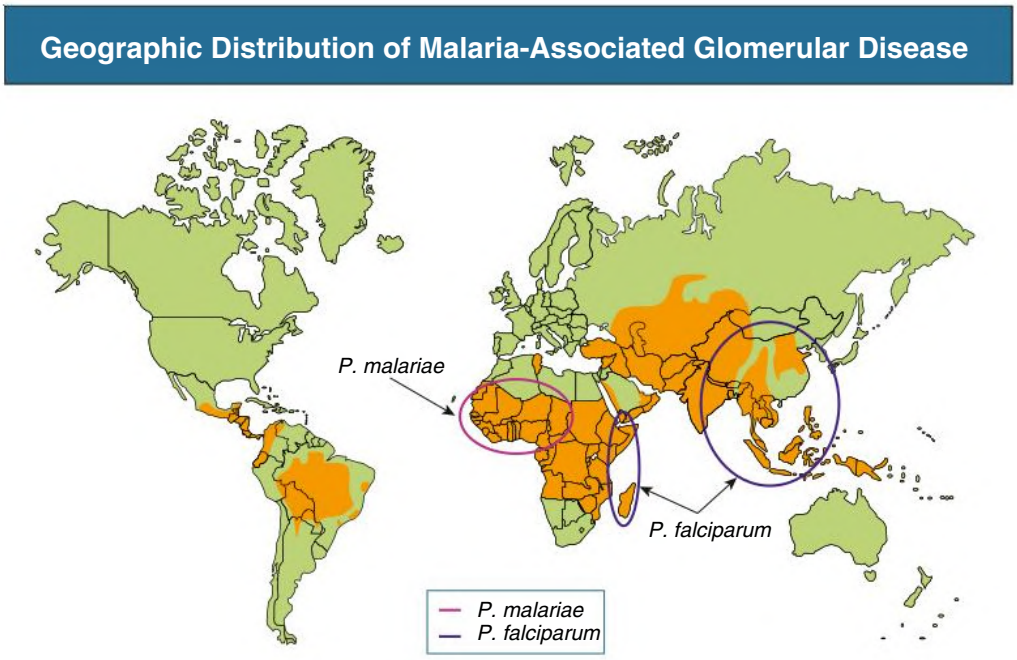

Fig. 57.6 Geographic Distribution of Malaria-Associated Glomerular Disease. Although malaria is endogenous to many areas of the world *(shaded orange),* the major areas where malaria-associated glomerular disease has been reported *(ringed)* and their respective species are shown.

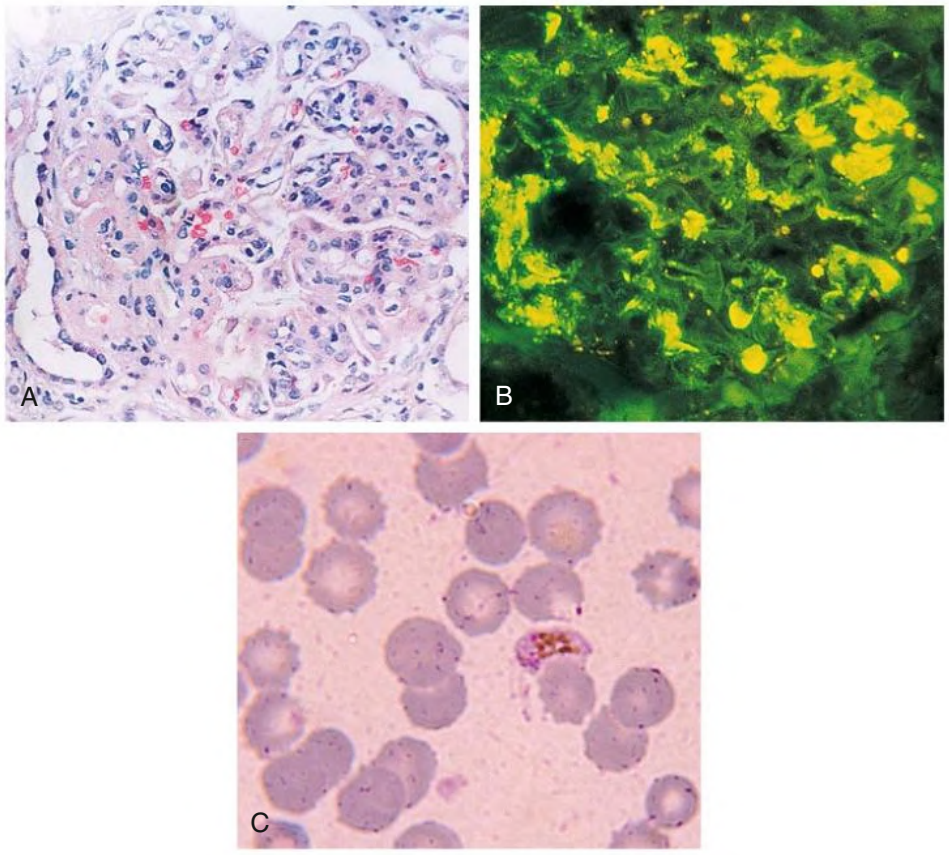

Fig. 57.7 Glomerulonephritis Associated With *Plasmodium falciparum* Malaria. (A) Light microscopy shows mesangial proliferative glomerulonephritis. (B) Immunofluorescence may reveal *P. falciparum* antigens in a mesangial pattern. (C) Peripheral blood smear confirms acute *P. falciparum* infection, with banana-shaped gametocytes and multiple ring forms in erythrocytes. (A, From Barsoum RS. Malarial nephropathies. *Nephrol Dial Transplant.* 1998;13[6]:1588–1597. B and C, Courtesy V. Boonpucknavig.)

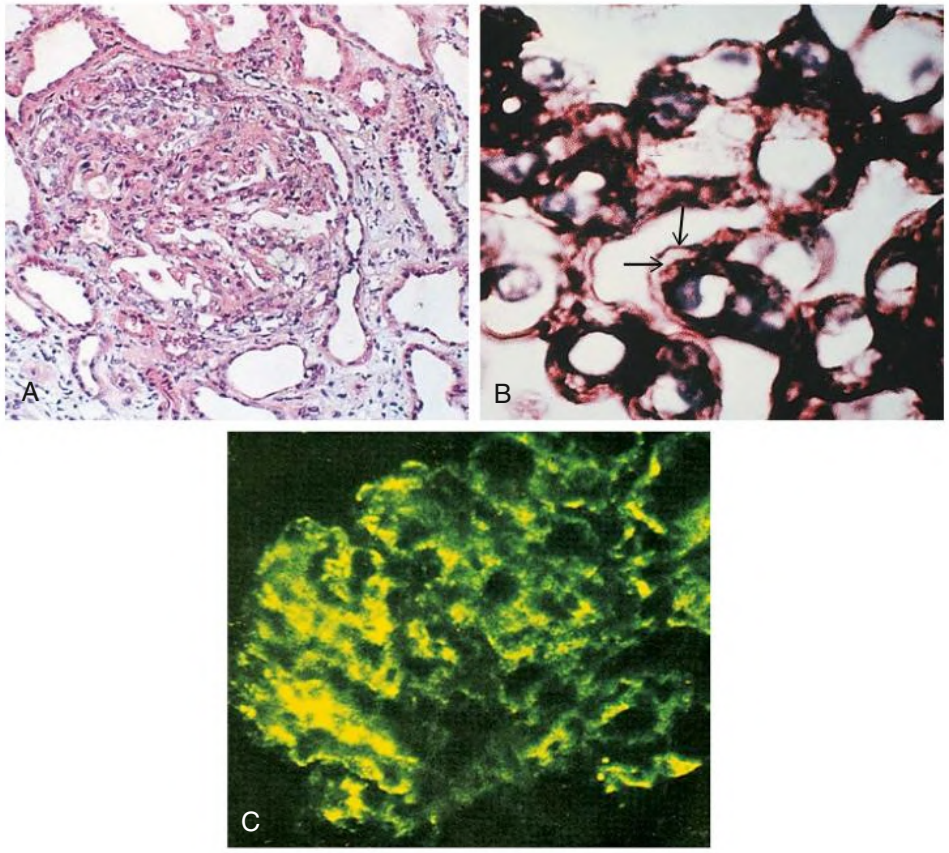

Fig. 57.8 Quartan Malarial Nephropathy. (A) Light microscopy shows sclerosing membranoproliferative glomerulonephritis. (B) Silver stain shows a double contour *(arrows)* of the basement membrane. (C) Malarial antigens are present on immunofluorescence. (From Barsoum RS. Malarial nephropathies. *Nephrol Dial Transplant*. 1998;13[6]:1588–1597.)

Loa is the least prevalent of the nephritogenic filariae. Associated glomerular disease includes MN and less commonly MPGN and FSGS.[52,57] Unlike the other forms of filariasis, treatment for *Loa loa* generally does not result in GN resolution. All three filaria parasites often occur with HBV and/or malaria coinfection, which independently can cause GN; it is unknown whether this affects the incidence or types of GN associated with filariasis.

Leishmaniasis

Leishmania are obligatory intracellular protozoa that infect 12 million humans and many animals. Of 30 known leishmanial spp., only visceral leishmaniasis (kala-azar) induced by *Leishmania donovani* or by the closely related *Leishmania infantum (Leishmania chagasi)* involves the kidney. Sixty percent of those infected with *L. donovani* have mild proteinuria and microscopic hematuria. There is glomerular immune complex deposition with MesPGN or an MPGN pattern; the latter may occur with cryoglobulinemia.[58,59] Amyloidosis may occur, usually associated with coincident HIV infection. Treatments for leishmaniasis (pentavalent antimony compounds, liposomal amphotericin B, miltefosine) have substantial adverse effects and high rates of resistance.

Schistosomiasis

Schistosomiasis is a common cause worldwide of glomerular disease and is discussed in Chapter 56.

SELF-ASSESSMENT QUESTIONS

1. At the present time, infection-related GN in wealthy countries is associated with debilitating conditions (neoplasia, diabetes, AIDS, alcoholism) and IgA deposits.
   A. True
   B. False
2. Patients with acute poststreptococcal GN usually have:
   A. low serum CH50 and C3 levels.
   B. low serum C4 levels.
   C. high serum C3 levels.
   D. high serum CH50 and high serum C4 levels.
3. Patients with infective endocarditis may have crescentic GN without immune deposits.
   A. True
   B. False
4. Combined antiviral therapy and immunosuppression (cyclophosphamide and steroids) is:
   A. contraindicated in patients with active HBV infection and associated GN.
   B. usually indicated in patients with active HBV infection and associated GN.

Human Immunodeficiency Virus Infection and the Kidney

Jeffrey B. Kopp, Mignon McCulloch, Avi Z. Rosenberg

INTRODUCTION

According to the United Nations acquired immunodeficiency syndrome (AIDS) program, an estimated 38 million individuals had human immunodeficiency virus (HIV)-1 in 2021, including 1.7 million with newly acquired infections. In 2019 an estimated 0.69 million deaths were attributed to HIV-related illness. In 2019 an estimated 25 million individuals were receiving antiretroviral therapy, representing 67% of all HIV-positive (HIV+) individuals. In 2019 around 150,000 children aged 0 to 9 years were newly infected with HIV. This brings the total number of children aged 0 to 9 years with HIV to 1.1 million (https://data.unicef.org/topic/hivaids). In the United States, an estimated 1.2 million individuals were HIV+ in 2019 and approximately 2000 patients were receiving renal replacement therapy (RRT; dialysis or kidney transplant) for HIV-associated kidney disease.

HIV-1 infection is associated with glomerular and tubulointerstitial disease, and patients with HIV infection are at risk for nephrotoxicity from antiretroviral therapy[1] and from other medications such as antibiotics and nonsteroidal antiinflammatory agents (NSAIDs).

Acute kidney injury (AKI), interstitial nephritis from medication and opportunistic infections, and coinfections with hepatitis B virus (HBV) and hepatitis C virus (HCV) are relatively common. Advances in treatment are to be celebrated but also mean that people with HIV are more likely to experience complications such as atherosclerosis, metabolic syndrome, type 2 diabetes, and end-stage kidney disease (ESKD). HIV-2 can cause immunodeficiency but rarely causes kidney disease. In this chapter, we use HIV to refer to HIV-1.

EPIDEMIOLOGY OF HIV CHRONIC KIDNEY DISEASE

High-Income Countries

There are relatively few data on the worldwide prevalence of chronic kidney disease (CKD) associated with HIV infection. In the European EUROSIDA observational study, only 3% had estimated glomerular filtration rate (eGFR) less than 60 mL/min/1.73 m^2 and only 0.3% had eGFR less than 30 mL/min/1.73 m^2.[2] In the United States, the incidence (absolute counts) of ESKD attributed to HIV continues to decline (from 893 individuals in 2006 to 525 in 2011).[3]

The United States Renal Data System (USRDS) reports that for the period from 2006 to 2010, there were 3834 cases of AIDS nephropathy (0.7% of total ESKD); 86% of the patients were Black and 15% were White. The unadjusted relative risk for ESKD was 4.7 for Black patients compared with Whites. This relative risk is less than previously estimated for HIV-associated nephropathy (HIVAN) and supports the idea that the distribution of kidney diseases associated with HIV infection is shifting. Patients reaching ESKD are also living longer. Among those who started dialysis in 2009 to 2011, mortality declined by 64% compared with 1988 to 1992 but remained nearly threefold higher than other dialysis patients.[3]

Lower- and Middle-Income Countries

Sub-Saharan Africa is home to approximately 70% of the global infections, with 26 million HIV+ people. In 2018, 470,000 people died with HIV in Africa. Globally, 91% of HIV+ children live in Africa. Of HIV+ individuals in sub-Saharan Africa, an estimated 54% have access to combination antiretroviral therapy (cART).

Prevention of mother-to-child transmission programs have resulted in a dramatically decreased number of childhood HIV cases. This condition may cease to exist in time with this preventive strategy.[4] In cases where there has been perinatal transmission, the use of highly active retroviral therapy (HAART) has also largely prevented HIV-associated kidney disease and thus decreased the mortality rate.

Adolescents may still acquire HIV infection, and thus it is important to focus on HIV prevention in this age group. Females aged 15 to 24 are the group with the highest rate of new HIV infection in sub-Saharan Africa.[5]

Compared with high-income countries, access to RRT is frequently limited in low- and middle-income countries. The prevalence of CKD, as assessed by the presence of proteinuria or eGFR, ranges widely in Africa, from 6% to 48.5%.[6] This wide variation may be partly ascribed to differences in study design, study population, and the definitions used for CKD. Based on single-center studies that used proteinuria as a marker of CKD in HIV+ subjects, the prevalence of CKD in HIV+ subjects ranges from 1% to 6% in Brazil to 20% in Iran and 27% in India.

In South Africa, HIVAN is the dominant kidney disease among HIV+ individuals and is documented in up to 80% of kidney biopsy specimens, which is consistent with findings in the United States in the pre-cART era. As in high-income countries, other kidney causes are also observed, including HIV-associated immune complex kidney disease (HIVICK) from postinfectious and other causes, membranous nephropathy, and interstitial nephritis. Some kidney biopsies show nonspecific changes (e.g., mesangial hyperplasia and chronic active interstitial nephritis) that do not fulfill the diagnostic criteria for HIVAN but do show regression on cART. The latter finding suggests that the diagnostic criteria for HIV-associated CKD may need to be broadened.

HIV-ASSOCIATED NEPHROPATHY

HIV infection is associated with various glomerular disorders (Table 58.1). The classic glomerulopathy of HIV infection is collapsing

TABLE 58.1 Kidney Diseases Associated With Human Immunodeficiency Virus (HIV) Infection or Its Treatment

	Entity	Frequency	Associations
Glomerular	HIV-associated nephropathy	Common	African descent; often advanced HIV disease
	HIV-associated immune complex kidney disease	Common	All ethnic backgrounds
	Thrombotic microangiopathy	Uncommon	
	Membranoproliferative glomerulonephritis ± cryoglobulin-associated vasculitis	Rare	Hepatitis C; enfuvirtide
	Membranous nephropathy	Uncommon	Hepatitis B
	Fibrillary and immunotactoid glomerulopathies	Rare	
	Amyloid nephropathy (AA type)	Rare	
	Minimal change nephropathy	Rare	Nonsteroidal antiinflammatory medication
Tubular	Acute kidney injury	Moderately common	Aminoglycosides, cidofovir, foscarnet
	Proximal tubule injury (Fanconi syndrome)	Moderately common	Tenofovir disoproxil, adefovir, cidofovir, didanosine
	Diabetes insipidus	Uncommon	Amphotericin, tenofovir disoproxil, didanosine, abacavir
	Chronic tubular injury	Moderately common	Amphotericin, cidofovir, adefovir, tenofovir disoproxil
	Crystal nephropathy	Uncommon	Indinavir, atazanavir; sulfadiazine, ciprofloxacin, intravenous acyclovir
Interstitial	Interstitial nephritis	Uncommon	Allergy to β-lactam, sulfonamides, ciprofloxacin, rifampin, proton pump inhibitor, allopurinol, phenytoin; also causes of crystal nephropathy listed previously
			BK virus
			Immune reconstitution inflammatory syndrome; generally advanced disease; after initiation of antiretroviral therapy

glomerulopathy (CG), also known as collapsing focal segmental glomerulosclerosis (FSGS) and as HIVAN.

Etiology and Pathogenesis

HIVAN occurs during both the acute and chronic phases of HIV infection; in the latter case, it is associated with higher viral RNA levels and lower CD4 T-lymphocyte counts. Studies from human kidney biopsies have shown that HIV can infect glomerular and tubular cells, setting up a chronic and possibly latent infection.[7] Specific HIV accessory proteins such as Vpr and Nef can damage kidney cells independent of direct infection. In transgenic mice, the expression of HIV accessory proteins Vpr or Nef in podocytes is associated with progressive CKD, loss of podocyte differentiation markers, and features suggestive of human CG and FSGS.[8] These transgenic mouse experiments also suggest that HIV gene products are toxic to tubular epithelial cells, resulting in both apoptosis and inhibition of cell proliferation.

Host factors also determine susceptibility to HIVAN, especially in individuals of African descent compared with those of European or Asian descent. Apolipoprotein L1, encoded by *APOL1* on chromosome 22, is a component of high-density lipoprotein particles. *APOL1* variants have been identified as a major cause of the predilection for chronic glomerular disease that characterizes populations of sub-Saharan African descent.[9,10] The presence of two *APOL1* codon-changing variants confer an odds ratio of 29 for HIVAN in the United States[11] and 89 in South Africa,[12] a strikingly large effect for a complex disease. Homozygosity, or dual heterozygosity for two risk alleles (termed G1 and G2; G1 is actually a haplotype, but the term allele is used here for simplicity), is observed in 72% of African Americans and South Africans with HIVAN, compared with only 12% of African American controls and 3% of South African controls. Among South Africans, a single copy of the APOL1-G1 variant confers an odds ratio [OR] of 21 for HIVAN. These variants appear to protect individuals from African sleeping sickness caused by *Trypanosoma brucei rhodesiense,* and this may explain the rapid rise in allele frequency in Africa, particularly West African populations, that has occurred in the past 40,000 years.[9]

In a U.S. study, among HIV+ individuals with proteinuria and two *APOL1* risk variants, 76% had FSGS or CG and had a nearly threefold increased risk of progression to ESKD compared with those with other biopsy findings. APOL1 high-risk genotype individuals manifested more CG and greater extent of glomerulosclerosis, tubular atrophy, and interstitial fibrosis.[13] HIV+ women with CKD with two APOL1 risk alleles had more severe proteinuria, more rapid decline in eGFR, and a 1.7- to 3.4-fold greater risk for incident CKD.[14]

The particular association between HIV infection and APOL1 kidney disease is likely a consequence of HIV infection promoting systemic interferon production, which, in turn, promotes expression of the *APOL1* gene.

At least seven mechanisms have been identified to explain the toxic effect of the *APOL1* variants on kidney cells. Evidence for these seven mechanisms have been shown in molecular studies, cell culture, or animal models. Most mechanisms are envisioned to be acting chiefly on podocytes to produce glomerular disease.

1. Increased flux through plasma membrane cation channels, either Na^+ and Ca^{2+} or K^+, the latter activating stress kinases and leading to cell swelling.[15]
2. Increased generation of interleukin (IL)-1β, leading to pyroptosis and podocyte loss.[16]
3. Disruption of an APOL1-mir193 axis, leading to dysfunction of the endoplasmic reticulum and protein production.[17]
4. Mitochondrial stress, leading to podocyte energy deficits.[18]
5. Activation of protein kinase R, leading to reduced protein synthesis.[19]
6. Formation of a tripartite complex of APOL1, soluble urokinase-type plasminogen activator receptor (suPAR), and αvβ3 integrin, resulting in integrin activation, altering podocyte-matrix interactions, and impairing podocyte function.[20]
7. Alterations in APOL1/APOL3 interactions.[21]

Some of these mechanisms have shown only or largely in cell culture studies or animal model, and their clinical relevance remains to be established. Novel therapies for APOL1 kidney disease are currently in clinical trials.

Clinical Manifestations of HIVAN

Patients with HIVAN typically present with proteinuria and reduced eGFR. Some patients present with edema, although edema is less common than with other conditions associated with nephrotic range proteinuria, suggesting a defect in tubular sodium handing. Imaging studies may reveal increased kidney size despite reduced eGFR and, in some cases, increased echogenicity; this unusual feature is shared with diabetic nephropathy and amyloid nephropathy. However, no ultrasound features predict the kidney histology, and kidney biopsy is required for diagnosis.

Pathology of HIVAN

HIVAN is indistinguishable from idiopathic collapsing FSGS (CG), with pathologic changes in glomeruli (proliferation and dysregulation of podocytes or podocyte stem cells, together with glomerular collapse), tubular injury (both acute and chronic injury, sometimes with microcystic tubular changes), and interstitial changes (chronic inflammation, fibrosis; Fig. 58.1). On electron microscopy (EM), both HIVAN and idiopathic collapsing FSGS may manifest tubuloreticular inclusions within dilated endosomal compartments within glomerular endothelial cells, which are believed to be markers for interferon-mediated injury. Some patients with progressive loss of kidney function (e.g., from HIVICK or interstitial nephritis) may develop postadaptive FSGS from the consequences of glomerular hyperperfusion and hyperfiltration.

Diagnosis and Differential Diagnosis

Indications for kidney biopsy include AKI without clear associated cause, especially with a nephritic sediment; nephrotic proteinuria; laboratory evidence of thrombotic microangiopathy (TMA); and unexplained CKD. In the past, some clinicians argued that nephrotic proteinuria in an individual of African descent is likely to be HIVAN, which is a form of collapsing FSGS or CG, and that a biopsy is not necessary. The widespread use of antiretroviral therapy (ART) in the current era makes this decision less tenable, and kidney biopsy is often indicated to guide prognosis and therapy, particularly when substantial proteinuria is present.

With the advent of ART, a wider range of HIV-associated kidney diseases is now seen. Rather than the initial pattern of HIVAN in individuals of African descent and HIVICK among all ethnic backgrounds, HIV-associated kidney diseases now includes FSGS, diabetic nephropathy, and arterionephrosclerosis (the term is used for the histopathology that is seen in some APOL1-associated kidney disease but also with aging). In patients with HIV and hepatitis, membranoproliferative glomerulonephritis associated with HCV should be considered. Other diagnoses include membranous nephropathy (associated with HBV infection, or presumably idiopathic, but possibly related to the polyclonal B cell expansion typical of HIV disease) and amyloidosis. Chronic tubular injury is usually associated with tenofovir disoproxil fumarate (TDF) therapy but may occur with other ART; when early diagnosis leads to cessation of the offending medication, CKD is

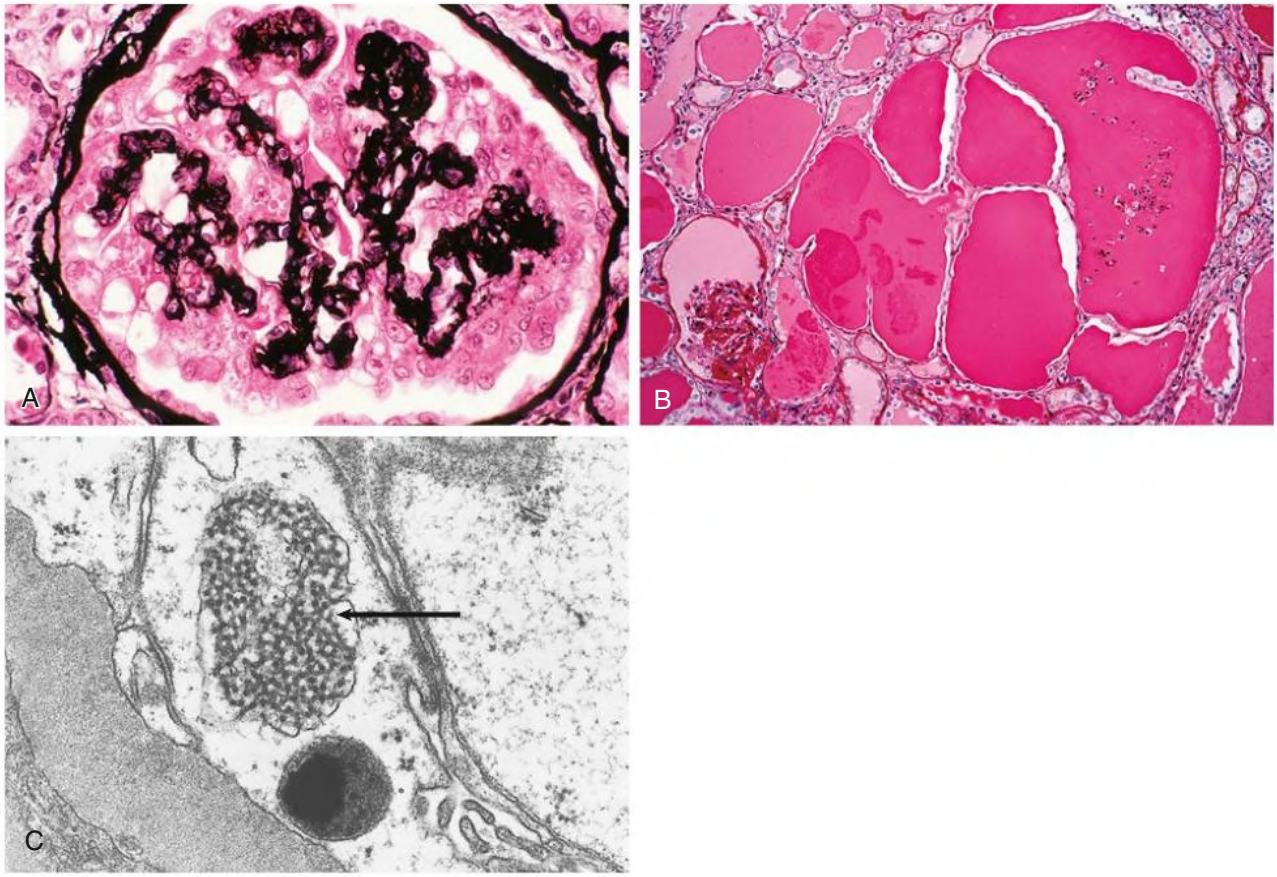

Fig. 58.1 Human Immunodeficiency Virus–Associated Nephropathy. (A) A globally collapsed glomerulus shows marked podocyte hypertrophy and hyperplasia (Jones methenamine silver). (B) At low power, the kidney parenchyma contains abundant tubular microcysts with proteinaceous casts. The glomerulus is collapsed with dilated urinary space (periodic acid–Schiff stain). (C) The glomerular endothelial cell pictured here contains a large intracytoplasmic tubuloreticular inclusion ("interferon footprint"; *arrow*) composed of interanastomosing tubular structures within a dilated cisterna of endoplasmic reticulum (electron micrograph).

usually averted. Despite the plethora of diagnoses, HIVAN remains the leading cause of ESKD in patients with HIV in the United States.

The diagnoses of HIVAN and HIVICK, and other diagnoses previously listed, are made by kidney biopsy. In some cases, nephrotic proteinuria and low CD4 T-lymphocyte count in individuals of African descent is sufficiently suggestive of HIVAN that some clinicians may opt not to biopsy the kidney. Plasma HIV RNA of less than 400 copies/mL at the time of presentation suggests another kidney disease. Among individuals of African descent, other possible diagnoses include primary or secondary FSGS (although a pathogenic role for HIV cannot be excluded in conferring susceptibility) and arterionephrosclerosis (see later discussion). In all individuals, diabetic nephropathy and HIVICK should be considered (see later discussion and Table 58.1).

Treatment of HIVAN

The HIV Medicine Association of the Infectious Diseases Society of America provides clinical practice guidelines for the management of HIV disease, with the most recent update published in 2020.[22] All HIV+ individuals should receive cART[1] beginning at the time of diagnosis. This may include a three-drug combination or two-drug combination that includes an integrase strand transfer inhibitor. The presence of kidney disease does not affect this recommendation.[23] In the era before cART was available, HIVAN progressed rapidly, with patients reaching ESKD in months to a few years. The marked decline in HIV-associated ESKD in the United States after the introduction of cART in the mid-1990s suggests that effective control of viral replication, achievable with cART, prevents HIVAN. Retrospective studies also suggest that cART treatment of HIVAN may prolong kidney survival.[24]

A growing number of prospective and retrospective studies have demonstrated rapid resolution or reduction in proteinuria within 6 months of commencing ART. The Development of Anti-Retroviral Therapy in Africa (DART) study, conducted in Uganda and Zimbabwe, demonstrated improvement of kidney function of 2 to 6 mL/min/1.73 m^2 after 4 to 5 years of ART.[25,26] Other studies suggest that ART is most effective when it is initiated before the onset of severe kidney disease.[27–31] In a few cases, regression of histologic lesions with cART has been demonstrated.[32,33] According to a French study, the pattern of kidney disease has changed since the introduction of ART, with a relative decrease in HIVAN and emergence of classic FSGS as the commonest cause of glomerular disease.[34] In this study, HIVAN occurred more frequently in Black patients with severe immunodeficiency and severe kidney failure, whereas FSGS patients were older, more likely to have received cART, more frequently had cardiovascular risk, and had more severe interstitial fibrosis on kidney biopsy.

Treatment of HIV-associated kidney disease also includes standard therapies for CKD, including control of BP and the use of an angiotensin-converting enzyme (ACE) inhibitor or angiotensin receptor blocker (ARB), combined with a thiazide diuretic, low sodium diet, and weight loss if obese. An aldosterone antagonist such as spironolactone or eplerenone, used in low doses, may potentiate the antiproteinuric effect of this regimen but requires monitoring to avoid hyperkalemia. A prospective and controlled, but nonrandomized, trial of HIVAN demonstrated improved kidney survival with ACE inhibitor therapy.[35] Glucocorticoids have shown benefit for HIVAN in a prospective and several retrospective studies, as reviewed recently.[36] Nevertheless, although there is no consensus, these medications should only be considered in HIVAN and HIVICK when viral replication is suppressed with cART and proteinuria or progressive kidney function decline continues. BP targets should be treated to achieve a systolic BP of less than 120 mm Hg consistent with the 2020 Kidney Disease Improving Global Outcomes (KDIGO).[1]

Natural History of HIVAN

Progression of CKD is more rapid in HIV+ individuals of African descent, probably reflecting the effect of the *APOL1* variants. Patients with HIVAN may progress to ESKD despite cART, but the use of these antiretroviral therapies may slow or even halt progression. Predictors of progression are a high degree of chronic damage on histology as well as severe kidney dysfunction at baseline, high-grade proteinuria, and presence of many sclerotic glomeruli.[37,38]

OTHER GLOMERULAR DISORDERS

HIV-Associated Immune Complex Disease

In populations of European and Asian ancestry, the most common glomerular disease associated with HIV disease is immune complex disease (reviewed in Cohen and Kimmel[39]; case series have been reported from high-income countries, including the United States,[40,41] the United Kingdom,[42] and France,[34] and from low-income countries, including Thailand[43] and India[44]). HIVICK is also seen in populations of African descent, although much less frequently than HIVAN, and most lack two *APOL1* risk alleles. Compared with those with HIVAN, HIVICK subjects tend to have lower HIV viral copy number and are more likely to have diabetes and hypertension.[45]

HIVICK can take various forms, including postinfectious glomerulonephritis, membranous nephropathy, and a lupus-like histologic pattern.[46] Patients with HCV coinfection may manifest a membranoproliferative glomerulonephritis (MPGN) pattern (see Chapter 22). Some patients may have only mesangial immunoglobulin A (IgA) deposits (especially those with microhematuria and nonnephrotic proteinuria), resembling idiopathic IgA nephropathy. Hence, the diagnosis of HIVICK may be fraught with challenges for the pathologist, who must exclude other immune complex disease.

HIVICK may be clinically indistinguishable from HIVAN, although hematuria may be more marked, and some patients present with lower levels of proteinuria. Kidney biopsy findings may vary from MPGN to focal or diffuse proliferative glomerulonephritis with endocapillary proliferation (Fig. 58.2). In some cases, changes consistent with HIVAN may also be present, including tubuloreticular inclusions within glomerular capillary endothelial cells. Immune deposits may be in mesangial, subendothelial, or subepithelial locations and may include IgG and IgM or IgG, IgM, and IgA (so-called "full house deposits"), often with C3. These forms resemble lupus nephritis, although lupus serologic test results are typically negative. If lupus serologies are positive, then in most cases the individual has lupus and HIV-1 infection, although early case reports suggest that some patients with HIV-1 infection may have false-positive lupus serology tests.[47]

The pathogenesis of HIVICK is not well understood and may involve various mechanisms. It is not known whether complexes form locally within the glomeruli or are passively trapped as from the glomerular microcirculation. In some cases, immune complexes include HIV antigens. Other cases may represent generalized polyclonal B-cell expansion that accompanies HIV disease.

An important issue is whether some or perhaps many HIVICK cases are not because of HIV-1 infection per se but instead are examples of idiopathic glomerular immune disease, in some cases possibly arising as a consequence of the immune reconstitution syndrome after institution of ART. Membranous nephropathy may appear after immune reconstitution, and such patients often have antibodies against the phospholipase-A2 receptor (PLA2R), the most common antigen associated with idiopathic membranous nephropathy.

HIVICK is often associated with progressive loss of eGFR. Foy and colleagues in the United States found that at 2 years after diagnosis, 70% of HIVAN cases and 32% of HIVICK cases had reached

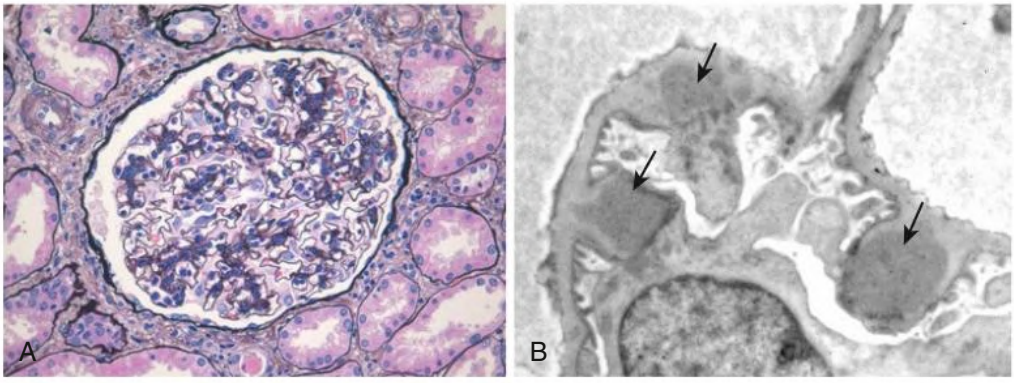

Fig. 58.2 Human Immunodeficiency Virus (HIV)-Associated Glomerulonephritis. This HIV-positive individual presented with microhematuria and nonnephrotic proteinuria with normal kidney function. Kidney biopsy shows mild mesangial expansion with mesangial and paramesangial deposits, together with varying numbers of subepithelial-based deposits *(arrows),* resulting in the "ball-and-cup" appearance. (Courtesy Professor Stewart Goetsch, University of the Witwatersrand, Johannesburg, South Africa.)

ESKD. Further, the use of cART or the attainment of viral suppression was not associated with lower risk of ESKD in HIVICK, whereas use of cART was associated with reduced likelihood of progression with HIVAN.[45] In contrast, a UK study reported a slower rate of progression of HIVICK to ESKD, but these authors considered HIV-associated IgA nephropathy to be a distinct entity and with a risk for progression that is intermediate between HIVAN and HIVICK.[42]

OTHER GLOMERULAR DISORDERS

Thrombotic microangiopathy may occur with HIV infection and is associated with low CD4 cell counts, high viral burden, and AIDS.[48] Fibrillary glomerulonephritis, immunotactoid glomerulopathy, and amyloidosis have also been reported in HIV infection, but a causal role for HIV infection has not been established.

SYSTEMIC INFLAMMATION AND ARTERIONEPHROSCLEROSIS

A paradigm shift has emerged over the past two decades, with the recognition that long-term suppression of HIV replication dramatically improves survival but at the cost of chronic inflammation and premature aging.[49] Peripheral inflammatory markers correlate with Framingham risk scores and Veteran Aging Cohort Scores,[50] and hypertension is common.[51] The causes of chronic inflammation in HIV disease are complex. Chronic immune activation is associated with lymphocyte depletion, manifesting as reduced numbers of $CD4^+$ and $CD8^+$ naïve T cells. Alterations in the intestinal microbiome and microbial translocation may contribute.[52]

Inflammation promotes disease processes that resemble premature aging (including atherosclerosis) and manifests in the kidney as arterionephrosclerosis. This disease involves systemic arterial intimal thickening, medial hypertrophy, duplication of the internal elastic lamina, and global glomerulosclerosis. These afferent arteriolar lesions predispose to glomerulosclerosis and hypertension by altering kidney autoregulation. Arterionephrosclerosis was traditionally ascribed to hypertension, but it is now apparent that other mechanisms often contribute. Arterionephrosclerosis is associated with genetic mutations (e.g., *APOL1*), metabolic disorders (e.g., diabetes, obesity, hyperlipidemia, metabolic syndrome, and HIV infection), and chronic inflammation (smoking, oxidative stress, hemodynamic shear stress, and renin-angiotensin system activation).[53] A U.S. study of HIV-1 patients reported that isolated arterionephrosclerosis was the most common single pathology,[54] and this trend has become stronger as more HIV+ individuals have achieved viral suppression and are living longer while taking ART for longer durations.

TUBULAR DISORDERS

HIV infection is associated with tubular disorders, often because of medications (see Table 58.1), the most common being tenofovir disoproxil fumarate (TDF). AKI most commonly occurs in outpatient settings, with prekidney causes (extracellular volume contraction, or reduced kidney blood flow because of nonsteroidal anti-inflammatory agents [NSAIDs]) and postrenal causes (including obstruction as a result of prostate disease, kidney stone, or crystalluria). Kidney causes of AKI include tubular injury from medication, particularly TDF; interstitial nephritis because of NSAIDs or antibiotics; and less commonly, acute presentations of glomerular disease. Risk factors for HIV-associated AKI include male sex, sub-Saharan African ancestry, low CD4 count, high viral load, diabetes, CKD, and hepatic disease.[55] Chronic proximal tubular injury manifests as various components of Fanconi syndrome: glycosuria, phosphaturia (sometimes associated with clinically significant hypophosphatemia), uricosuria, tubular proteinuria (predominantly low-molecular-weight proteins), and aminoaciduria. Diabetes insipidus may also be present, indicating that the distal nephron is also involved.

NEPHROTOXICITY AND DOSING OF ART AND ASSOCIATED DRUGS

Current Antiretroviral Drug Regimens and Kidney Toxicity

As of 2021, there are 25 antiretroviral medications and 24 antiretroviral medication combination formulations approved for use in the treatment of HIV disease in the United States. Recommendations for first-line therapy of HIV in adults include a combination of three medications. These are TDF, a nucleotide reverse transcriptase inhibitor (NRTI); either lamivudine or emtricitabine, nucleoside reverse transcriptase inhibitors, also abbreviated NRTI; and efavirenz, a nonnucleoside reverse transcriptase inhibitor (NNRTI). The difference between a nucleotide and a nucleoside is that the latter must be phosphorylated to become active. To underscore its ubiquity, TDF is a component of four of the six regimens currently recommended for treatment-naïve patients and hence widely used globally. TDF nephrotoxicity is discussed later. By contrast, NNRTIs have an excellent kidney safety profile.

In addition to these two drug classes (NRTI, NNRTI), there are six other classes of antiretroviral medications currently in clinical use

TABLE 58.2 Adjustments in Drug Dosing for Selected Antiretroviral Medications

Medication Class	Medication	Adjustment for GFR	Dosing in Dialysis
NRTI	Abacavir	No change	No change
	Didanosine[a]	Reduce for eGFR < 60	No dose after dialysis
	Emtricitabine	Reduce for eGFR < 50	No change; dose after dialysis
	Lamivudine	Reduce for eGFR < 30	Reduce dose; dose after dialysis
	Stavudine[a]	Reduce for eGFR < 50	Reduce dose
	TDF	Reduce for eGFR < 50	Reduce dose; dose after dialysis
	Tenofovir alafenamide	Not recommended if eGFR < 15 and not on hemodialysis	No change
	Zidovudine	Reduce for eGFR < 15	Reduce dose; dose after dialysis
NNRTI	Doravirine	No change	Not studied
	Efavirenz	No change	No change
	Etravirine	No change	No change
	Nevirapine	No change eGFR ≥ 20, not recommended eGFR< 20	Additional 200 mg dose of immediate release formulation recommended after dialysis
	Rilpivirine	Use with caution in severe CKD	No data
Protease inhibitor	Atazanavir	No change	Depends on antiretroviral treatment status
	Darunavir	No change	No data
	Fosamprenavir	No data	No data
	Indinavir[a]	No change	No change
	Lopinavir	No data	Avoid once-daily dosing regimen
	Nelfinavir	No data	No data
	Saquinavir[a]	Not recommended for severe CKD	No data
	Tipranavir	Probably no change	No data
Fusion inhibitor	Enfuvirtide	No change	No change
Entry inhibitor (gp41)	Maraviroc^	eGFR < 30: dosing depends on concomitant medications	Dosing depends on concomitant medications
INSTI	Cabotegravir[a]	eGFR < 15: no data	No data
	Dolutegravir	No change; use caution in INSTI-experienced patients with severe renal impairment	No data
	Raltegravir	No change	Dose after dialysis
	Bictegravir	Not recommended	eGFR < 30 acceptable in dialysis if benefits outweigh risks
Pharmacokinetic enhancer	Cobicistat	No change For eGFR < 70, avoid combination with TDF	No data
	Ritonavir	No change	No data
CD4 postattachment inhibitor	Ibalizumab	No data	No data
gp120 attachment inhibitor	Fostemsavir	No change	No change

As of 2021, there are 30 antiretroviral medications and 24 antiretroviral medication combination formulations approved for use in the treatment of HIV disease in the United States.

[a]No longer available in the United States.

CCR5, C-C chemokine receptor 5; *CKD,* chronic kidney disease; *CrCl,* creatine clearance; *eGFR,* estimated glomerular filtration rate; *gp,* glycoprotein; *HIV,* human immunodeficiency virus; *INSTI,* integrase strand-transfer inhibitor; *NNRTI,* nonnucleoside reverse transcriptase inhibitor; *NRTI,* nucleoside reverse transcriptase inhibitor; *TDF,* tenofovir disoproxil fumarate.

(Table 58.2). These include protease inhibitors, fusion inhibitors (GP41 antagonist), an entry inhibitor (CCR5 antagonist), integrase inhibitor, integrase strand inhibitor (cabotegravir), and postattachment inhibitors, as well as a pharmacokinetic enhancer. Two long-acting injectable agents are available, cabotegravir and rilpirivine (NNRTI). Of these six classes, only protease inhibitors exhibit kidney toxicity. Indinavir was a formerly common cause of tubular injury but is rarely used at present and has been discontinued in the United States. Case series show that in individuals taking ritonavir-boosted atazanavir, urinary crystals composed of atazanavir affect 10% of subjects[56] and kidney stones occur at a rate of 2.4 cases per 100 patient-years of therapy.[57] Risk factors for nephrolithiasis include alkaline urine and kidney impairment; serum levels of atazanavir were not associated with stones.[58] Atazanavir has been also associated with interstitial nephritis.[59] Atazanavir is no longer commonly used.

Tenofovir Disoproxil Fumarate

TDF is the most common cause of tubular injury in HIV+ individuals and manifests primarily as proximal tubular dysfunction with Fanconi syndrome. TDF is taken up by proximal tubular cells by one or more organic anion transporters and converted to the active drug that inhibits DNA repair and DNA replication in host cells and in HIV. TDF also causes mitochondrial enlargement and dysmorphic changes and is associated with cellular adenosine triphosphate (ATP) depletion.[60] A mild decrease in GFR has also been associated with TDF use, but usually it is not severe enough to require discontinuation of treatment.

TABLE 58.3 Kidney Toxicity of Antiretroviral Therapy

Antiretroviral Class	Antiretroviral Therapy	Kidney Effect	Clinical Recommendations
Protease inhibitors	Indinavir	Nephrolithiasis, crystalluria, dysuria, papillary necrosis, acute kidney injury, interstitial nephritis Ritonavir may increase toxicity of indinavir	Daily fluid intake of >2 L/day
	Atazanavir Ritonavir	Crystalluria, stones, interstitial nephritis Increases levels of TDF	Daily fluid intake of >2 L/day
Reverse transcriptase inhibitors	TDF	Kidney tubular damage: proximal tubular dysfunction, Fanconi syndrome, nephrogenic diabetes insipidus, acute tubular necrosis, acute kidney injury	Patients taking TDF should be monitored for signs of tubular dysfunction, including elevated serum creatinine, hypophosphatemia, low serum uric acid, acidosis, glycosuria, and proteinuria

TDF, Tenofovir disoproxil, fumarate.

Nonetheless, full recovery of kidney function may take months to years after stopping TDF.[61] In some cases, recovery is partial or progresses to CKD.[62] Risk factors for TDF-induced kidney toxicity include low CD4 cell count, prior kidney impairment, longer duration of therapy, and combined therapy with didanosine and protease inhibitors (lopinavir and ritonavir); the latter agents elevate TDF plasma levels, which, in turn, are associated with a higher risk of nephrotoxicity.[63]

TDF is taken up into the kidney tubular epithelial cell from basolateral space by the organic anion transporter (OAT) 1 and OAT3 and is secreted into the tubular lumen by the multidrug resistance protein (MRP) 4. Mutations in *ABCC4,* encoding MRP4, are associated with increased plasma TDF concentrations and nephrotoxicity risk[64] and mutations in *ABCC10,* encoding MRP10, are associated with increased risk of phosphate wasting.[65] On the other hand, the use of MRP inhibitors such as NSAIDs, salicylates, and dipyridamole does not increase toxicity.[66]

Tenofovir-alafenamide (TAF) has proven effective and well-tolerated. Like TDF, TAF is a prodrug but, unlike TDF, it is not a substrate for the OAT1 and OAT2 transporters and thus is not taken up by tubular cells. Currently available data suggest lower levels of kidney toxicity compared with TDF but longer trials will be required to confirm this.[67] TAF is also associated with less phosphaturia and better preserved bone mineralization in adults older than 60 years.

ANTIRETROVIRAL THERAPY DOSING IN CHRONIC KIDNEY DISEASE

Many antiretroviral medications are partially or completely eliminated by the kidney and require dosage adjustment in CKD. Certain drug classes, such as the protease inhibitors and the NNRTIs, are extensively metabolized by the liver and do not require dosage adjustment. Most of the NRTIs are excreted unchanged in the urine and require dosage adjustment, except for abacavir, which has substantial extrarenal biotransformation that requires little if any dosage adjustment. In uremia, drug dosages may be affected by altered gastric pH and altered volumes of distribution. Factors that influence dialyzability of antiretroviral medications relate to the properties of the particular dialysis membrane and molecular weight, degree of protein binding, molecular charge, and water solubility of the drug. Drugs that are substantially removed by hemodialysis should be taken after dialysis sessions. If the drug is removed in peritoneal dialysis effluent, the dose may have to be adjusted. Dosage recommendations (Table 58.3) in both hemodialysis and peritoneal dialysis are limited; there is a recommendation for NRTI dosing in patients undergoing venovenous hemofiltration.[68]

END-STAGE KIDNEY DISEASE

With the increasing survival of HIV+ individuals with treatment and the declining cost of cART, the incidence of HIV-associated ESKD will likely increase worldwide, as it has in high-income countries. Currently, survival among dialysis-dependent HIV+ patients who are stable on cART is comparable to that among dialysis patients without HIV infection, and choice of dialysis modality (hemodialysis versus peritoneal dialysis) does not have an impact on survival.

Immunization schedules are the same as for non–HIV-negative dialysis patients.[69] In both CKD and HIV infection, anemia is independently associated with shorter survival. The response to recombinant erythropoietin (EPO) in HIV+ patients with ESKD is similar to that in HIV-negative patients.[70] Measurements of iron indices are complicated in HIV+ patients because levels of ferritin (an acute phase reactant) are often elevated in patients with HIV infection. Elevated soluble transferrin receptor concentrations are more reliable than serum ferritin to distinguish iron deficiency in inflammatory disease states.[71]

Hemodialysis

Strict adherence to universal precautions is the best form of prevention of HIV transmission in dialysis units, and there is no reason for these patients to be isolated. Even reprocessing of dialyzers from HIV+ patients does not place staff members at increased risk for infection, if necessary sterile precautions are undertaken. The risk of viral seroconversion after a needle-stick injury has been estimated as 6 in 1000 for HCV, 4 in 1000 for HBV, and 2 in 1000 for HIV.[72] ART may reduce the risk of transmission after a needle stick injury, and postexposure prophylaxis for 28 days with a combination of two reverse transcriptase inhibitors and one protease inhibitor is recommended. Native arteriovenous fistulas are the preferred types of access for all patients with ESKD because of better patency rates and lower complication rates, compared with other access options. A recent study from South Africa showed similar patient survival outcomes for HIV+ and HIV-negative hemodialysis patients, except for increased incidence of tuberculosis in the HIV+ group.[73]

Peritoneal Dialysis

HIV-1 remains infectious at room temperature in peritoneal dialysis (PD) exchange tubing for up to 48 hours and for up to 7 days in peritoneal effluent.[74] Dialysate should therefore be handled as a contaminated body fluid.[74] Sodium hypochlorite (50% solution) and household bleach (10% solution), each further diluted 1 to 512, are effective at inactivating HIV in dialysate. PD patients should be

instructed to pour dialysate into the home toilet and to dispose of dialysate bags and lines by tying them in plastic bags and disposing of the plastic bags in conventional home garbage.

Kidney Transplantation

The past few years have seen a surge of interest in kidney transplantation for HIV+ patients with ESKD. In a report of 150 kidney transplants from HIV-negative donors (both living and deceased) to HIV+ recipients,[75] acute rejection rates were higher than in other subjects, but HIV replication remained controlled. Similar outcomes were reported subsequently from other centers, including 25 HIV+ recipients who received 43 kidneys from HIV+ deceased donors in South Africa[76,77] and 92 subjects in the United States.[78] With longer-term follow-up, compared with HIV-negative recipients, HIV+ recipients had a marginally increased risk of graft loss and no increased risk of death.[79] HIV+ pediatric recipients have also received kidneys from HIV-negative donors with good outcomes.[80]

Interestingly, Canaud et al. reported that kidneys from HIV-negative donors became infected after transplantation into HIV+ recipients, with HIV RNA detected in podocytes and tubular cells.[81] In 2013 the HOPE (HIV Organ Policy Equity) Act was passed by the U.S. Congress, which legalized research involving HIV+ living donors providing kidneys to HIV+ recipients, and studies with this population are being developed.[82]

EVALUATION FOR KIDNEY DISEASE

HIV+ individuals should undergo regular evaluation for kidney disease, probably at least every 6 months and more frequently if kidney disease is suspected (Fig. 58.3). Early identification of kidney injury disease offers the prospect of discovering kidney injury when it first appears, defining the nature of the process, removing provocative factors when possible (particularly medications), and initiating therapy to slow, halt, or possibly reverse the disease process.

Periodic testing should include a history of nephrotoxic medications and measurement of BP, serum creatinine, blood urea nitrogen, and urine protein/creatinine ratio. Three studies in HIV+ patients have compared the CKD-EPI (Chronic Kidney Disease Epidemiology Collaboration) equations against the gold standard iothalamate GFR: All three concluded that the CKD-EPI equation correlated well with measured GFR. When doses prescribed were compared with those recommended by the CKD-EPI eGFR, 6% to 19% of patients received an inappropriate dose; these subjects tended to be older and were more likely to have diabetes.

Most proteinuria in HIV+ patients is tubular in origin. In a study from London, 10% of subjects had proteinuria (defined as protein/creatinine ratio > 200 mg/g), most of which was not albumin; 17% had microalbuminuria, and 67% had increased excretion of the low molecular protein neutrophil gelatinase–associated lipocalin (NGAL).[83] Microalbuminuria, defined as 20 to 200 mg/g of creatinine, may indicate early glomerular disease (including in diabetic nephropathy, arterionephrosclerosis, HIV-associated glomerular disease), tubular disease, metabolic syndrome, or systemic inflammation. In six of seven South African patients with persistent microalbuminuria, HIVAN was present on kidney biopsy,[84] documenting that this disease may have an insidious presentation. Modestly elevated albuminuria may be persistent or intermittent and may reflect other processes, such as diabetes and hypertension. Indeed, in HIV+ individuals, microalbuminuria is associated with Framingham risk score,[85] endothelial dysfunction,[86] and intimal medial thickness and with all-cause mortality.[87]

SELF-ASSESSMENT QUESTIONS

1. In individuals of African descent with HIV infection, genetic variants in the *APOL1* gene are associated with which of the following kidney biopsy diagnoses?
   - **A.** HIV-associated nephropathy (collapsing glomerulopathy) or focal segmental glomerulosclerosis
   - **B.** Membranous nephropathy
   - **C.** Immune complex glomerulonephritis
   - **D.** IgA nephropathy
2. An HIV-positive individual is receiving antiviral therapy and has suppressed viral replication. At a routine clinic visit, reduced serum phosphate and uric acid along with glycosuria are noted. Which of the following is the most likely explanation for these abnormalities?
   - **A.** Efavirenz
   - **B.** Allopurinol
   - **C.** Tenofovir disoproxil
   - **D.** Ritonavir
3. The clinician of the patient in question 2 was not provided with the laboratory results, and no changes were made in the clinical management of the patient. At the next visit 6 months later, the serum creatinine has risen and a kidney biopsy is performed. Which of the following findings would be most *specific* in clarifying the cause of the injury?
   - **A.** Arterionephrosclerosis
   - **B.** Focal global glomerulosclerosis
   - **C.** Tubular atrophy and interstitial nephritis
   - **D.** Giant mitochondria within the tubular cells

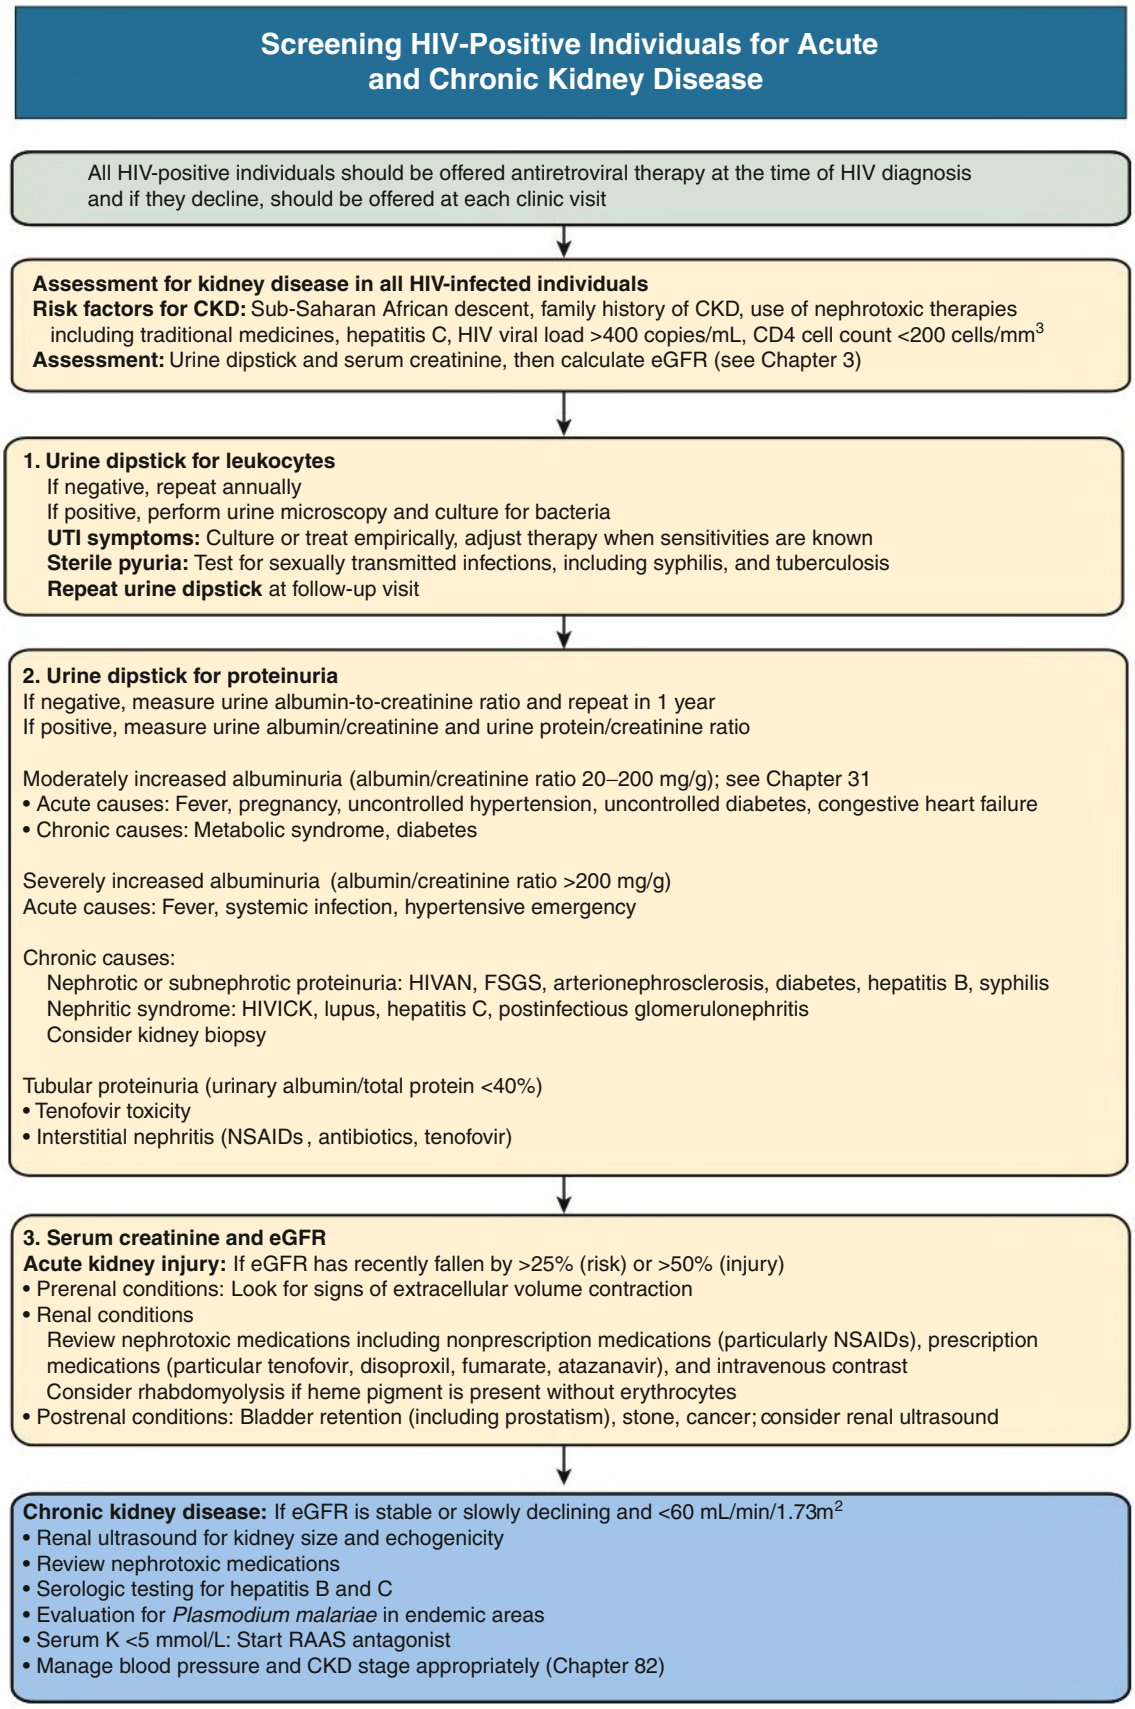

Fig. 58.3 Management Algorithm for Screening of Human Immunodeficiency Virus (HIV)-Positive Antiretroviral Therapy–Naive Patients for Chronic Kidney Disease. Tuberculosis may be pulmonary or extrapulmonary. Antiproteinuric agents may be used in normotensive individuals with gradual uptitration of dose, depending on tolerance and severity of proteinuria. *CKD,* chronic kidney disease; *eGFR,* estimated glomerular filtration rate, calculated by the Cockcroft-Gault formula or the modified Modification of Diet in Renal Disease (MDRD) formula; *FSGS,* focal segmental glomerulosclerosis; *HIVAN,* HIV-associated nephropathy; *HIVICK,* HIV-associated immune complex kidney disease; *NSAID,* nonsteroidal anti-inflammatory drug; *RAAS,* renin-angiotensin-aldosterone system; *STI,* sexually transmitted infection; *UTI,* urinary tract infection.

Kidney Diseases Associated With Coronaviruses

Thiago Reis, Molly Fisher, Cynthia C. Nast, Michael J. Ross

INTRODUCTION

The first cases of COVID-19 were reported in Wuhan, China, in late 2019, and by mid-March 2020, the World Health Organization officially declared a pandemic.[1] COVID-19 has since caused millions of deaths worldwide, and acute kidney injury (AKI) and other kidney syndromes are important complications COVID-19.[2] Moreover, COVID-19 has disproportionately impacted persons with kidney failure who receive chronic dialysis and are kidney transplant recipients (KTRs).

SARS-COV-2 AND VIRAL PATHOGENESIS

The virus that causes COVID-19 is SARS-CoV-2. Coronaviruses are enveloped, single-stranded RNA viruses that infect humans, other mammals, and nonmammalian species.[1] The first coronavirus found to induce severe disease in humans was severe acute respiratory syndrome coronavirus (SARS-CoV), which caused the first reported SARS outbreak in China in 2002 and subsequent sporadic outbreaks. In 2012, the Middle Eastern respiratory syndrome (MERS), caused by MERS-CoV, was reported on the Arabian Peninsula. SARS-CoV and MERS-CoV use the same receptor (ACE2) as SARS-CoV-2 to infect host cells.[3] Kidney injury is a common complication of MERS but probably occurs less often in patients with SARS.[4,5]

Cellular entry of SARS-CoV-2 is mediated by binding of the viral spike (S) protein to ACE2 on the surface of target cells and subsequent cleavage/activation of S by the type 2 transmembrane serine protease (TMPRSS2), thereby enabling the S protein to mediate entry of the virus into the host cell (Fig. 59.1), leading to cellular injury and activation of inflammatory responses.[1]

Robust innate immune responses, including interferon production early after SARS-CoV-2 infection, are important for limiting the severity of COVID-19.[6] However, in hospitalized patients with established COVID-19, high levels of inflammatory mediators predict increased risk of AKI, mechanical ventilation, and mortality, whereas immunosuppression with high-dose corticosteroids reduces mortality.[1,7] Similarly, dysregulated activation of coagulation in COVID-19 causes microvascular and, less often, macrovascular occlusion, which is an important contributor to lung injury,[1] but the role of dysregulated coagulation in COVID-19–associated kidney injury is less clear.

DOES SARS-COV-2 INFECT THE KIDNEY?

The receptor ACE2 is strongly expressed in proximal tubular cells, whereas other kidney cells, including podocytes, express ACE2 at lower levels.[8] Studies have reported the presence of viral antigens and nucleic acids in kidney autopsy and biopsy specimens, and electron micrographs of intracellular structures that appeared to be consistent with SARS-CoV-2 virions.[8] Subsequent studies suggested that technical limitations of the assays used for SARS-CoV-2 antigen and nucleic acid detection as well as difficulty in differentiating intracellular organelles from virions may have led to some false positive results.[9] More recently, viral RNA and protein have been detected in kidney tubular cells, where the nucleocapsid and spike proteins colocalized with ACE2.[10] Therefore, it is likely that kidney tubular cells become infected by SARS-CoV-2, but it is unknown if this causes clinically apparent kidney injury.

COVID-19 ACUTE KIDNEY INJURY

Epidemiology

The incidence of COVID-19–associated AKI (COVID-19 AKI) is high, ranging from 17% to 46% in large cohorts of hospitalized patients with COVID-19.[11-13] This variability likely reflects differences in disease severity, age, and comorbidities, and it is not clear whether the incidence and severity of AKI is higher in patients with COVID-19 than otherwise similar patients without COVID-19. There is significant heterogeneity in the severity of COVID-19 AKI with the proportion of stage 3 AKI, ranging from 11% to 42% with as many as 19% requiring kidney replacement therapy (KRT).[12-14] In a multicenter cohort study of intensive care unit (ICU) patients from 67 US hospitals, 21% developed AKI requiring KRT within 14 days of ICU admission.[7]

Risk Factors for COVID-19 AKI

Although many factors contribute to AKI in patients with COVID-19 (Fig. 59.1), hypovolemia and sepsis are the most common causes reported.[13] Risk factors associated with the incidence and severity of COVID-19 AKI include older age, male sex, Black race, obesity, hypertension, and diabetes mellitus. The presence of chronic kidney disease (CKD) and CKD stage are strongly associated with increased risk of COVID-19 AKI and the need for KRT.[7,11-13]

Increased severity of illness, including hypotension, hypoxia, and the need for mechanical ventilation are associated with increased risk of COVID-19 AKI.[7,13] Hypovolemia is a major contributor to COVID-19 AKI. COVID-19 illness leads to hypovolemia by increasing insensible losses (fever and tachypnea), reducing oral intake (sore throat, nausea, and anorexia), and increasing gastrointestinal losses (diarrhea).[15] Some groups have reported partial Fanconi syndrome with wasting of low-molecular-weight proteins, amino acids, uric acid, and phosphate but not glucose.[15] It is unknown whether primary tubular wasting contributes to hypovolemia in COVID-19.

Elevated serum biomarkers of inflammation (C-reactive protein and ferritin) and/or coagulation (D-dimer) are associated with

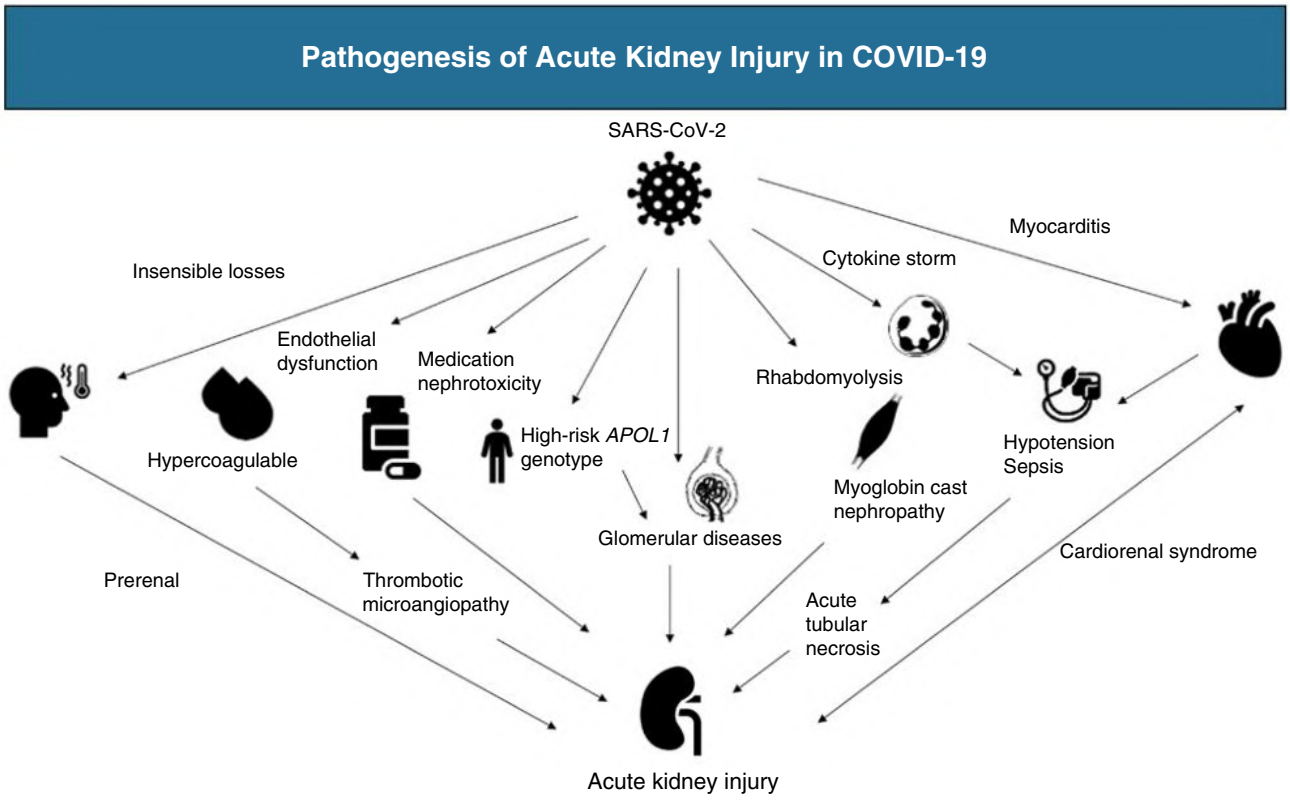

Fig. 59.1 Pathogenesis of acute kidney injury in patients with COVID-19.

increased risk of COVID-19 AKI in retrospective analyses[7]; however, the value of biomarkers as independent predictors of COVID-19 AKI remains to be demonstrated.

Histopathology of COVID-19 AKI

Small case series have reported pathologic findings in autopsy and kidney biopsy specimens from patients with COVID-19 AKI. Acute tubular injury (ATI) or tubular necrosis were identified in up to 90%, and glomerular and peritubular capillary congestion were common findings without additional glomerular lesions or fibrin thrombi[16-20] (Fig. 59.2). Myoglobin casts indicative of rhabdomyolysis have been found in up to 10% of biopsies showing ATI.

Treatment of COVID-19 AKI

There are no specific treatments to prevent or reduce the severity or duration of COVID-19 AKI. Treatment is supportive and includes optimization of kidney perfusion and minimizing exposures that may exacerbate kidney injury. Though studies have not demonstrated that a specific KRT modality results in superior clinical outcomes in patients with COVID-19, continuous kidney replacement therapy (CKRT) is preferred in hemodynamically unstable patients. Because patients with COVID-19 often require prone positioning to improve oxygenation, placement of dialysis catheters in the internal jugular rather than the femoral vein allows for easier access during proning. Anticoagulation is often required during KRT because patients with COVID-19 are at increased risk of thrombotic complications, including vascular access and dialysis circuit clotting. Small retrospective studies have reported increased CKRT filter life span with anticoagulation, but the optimal approach to anticoagulation for CKRT in patients with COVID-19 remains undetermined.[21]

In regions where the incidence of COVID-19 AKI has overwhelmed KRT capacity, several strategies have been used to increase KRT availability. Increased blood and dialysate flow rates and shortened

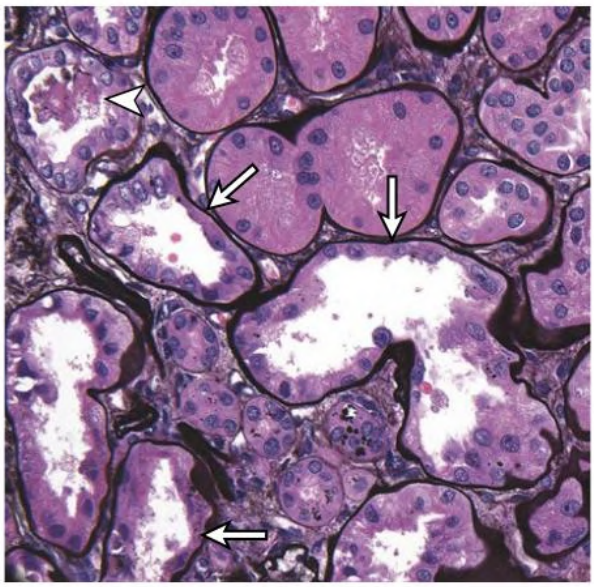

Fig. 59.2 Acute Tubular Injury in a Patient With COVID-19 and Acute Kidney Injury. Proximal tubular cells show loss of brush border staining, flattening, and degenerative change *(arrows)* with cellular debris in a tubular lumen *(arrowhead)*.

treatments for intermittent HD can allow for a greater number of treatments. Similarly, flows on CKRT machines can be increased to provide prolonged intermittent kidney replacement therapy, allowing CKRT machines to be used for multiple patients each day.[21] Finally, several centers have reported using acute peritoneal dialysis in patients with COVID-19 AKI.[21] Important advantages of peritoneal dialysis include scalability due to lack of requirement for a dialysis machine or high volumes of dialysate-quality water, and elimination of issues with dialysis circuit and vascular access clotting. Though studies reported

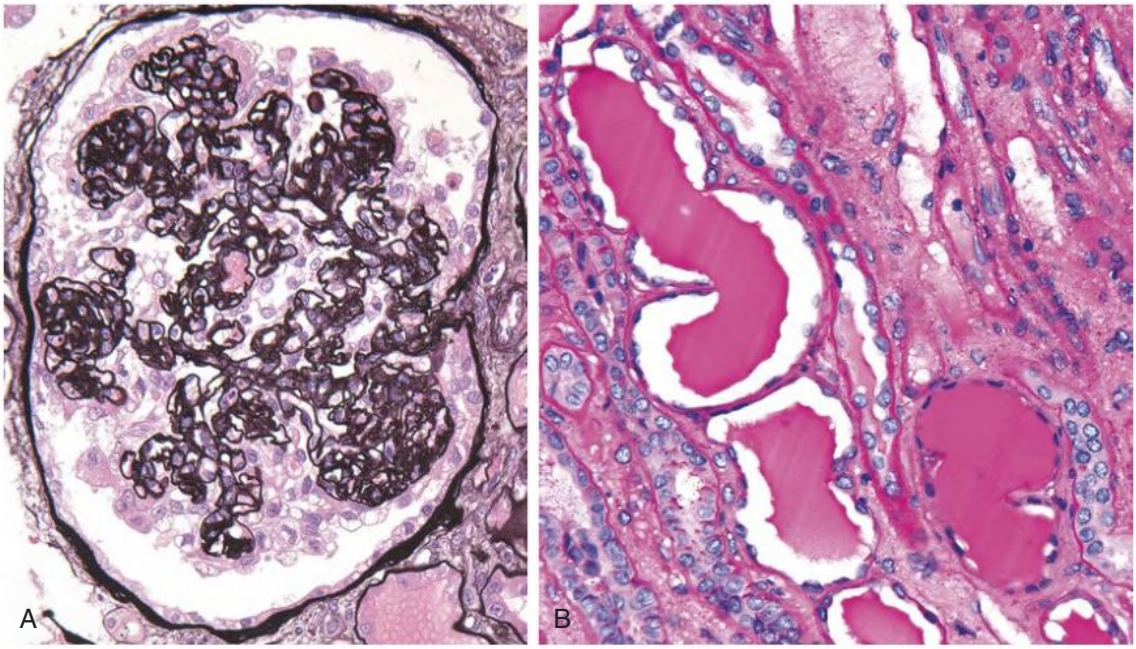

Fig. 59.3 Collapsing Glomerulopathy in an African American Patient With Moderately Symptomatic COVID-19 and Nephrotic Syndrome. (A) Global epithelial cell hypertrophy and hyperplasia with wrinkling and retraction of glomerular capillaries. (B) Microcystic tubules with proteinaceous casts.

clinical outcomes that appear to be acceptable with acute peritoneal dialysis in patients with COVID-19 AKI, peritoneal dialysis was sometimes difficult to perform in the most acutely ill patients, especially those who required prone positioning.

Prognosis of COVID-19 AKI

COVID-19 AKI often has a prolonged course and 35% to 40% of hospitalized patients with COVID-19 AKI meet criteria for acute kidney disease (i.e., AKI persisting for >7 days).[12,13] Of those with acute kidney disease, 36% had resolution to baseline kidney function during follow-up. However, 14% of patients with complete AKI resolution at discharge subsequently developed acute kidney disease, and 30% of survivors with AKI requiring KRT remained dialysis-dependent at the time of hospital discharge.[12]

Mortality among patients with COVID-19 AKI is high, ranging from 19% in those with stage 1 AKI to more than 60% in those with stage 3D AKI and/or highest severity of illness.[7,11-13] Among ICU patients with COVID-19 AKI, older age, receipt of two or more vasopressors at time of KRT initiation, and daily urine output less than 100 mL are associated with higher 28-day mortality.[7]

COVID-19–ASSOCIATED GLOMERULAR DISEASES

Clinical Presentation and Histopathology

Collapsing glomerulopathy (CG), minimal change disease (MCD), membranous nephropathy, and pauci-immune crescentic glomerulonephritis are the predominant glomerular lesions observed in patients with COVID-19.[22-24a] Clinical features of COVID-19–associated CG and MCD are new onset nephrotic syndrome or nephrotic range proteinuria with AKI. Collapsing glomerulopathy (Fig. 59.3) has been reported predominantly in persons of African ancestry, and high-risk *APOL1* genotypes have been identified in the great majority of patients with CG who underwent testing, suggesting that genetic susceptibility likely contributes to risk of CG in patients with COVID-19.[22-24a] Severe COVID-19 is associated with coagulopathy and microvascular thromboses which can resemble immune-triggered, complement-mediated thrombotic microangiopathy (TMA). COVID-19–associated TMA (Fig. 59.4) is characterized by microangiopathic hemolytic anemia, thrombocytopenia, and severe AKI requiring KRT. Those with a predisposing risk factor for endothelial injury, such as hypertension, drug exposure, or a genetic or acquired defect in the alternative complement pathway, may be at increased risk.[19,22,25] COVID-19 also has been associated with immune-mediated glomerular disease. Cases of anti–glomerular basement membrane (anti-GBM) disease, antineutrophil cytoplasmic antibody (ANCA)-associated vasculitis, immunoglobulin A (IgA) nephropathy, and membranous nephropathy (MN) have been reported in patients with COVID-19.[22,26,27] These glomerular diseases may manifest concurrently or several weeks after resolution of the acute infection, and it is unknown if this is chance occurrence or is pathogenetically linked. Interestingly, IgA nephropathy may occur de novo or be exacerbated after SARS-CoV-2 infection, and gross hematuria and/or transient worsening of kidney function have occurred after COVID-19 vaccination in patients with IgA nephropathy, possibly due to augmented immune injury.[28-31]

Treatment and Prognosis

Despite a 50% or higher incidence of severe AKI requiring KRT in patients with COVID-19–associated CG, kidney function and proteinuria improve in many patients up to 90 days after resolution of infection. Therefore, those who are discharged on KRT should be monitored closely for recovery of kidney function.[19,22,23,25] All patients should receive supportive care directed at blood pressure control and maintaining euvolemia. Treatment with immunosuppression can be considered in those with severe nephrotic syndrome or persistent nephrotic range proteinuria that fails to improve despite resolution of infection, though potential risks of immunosuppression in patients with active or recent infection must be considered.

COVID-19–associated TMA is associated with a poor prognosis including dialysis dependence and high mortality. In the absence of controlled clinical studies to guide treatment, clinicians may consider interventions used for non–COVID-19–related TMA including plasma exchange and terminal complement inhibitors.

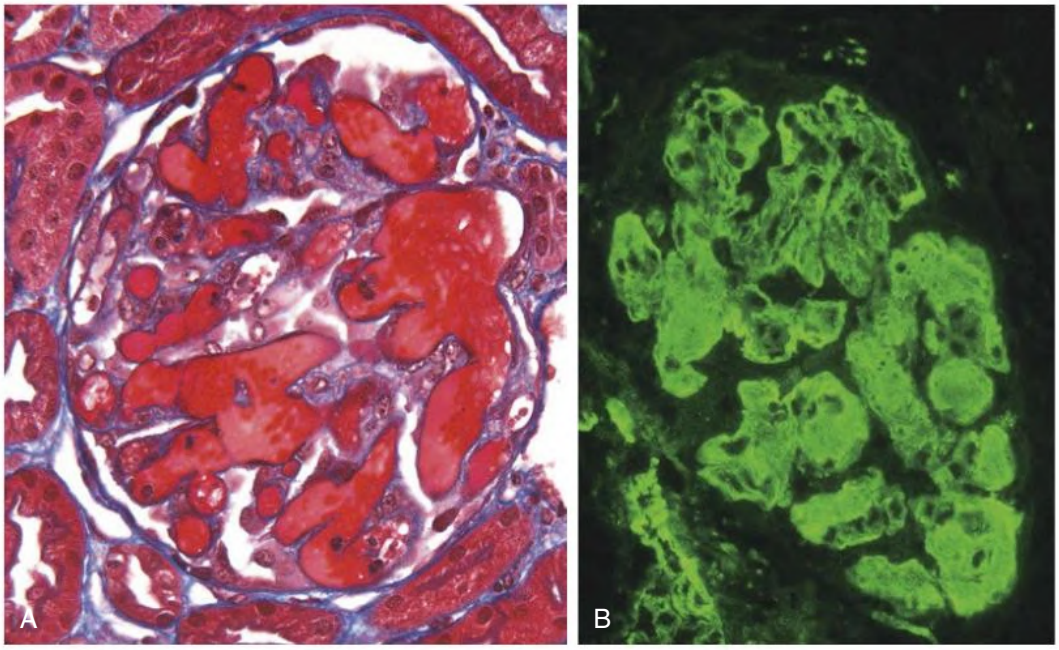

Fig. 59.4 Thrombotic Microangiopathy in a Patient With COVID-19 Presenting With Hypertension, Anemia, Thrombocytopenia, Hematuria, and Proteinuria. (A) Glomerulus with global capillary thrombosis. (B) Immunofluorescence showing extensive glomerular fibrin deposition.

COVID-19 IN PATIENTS WITH KIDNEY FAILURE REQUIRING CHRONIC DIALYSIS

COVID-19 incidence and mortality are significantly increased in patients with end-stage kidney disease (ESKD). Male sex, older age, and residence in a congregate setting have been consistently identified as risk factors for contracting COVID-19, whereas home dialysis has been associated with a reduced risk of infection compared with in-center dialysis.[32]

Hospitalization rates approach 60% or higher among chronic dialysis patients with COVID-19 compared with 15% to 20% observed in the general population.[33,34] Moreover, ESKD patients hospitalized with COVID-19 have 1.4-fold higher odds of in-hospital death after adjusting for demographics and comorbidities, suggesting ESKD is an independent risk factor for mortality due to COVID-19.[35] National and international registries estimate short-term mortality of 20% or greater among all dialysis patients with COVID-19 and 40% mortality in those who require hospitalization, underscoring the importance of prevention in this vulnerable population.[36]

Patients receiving in-center dialysis are at increased risk for contracting COVID-19 due to the requirement of transportation to and from dialysis and frequent contact with caregivers, health care providers, nonmedical staff, and other patients.[37] Thus, prevention of infection at the dialysis unit is critical. Screening for signs and symptoms of COVID-19 should be performed prior to each dialysis session. Additionally, some centers perform weekly point-of-care testing of all dialysis patients, which may lead to early detection of COVID-19 prior to symptom onset and may help prevent disease spread. For patients with suspected or confirmed COVID-19, dialysis must be provided in a location and manner that minimizes risk to staff and patients.[37]

COVID-19 IN KIDNEY TRANSPLANT RECIPIENTS

Epidemiology and Risk Factors

Compared to the general population, kidney transplant recipients are at increased risk of hospitalization and death from COVID-19 due to treatment with immunosuppressive medications and excess burden of comorbidities. The incidence of AKI may exceed 50%, and allograft loss has been reported in 4% to 11% of patients.[38] Large registries of KTRs with symptomatic COVID-19 report hospitalization rates of 87% to 100% and mortality of 19% to 32%.[38,39] However, routine testing for SARS-CoV-2 IgG antibodies in asymptomatic patients suggests that a significant proportion of KTRs have a mild disease course. One transplant center that performed routine testing for SARS-CoV-2 antibodies found that 42% of KTRs who tested positive were asymptomatic or had mild symptoms not requiring medical attention.[40]

Treatment and Management of Immunosuppression

Decisions regarding reduction in immunosuppression in KTRs should be based on severity of illness and weighed against the risks of allograft loss. Factors to consider when reducing immunosuppressive medications include allograft function, history of rejection, and presence of donor-specific antibodies. Most centers recommend a 50% dose reduction or complete cessation of the antimetabolite in KTRs with COVID-19.[41,42] In patients with worsening symptoms or evidence of COVID-19 pneumonia, the calcineurin inhibitor (CNI) should be reduced to target the lower limit of the therapeutic range, and an increase in corticosteroid dosing can be considered. In those requiring ventilatory support, CNI withdrawal should be considered, and corticosteroid dosing should be increased to prevent acute rejection.

Recipient and Donor Screening and Selection

Both donor and prospective KTRs should have negative SARS-CoV-2 reverse transcriptase polymerase chain reaction (RT-PCR) testing prior to transplantation. Screening with chest computed tomography may reveal signs of COVID-19–related disease preceding a positive test and may be considered.[38] Donors with active or recent COVID-19 should be declined or deferred. T cell–depleting induction therapy may reduce viral clearance and decrease the ability to mount an immune response to SARS-CoV-2. In highly sensitized patients who require potent immunosuppression, it may be reasonable to delay transplantation until vaccination. Though it is unknown how

long transplantation should be deferred in prospective KTRs who test positive, the American Society of Transplantation suggests waiting for resolution of symptoms and at least 2 negative SARS-CoV-2 RT-PCR tests.[43]

RENIN-ANGIOTENSIN SYSTEM INHIBITORS IN COVID-19

The ACE2 receptor, the entry receptor for SARS-CoV-2, is upregulated by angiotensin-converting enzyme (ACE) inhibitors and angiotensin II (Ang II) receptor blockers (ARB), leading to theoretical concerns that these medications may increase susceptibility to COVID-19. However, ACE2 is a carboxypeptidase that reduces Ang II levels by cleaving Ang II to Ang (1–7) and by cleaving Ang I to Ang (1–9), which is converted by ACE to Ang (1–7), which binds the MAS receptor.[44] These effects of ACE2 are cytoprotective, and increased lung expression of ACE2 is associated with improved outcomes in lung injury,[3] leading investigators to study whether ACE inhibitors and/or ARB are protective or harmful in patients with or at risk for COVID-19. At this time, there is no compelling evidence that ACE inhibitors/ARBs affect susceptibility to or severity of COVID-19, and major medical societies, including the American Society of Nephrology and the American Heart Association, have issued statements urging clinicians to continue prescribing these medications for patients who are likely to otherwise benefit from them.

ANTI–SARS-COV-2 THERAPIES AND VACCINES IN PATIENTS WITH KIDNEY DISEASE

At this time, no evidence-based recommendations can be made regarding the use of antiviral therapies in patients with kidney disease and COVID-19. Most clinical trials evaluating the use of these medications have excluded patients with severe kidney disease and/or KTRs. Monoclonal anti-SARS-CoV-2 therapies do not require dose adjustment for kidney function. Remdesivir is not currently recommended in those with eGFR less than 30 mL/min/1.73 m^2, though small series have reported its use in patients with ESKD or AKI requiring dialysis.[45] The carrier molecule of remdesivir is eliminated by the kidney and may accumulate in those with eGFR less than 30 mL/min/1.73 m^2. One study using postmarketing data found that remdesivir was associated with sevenfold higher odds of AKI compared with other COVID-19 therapies.[46] Therefore, caution should be used in patients with reduced eGFR and in those at high risk for development of AKI. The optimal timing of hemodialysis relative to remdesivir dosing remains to be determined.

Data on vaccine efficacy for prevention of COVID-19 in patients with severe CKD are currently lacking. Small preliminary studies suggest that patients with ESKD receiving dialysis mount vigorous antibody responses after vaccination[47]; however, KTRs may have weakened antibody responses.[48] Given the increased risk of COVID-19–related complications in patients with kidney disease, it is important to prioritize these patients for vaccination and to optimize approaches to maximize the efficacy of vaccination in this vulnerable population.

CONCLUSIONS

Acute and chronic kidney injury are important complications of COVID-19 and determinants of clinical outcomes in patients with COVID-19. Further research is needed to identify novel strategies to prevent and treat COVID-19 induced kidney injury and to determine optimal approaches to improve outcomes in patients with COVID-19 who have kidney disease.

Nephrolithiasis and Nephrocalcinosis

Wei Chen, David A. Bushinsky

NEPHROLITHIASIS

Epidemiology

Kidney stones are common in high-income countries, with an annual incidence of more than 1 in 1000 persons and a lifetime risk for forming stones of approximately 9% in women and 13% in men.[1-4] In the United States the prevalence of nephrolithiasis increased from 3.2% in the late 1970s to 5.2% in the 1990s, to 8.8% in the first decade of the 2000s, and further to approximately 10% in the 2010s, in parallel with the rising incidence of obesity, insulin resistance, and type 2 diabetes mellitus.[5-7] Factors that determine kidney stone prevalence include age, sex, race, and geographic distribution. Incidence peaks in the third and fourth decades, and prevalence increases with age until approximately 70 years in men and 60 years in women. Men are more prone to stone formation than women.[5] In the United States, Whites are more likely to develop kidney stones than African Americans, Hispanics, or Asian Americans, but the prevalence is rising in non-Whites as well.[5] The tendency in the United States for the development of stones also depends on geographic location, with an increasing prevalence from north to south and, to a lesser degree, from west to east. The increase in nephrolithiasis rates from north to south may be due to increased environmental temperatures, and greater sunlight exposure leading to an increase in insensible losses through sweating and more concentrated urine.[1,8] The higher urine calcium excretion in a smaller urine volume will increase the risk for supersaturation for calcium-containing crystals, thereby promoting stone formation.

Stone type varies with worldwide geography and genetic predisposition. In the Mediterranean and Middle East, 75% of stones are composed of uric acid. In the United States, the majority of stones are calcium oxalate and/or calcium phosphate (>70%), with less than 10% being pure uric acid stones. Magnesium ammonium phosphate (struvite) stones account for 10% to 25% of stones formed (with a higher incidence in the United Kingdom), and cystine stones constitute 2% of all stones formed (Fig. 60.1).[9]

Kidney stones are associated with systemic conditions including chronic kidney disease (CKD), cardiovascular disease, and bone disease. In a Canadian cohort,[10] having one or more episodes of kidney stones was associated with increased risk for end-stage kidney disease (ESKD; adjusted hazard ratio [HR], 2.16; 95% confidence interval [CI], 1.79–2.62) and development of CKD (HR, 1.74; 95% CI, 1.61–1.88). The risk for CKD development was greater in women than in men and in people younger than 50 years. However, the absolute increase in the rate of adverse kidney outcomes associated with kidney stones was small; the unadjusted rate of ESKD was 2.48 and 0.52 per million person-days in people who developed kidney stones and in people without stones, respectively. Development of kidney stones was associated with increased risk for coronary heart disease in women but not in men, and with greater aortic calcification.[11,12] Those with calcium-based stones were shown to have lower bone mineral density and higher risk of fracture than non–stone formers.[12-14]

Pathogenesis

Stones occur in urine that is supersaturated with respect to the ionic constituents of the specific type of stone. Supersaturation depends on the product of the free ion activities of stone components rather than on their molar concentrations. The free ion activities of stone components can be affected by the concentration of the crystal components, presence of inhibitors, and urine pH. An increasing concentration of the components of the crystal increases their free ion activity. When calcium and oxalate are dissolved in pure water, the solution becomes saturated when the addition of any more calcium or oxalate does not result in further dissolution. However, urine, unlike pure water, contains numerous calcification inhibitors that can form soluble complexes with the ionic components of the stone. The interactions with these inhibitors (e.g., citrate) may result in a decrease in free ion activity that allows the stone constituents to increase in total concentration to levels that would normally cause stone formation in pure water. Urinary pH also influences free ion activity. The level of chemical free ion activity in which stones will neither grow nor dissolve is referred to as the *equilibrium solubility product,* or the upper limit of metastability. Above this level, the urine will be supersaturated, and any stone present will grow in size.

When the solution becomes supersaturated with respect to a solid phase, ions can join together to form the more stable, solid phase, a process termed *nucleation.* Homogeneous nucleation refers to the joining of similar ions into crystals. The more common and thermodynamically favored heterogeneous nucleation results when crystals grow adjacent to crystals or other substances in the urine, such as sloughed epithelial cells. Calcium oxalate crystals, for example, can nucleate with uric acid crystals. These small crystals may then aggregate to form larger stones, which would pass into the urine, causing crystalluria, if they did not anchor to the urothelium.

Calcium oxalate crystals anchor on areas of calcium phosphate deposits termed *Randall plaques,* which are located in the renal papillae. Randall plaques appear to originate around the thin loop of Henle. In the outer medulla, the vascular bundles are surrounded by the thick ascending limb, which absorbs calcium independently of water. As the delivery of calcium to the thick ascending limb increases, the calcium concentration in the vascular bundles increases. This promotes supersaturation of crystals in the thin limb, which fosters plaque formation.

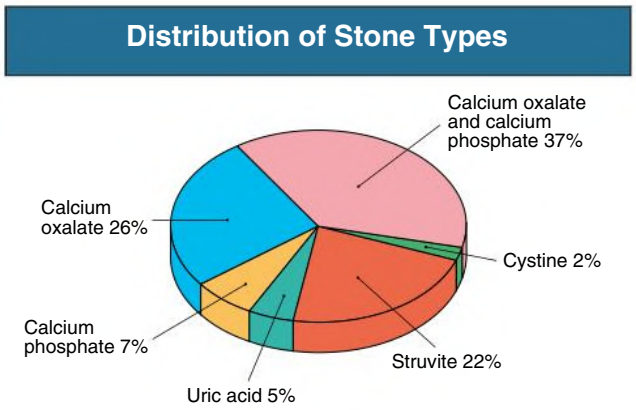

Fig. 60.1 Proportion of stone types in a typical U.S. population.

Fig. 60.2 Ureteral Calculus. A 1-cm-wide calcium oxalate stone that provoked ureteral colic and required surgical removal.

TABLE 60.1 Clinical Presentations of Nephrolithiasis

Presentation	Characteristics
Pain	Ureteral colic, loin pain, dysuria
Hematuria	–
Urinary tract infection	Recurrent, chronic infection, pyelonephritis
Asymptomatic urine abnormality	Microhematuria, proteinuria, sterile pyuria
Interruption of urinary stream	–
Calculus anuria	–

BOX 60.1 Causes of Hematuria

- Nephrolithiasis
- Infection: cystitis, prostatitis, urethritis, acute pyelonephritis, tuberculosis, schistosomiasis
- Malignancy: renal cell carcinoma, transitional cell carcinoma, prostate cancer, Wilms tumor
- Trauma
- Glomerular disease
- Interstitial nephritis
- Polycystic kidney disease
- Papillary necrosis
- Medullary sponge kidney
- Miscellaneous: loin pain–hematuria syndrome, arteriovenous malformation, chemical cystitis, caruncle, factitious

This theoretical mechanism is referred to as *vas washdown* and has yet to be proven experimentally.[15] Calcium oxalate crystals attach to Randall plaques, allowing significant stone growth.[16] Clinically apparent stone disease occurs when the calcium oxalate crystals break off from the Randall plaques and cause injury or obstruction.

Several genetic polymorphisms have been implicated in the pathogenesis of calcium stones in genome-wide association studies. They include genes coding for proteins regulating tubular calcium and phosphate reabsorption (e.g., calcium-sensing receptor, vitamin D receptor, and claudins), genes coding for proteins preventing calcium salt precipitation (e.g., matrix Gla protein), and genes coding for aquaporin in the proximal tubule.[3,17] Besides genetic polymorphisms, microbiome and exposure to antibiotics have also been implicated in the pathogenesis of nephrolithiasis. Exposure to sulfas, fluoroquinolones, cephalosporins, nitrofurantoin/methenamine, and broad-spectrum penicillin was associated with increased odds of nephrolithiasis.[18,19] Antibiotics may change the composition of the intestinal microbiome and alter the metabolism of macronutrients and ionic absorption, thus affecting the risk of nephrolithiasis.

Clinical Manifestations

The two most characteristic symptoms of nephrolithiasis are pain and hematuria. Other presentations include urinary tract infection (UTI) and acute kidney injury caused by obstructive uropathy if stones cause bilateral kidney outflow tract obstruction or unilateral obstruction in a single functioning kidney (Table 60.1).

Pain

The classic manifestation of pain in patients with nephrolithiasis is ureteral colic. Pain is of abrupt onset and intensifies over time into an excruciating, severe flank pain that resolves only with stone passage or removal. The pain may migrate anteriorly along the abdomen and inferiorly to the groin, testicles, or labia majora as the stone moves toward the ureterovesical junction. Gross hematuria, urinary urgency, frequency, nausea, and vomiting may occur. Stones smaller than 5 mm usually pass spontaneously with hydration, whereas progressively larger stones are increasingly likely to require urologic intervention (Fig. 60.2).[16] Ureteral colic may occur with the passage of clots from hematuria of any cause ("clot colic") or with papillary necrosis. Nephrolithiasis also may provoke less-specific loin pain that poorly localizes to the kidney and therefore has a wide differential diagnosis, particularly if not associated with other urinary symptoms. The finding of a stone on radiologic examination does not preclude a coincidental cause of pain from another source.

Hematuria

Stone disease is a common cause of hematuria. Macrohematuria occurs more commonly with large calculi and during UTI and colic. Although typically associated with loin pain or ureteral colic, the hematuria of nephrolithiasis also may be painless. The clinical differential diagnosis of hematuria is wide (Box 60.1). Painless microhematuria in children may occur with hypercalciuria in the absence of demonstrable stones.

Loin Pain–Hematuria Syndrome

Loin pain–hematuria syndrome is a poorly understood condition that must be considered in the differential diagnosis of nephrolithiasis. It is diagnosed by exclusion when patients (most typically young and middle-aged women) present with loin pain and persistent microhematuria or intermittent macrohematuria.[20] Careful evaluation is required to exclude small stones, tumor, UTI, and glomerular disease.

Angiographic abnormalities implying intrarenal vasospasm or occlusion have been reported, as have kidney biopsy abnormalities typified by deposition of complement C3 in arteriolar walls. However, these findings are not consistent, nor do they provide a coherent framework to explain the pathogenesis of this condition.

In one study, 43 consecutive patients with clinical manifestations of loin pain–hematuria syndrome were evaluated by kidney biopsy after other causes of their symptoms had been excluded with at least two imaging studies.[20] Thirty-four patients were considered to have idiopathic loin pain–hematuria syndrome after nine with histologic evidence of immunoglobulin A nephropathy were excluded. Of these, 66% had glomerular basement membranes that were either unusually thick or thin on electron microscopy and 47% had a history of kidney stones, though none had obstructing stones at the time of imaging assessment. Evidence of glomerular hematuria was more common in biopsy samples of patients with loin pain–hematuria syndrome compared with those of healthy living kidney donors who also underwent kidney biopsy. The investigators postulated that the structurally abnormal glomerular basement membranes in the majority of these patients may lead to rupture of the glomerular capillary walls, with consequent hemorrhage into the renal tubules and tubular obstruction by red blood cells, triggering kidney edema, stretching of the renal capsule, and severe flank pain.

Loin pain–hematuria syndrome is a chronic condition requiring reassurance, careful management of analgesia, and ongoing psychological support. The condition usually remits after several years. Denervation of the kidney by autotransplantation is rarely successful. The extreme measure of nephrectomy has been used, but pain often recurs promptly in the contralateral kidney. Bilateral nephrectomy and kidney replacement therapy have been reported as an approach of very last resort. Referral to a pain clinic can assist in providing psychiatric counseling, analgesia, and exclusion of other disorders. In one retrospective study, patients who eventually came to accept a nonsurgical approach along with pain-coping strategies that did not involve narcotic analgesics had the most successful outcomes.[21]

Asymptomatic Stone Disease

Even large staghorn calculi may be asymptomatic and discovered only during the investigation of unrelated abdominal or musculoskeletal symptoms. Obstructive uropathy caused by calculi also may be painless; therefore, nephrolithiasis always should be considered in the differential diagnosis of unexplained kidney failure. In an outbreak of melamine-associated nephrolithiasis in Chinese infants, the majority of patients brought to a screening clinic had no symptoms or signs of stones, and the diagnosis of nephrolithiasis was made only by ultrasound in at-risk infants and toddlers.[22]

Clinical Evaluation of Stone Formers

All patients with recurrent nephrolithiasis merit metabolic evaluation to determine the cause of their kidney stones.[23] Patients with a single stone should at least undergo a basic evaluation. Those with metabolically active stones (stones growing in size or number within 1 year), all children, non–calcium stone formers, and patients in demographic groups not typically prone to stone formation warrant a complete evaluation, which includes a 24-hour urine collection made with the patient ingesting his or her typical diet.

Basic Evaluation

The evaluation of stone formers includes a careful history and physical examination and requires specific data gathering on stone formation, diet, and specific laboratory studies, as shown in Box 60.2.

BOX 60.2 Basic Evaluation of Nephrolithiasis

- Stone history
  - Number of stones formed
  - Frequency of stone formation
  - Age at first onset
  - Size of stones passed or still present
  - Kidney involved (left, right, or both)
  - Stone type, if known
  - Need for urologic intervention such as extracorporeal shock wave lithotripsy or percutaneous nephrolithotomy
  - Response to surgical procedure
  - Association of stones with urinary tract infections
- Medical history
- Medications
- Family history
- Occupation and lifestyle
- Fluid intake and diet
- Physical examination
  - Evidence of systemic causes of stones (e.g., tophi)
- Laboratory data
  - Urinalysis
  - Urine culture
  - Stone analysis
- Blood chemistry
  - Sodium, potassium, chloride, bicarbonate
  - Creatinine, calcium, phosphorus, uric acid
  - Intact parathyroid hormone level if calcium elevated
- Radiologic evaluation
  - Abdominal radiograph (no contrast)
  - Noncontrast computed tomography
  - Ultrasound (generally recommended)

History. The history may uncover a systemic cause for nephrolithiasis. Any disease that can lead to hypercalcemia (including malignancy, hyperparathyroidism, and sarcoidosis) can result in hypercalciuria and increase the risk for calcium stone formation. A number of malabsorptive gastrointestinal disorders (including Crohn disease and celiac disease) can result in calcium oxalate stone formation as a result of volume depletion and hyperoxaluria. Uric acid stones often occur in patients with a history of gout and insulin resistance.[9]

The stone history (see Box 60.2) includes the number and frequency of stones formed, patient age at incidence of first stone, size of stones, stone type (if known), and whether the patient required surgical removal of the calculi. This information indicates the severity of the stone disease and provides clues to the cause of the stone formation. For example, large staghorn calculi that do not pass spontaneously and recur despite frequent surgical intervention are more consistent with struvite than calcium oxalate stones. Stones that develop at a young age may be caused by cystinuria or primary hyperoxaluria. Stone response to intervention is also significant; cystine stones, for example, do not fragment well with lithotripsy. If stones recur frequently in a single kidney, a congenital abnormality in that kidney, such as megacalyx or medullary sponge kidney, should be explored.

Family history is important because a number of stone types have a genetic basis. Idiopathic hypercalciuria appears to be a polygenic disorder. Mutations in the claudins, which regulate calcium reabsorption in the thick ascending limb of the loop of Henle, cause familial hypercalciuria and nephrocalcinosis. A genome-wide association study in

BOX 60.3 Medications Associated With Nephrolithiasis and Nephrocalcinosis

Calcium Stone Formation
- Loop diuretics
- Vitamin D
- Corticosteroids
- Calcium supplements
- Antacids (calcium and noncalcium antacids)
- Theophylline
- Acetazolamide[a]
- Amphotericin[a]
- Topiramate

Uric Acid Stone Formation
- Salicylates
- Probenecid
- Melamine (in contaminated infant formula and milk products)

Medications That May Precipitate Into Stones
- Triamterene
- Acyclovir (if infused rapidly intravenously)
- Indinavir
- Nelfinavir

[a] Associated with nephrocalcinosis.

BOX 60.4 Foods High in Oxalate and Purine

High-Oxalate Foods (Avoid in Setting of Hyperoxaluria)
- Green beans
- Beets
- Celery
- Green onions
- Leeks
- Leafy greens: collard greens, dandelion greens, Swiss chard, spinach, escarole, mustard greens, sorrel, kale, rhubarb
- Cocoa
- Chocolate
- Black tea
- Berries: blackberries, blueberries, strawberries, raspberries, currants, gooseberries
- Orange peel
- Lemon peel
- Dried figs
- Summer squash
- Nuts, peanut butter
- Tofu (bean curd)

High-Purine Foods (Avoid in Setting of Hyperuricosuria)
- Organ meats: sweetbreads, liver, kidney, brains, heart
- Shellfish
- Meat: beef, pork, lamb, poultry
- Fish: anchovies, sardines (canned), herring, mackerel, cod, halibut, tuna, carp
- Meat extracts: bouillon, broth, consommé, stock
- Gravies
- Certain vegetables: asparagus, cauliflower, peas, spinach, mushrooms, lima and kidney beans, lentils

patients with kidney stones identified sequence variants in the gene encoding claudin 14 that were associated with hypercalciuria.[24]

Cystinuria is usually autosomal recessive, and hyperuricosuria has been associated with rare inherited metabolic disorders. Nephrolithiasis and nephrocalcinosis can result from a variety of monogenic disorders, such as Dent disease (X-linked recessive nephrolithiasis), McCune-Albright syndrome, osteogenesis imperfecta type 1, and congenital lactate deficiency (see also Chapter 50). The various genetic disorders can lead to hypercalciuria by increasing bone resorption, affecting intestinal absorption, by decreasing renal tubular reabsorption transport, or by unknown mechanisms.[1,16,24]

Certain medications can potentiate calcium stone formation (e.g., loop diuretics are calciuric) or may predispose to uric acid lithiasis (salicylates, probenecid) (Box 60.3). Drugs can also precipitate into stones themselves, such as rapidly infused intravenous acyclovir, high-dose sulfadiazine, triamterene, and the antiretroviral agents indinavir and nelfinavir.[25] In addition, some medications (e.g., acetazolamide, topiramate) promote nephrolithiasis by inhibiting carbonic anhydrase activity. With these drugs, the metabolic acidosis that ensues, along with lower urine citrate, higher urine pH, and increased urinary calcium excretion, predisposes to calcium phosphate stone formation.

The social history should include details regarding occupation and lifestyle. Surgeons and real-estate agents, for example, may minimize fluid intake to avoid bathroom breaks during the workday. Those who engage in vigorous physical activities, such as running, may not rehydrate adequately to keep up with insensible losses, producing excessively concentrated urine and precipitation of stone crystals in those prone to nephrolithiasis.

A dietary history and review of fluid intake are essential in determining potential causes or contributors to stone formation. The patient should be asked about commonly consumed foods, with attention paid to sodium-containing foods, as well as quantities of calcium, animal protein, purine, and oxalate (Box 60.4). Dietary calcium intake should be reviewed, because many patients with nephrolithiasis are erroneously instructed to eliminate all calcium from their diet, a suggestion that can result not only in bone demineralization, particularly in women and children, but also in an increase in stone formation.[2-4,26] Sugar-sweetened soda appears to be associated with a greater risk for stone formation, whereas consumption of coffee, tea, beer, wine, and orange juice appears to be associated with a lower risk.[27] The exact mechanism of nephrolithiasis from soda is not known but is likely related to the high fructose content of soda, which may trigger a vasopressin-dependent concentration of urine, lower urinary pH, and cause uricosuria.[28,29]

Physical examination. Most patients with idiopathic hypercalciuria are healthy and have normal findings on physical examination. Patients with hyperuricosuria and uric acid stone formation may display tophi. Central obesity is associated with a predisposition to metabolic syndrome and uric acid stones. Paraplegic patients with a chronic indwelling bladder catheter may be predisposed to chronic UTI and struvite stones.

Laboratory findings. Urine pH is generally high in patients with struvite and calcium phosphate stones but low in patients with uric acid and calcium oxalate stones. Bacteriuria with urine pH greater than 7.0 suggests struvite stones. Urine should be cultured, and because many bacteria produce urease even when urine bacterial colony counts are low, the microbiology laboratory should be instructed to type the organism even if there are fewer than 10^5 colony-forming units/mL. The specific gravity, if high, will confirm inadequate fluid intake in many patients. Hematuria may imply active stone disease with crystal or stone passage. Examination of the urine may reveal red blood cells along with characteristic crystals (Fig. 60.3).

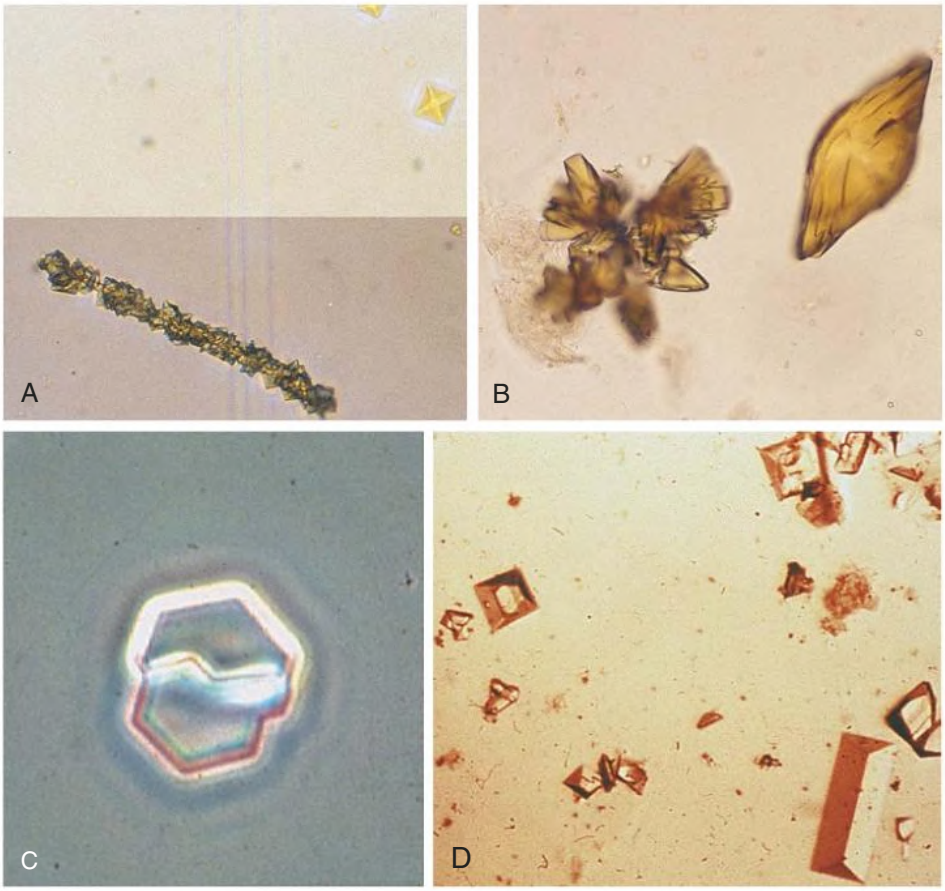

Fig. 60.3 Urine Crystals. (A) Oxalate crystals: a pseudocast of calcium oxalate crystals accompanied by crystals of calcium oxalate dihydrate. (B) Uric acid crystals: complex crystals suggestive of acute uric acid nephropathy or uric acid nephrolithiasis. (C) A typical hexagonal cystine crystal; a single crystal provides a definitive diagnosis of cystinuria. (D) Coffin lid crystals of magnesium ammonium phosphate (struvite). (Courtesy Dr. Patrick Fleet, University of Washington, Seattle.)

Blood tests required in the basic evaluation are serum electrolytes (sodium, potassium, chloride, and bicarbonate), creatinine, calcium, phosphorus, and uric acid. If the serum calcium is elevated or at the upper limit of normal, serum parathyroid hormone level should be measured, especially if the serum phosphorus is low. A low potassium or bicarbonate level may indicate a cause for hypocitraturia, such as distal renal tubular acidosis.

Stone analysis. Patients should be encouraged to retrieve any stone they excrete for chemical analysis, which may help define the underlying metabolic abnormality and guide therapy.

Imaging. Current imaging techniques used to evaluate stones include plain abdominal radiograph, unenhanced helical computed tomography (CT), and kidney ultrasound. Plain abdominal radiography performed with views of the kidneys, ureters, and bladder (KUB) may reveal opacifications in the areas of the kidneys and ureters that could be a result of calcium, cystine, or struvite stones (Fig. 60.4). Uric acid and xanthine calculi are radiolucent and will not be visible on plain films. Unenhanced helical CT scanning, also known as spiral CT, or CT urography, has replaced contrast intravenous urography (IVU) as a diagnostic test for acute ureteral colic because it is more sensitive and specific for ureteral stones and ureteral obstruction, and avoids the need for contrast (see Fig. 60.5A). Results from CT urography are available in minutes rather than hours, and this is an advantage in the emergency setting. There are several disadvantages of CT imaging: radiation dose from a CT urography is approximately three times that of a conventional IVU; CT urography is more expensive and is associated with a high rate of incidental findings that could lead to inappropriate referral and treatment. In addition, an experienced radiologist is required for optimal interpretation of the images, and may not be available at all times in urgent care facilities. CT urography should be avoided or limited in patients at risk for radiation exposure, such as children and pregnant women. Low-dose CT reduces radiation exposure and provides similar information to that provided by standard CT. However, low-dose CT is not recommended for patients with a body mass index greater than 30 kg/m^2.[30]

Kidney ultrasound has a lower sensitivity and specificity than CT but does not expose patients to ionizing radiation and is less expensive. A recent study indicated that ultrasonography may be a better choice than CT, especially for those patients who must avoid radiation exposure (Fig. 60.5B). In a multicenter, comparative effectiveness trial, 2759 patients who presented to the emergency department (ED) with suspected nephrolithiasis were randomized to undergo either initial ultrasound or abdominal CT.[31] Ultrasound was associated with lower cumulative radiation exposure than initial CT. There were no significant differences in high-risk diagnoses with complications (e.g., abdominal aortic aneurysm with rupture, pneumonia with sepsis), serious adverse events, pain scores, return visits to the emergency department, or hospitalizations between the ultrasound (whether assigned to either point of care in the emergency department or to the radiology department) and CT. Ultrasonography is the first-line imagining modality for pregnant women and patients younger than 14 years.[30]

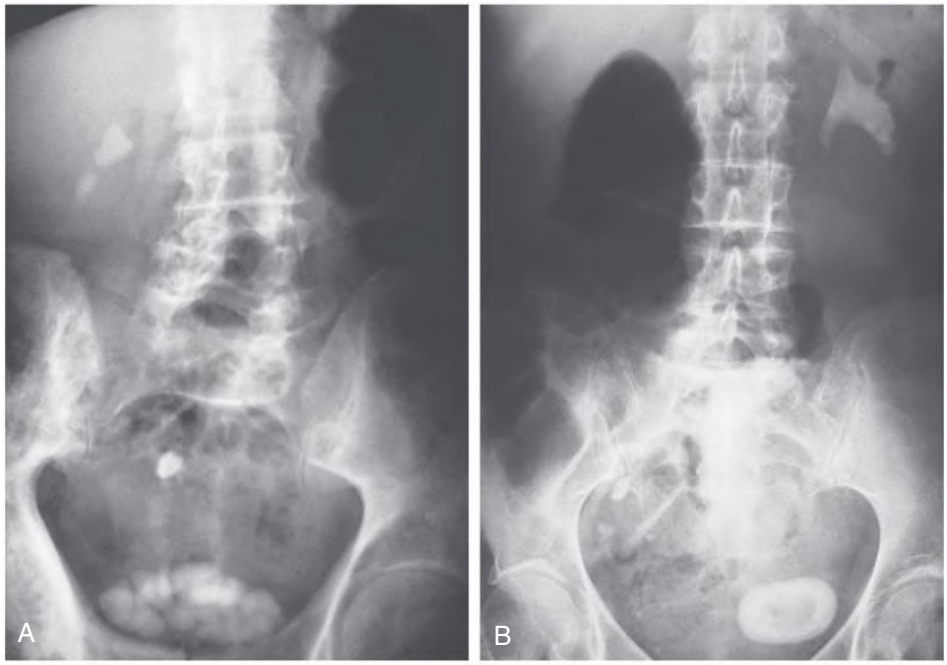

Fig. 60.4 Radiopaque Kidney Calculi. (A) Radiograph showing multiple cystine stones in the right kidney, right ureter, and bladder. (B) Struvite stones: left staghorn calculus and a single bladder stone.

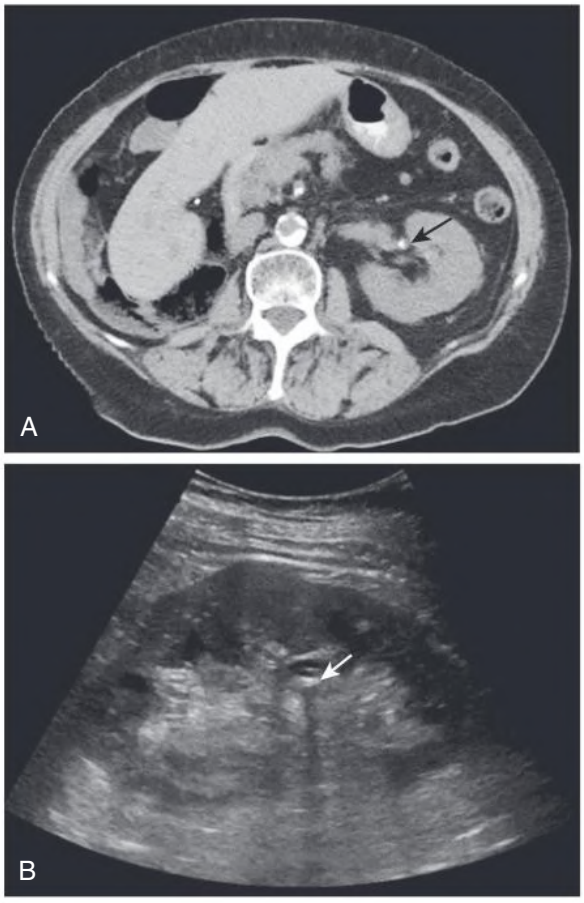

Fig. 60.5 Kidney Calculi. (A) Unenhanced computed tomography scan showing a nonobstructing left kidney stone *(arrow)* in a patient with right nephrectomy. (B) Ultrasound of the left kidney (sagittal view) from the same patient showing a stone with an acoustic shadow behind it *(arrow)*.

Periodic monitoring, if deemed necessary, should be obtained with an ultrasound scan rather than KUB or CT, whenever possible, to minimize radiation exposure. The combination of ultrasound and KUB is more sensitive in detecting stones than either test alone, while minimizing radiation compared with CT. Many patients with stones have recurrent disease and may require repeated imaging. Children and young adults are at higher risk for consequences from radiation exposure, and studies in this population should be limited. Especially when caring for patients who may father or subsequently carry offspring, every effort should be made to limit radiation exposure. In general, we do not order routine follow-up radiographic examinations and do not order radiographic examinations unless patients are symptomatic and the results will alter subsequent care. If radiographs are ordered, every effort should be made to limit radiation exposure, as the results of a noncontrast study alone are often sufficient to guide therapy.

Complete Evaluation

A complete evaluation should be arranged for patients with multiple or metabolically active stones (i.e., stones that increase in size or number within a year), in all children, in patients from demographic groups not typically prone to stone formation, and in those with stones other than those containing calcium.[23]

The complete evaluation should include a measure of urine volume and the quantity of calcium, oxalate, phosphorus, uric acid, sodium, citrate, and creatinine excreted in a 24-hour urine collection (Table 60.2). Urine creatinine is useful in assessing adequacy of the collection; men should excrete more than 15 mg/kg (132.6 μmol/kg), and women should excrete more than 10 mg/kg (88.4 μmol/kg) daily. Patients should be encouraged to perform the urine collection on a typical day while eating their usual diet, although many patients prefer to collect the urine on weekends when their diet and habits may differ from those during usual workdays. Specialized testing, such as urine collections during high- or low-dietary calcium intake, is not recommended. Careful instructions should be given to avoid overcollection or undercollection. Patients should be instructed to discard the first morning

TABLE 60.2 Optimal 24-Hour Urine Values in Recurrent Nephrolithiasis

24-Hour Urine Values	
Volume	>2–2.5 L
Calcium	<4 mg/kg (0.1 mmol/kg), ~300 mg (7.5 mmol) in men, ~250 mg (6.3 mmol) in women
Oxalate	<40 mg (0.36 mmol)
Uric acid	<750 mg (4.5 mmol) in women and <800 mg (4.7 mmol) in men (can be pH dependent)
Citrate	>320 mg (17 mmol)
Sodium	<2000 mg (87 mmol)
Phosphorus	<1100 mg (35 mmol)
Creatinine	>10 mg/kg (88 µmol/kg) in women and >15 mg/kg (132 µmol/kg) in men, if specimen is a complete collection
Urine Supersaturation Values	
Calcium oxalate supersaturation	<5
Calcium phosphate supersaturation	0.5–2
Uric acid supersaturation	0–1

urine at the start of the collection and collect all urine for the next 24 hours, including the first urine collection on the second morning.

A disadvantage of the standard 24-hour urine collection is that laboratories vary in the preservatives required to process the various constituents. Many laboratories require more than one collection to measure all the urinary constituents, reducing compliance and therefore the accuracy of the results, and supersaturation is often not calculated.

A better approach available in some speciality laboratories is to undertake a 24-hour urine collection for the relevant urinary constituents and calculation of supersaturation for the common solid phases of calcium oxalate, brushite (calcium phosphate), and uric acid (see Table 60.2). Urine for supersaturation analysis has been shown to correlate well with stone composition, and the risk for stone formation rises with increasing supersaturation. Determination of supersaturation is far more informative and helpful for planning proper therapy than evaluation of only the individual urinary constituents.

Patients can bring their specimens to a local laboratory or may send them to specialized laboratories that measure calcium, oxalate, citrate, uric acid, creatinine, sodium, potassium, magnesium, sulfate, phosphorus, chloride, urine urea nitrogen, and pH. Calculation of supersaturation from a 24-hour urine specimen will provide values lower than the peak postprandial supersaturation and peak nighttime supersaturation, either of which may initiate stone formation. Patients should stop taking any vitamin C or multivitamins containing more than 100 mg of vitamin C for at least 5 days before the urine collection because the antioxidants in the vitamin may interfere with the assay.

General Treatment

Intervention for stone removal may be required when pain, obstruction, and/or infection resulting from nephrolithiasis do not respond to conservative management. Surgical management of stones includes extracorporeal shock wave lithotripsy (ESWL) and both endoscopic and percutaneous surgical removal of stones, and is further discussed in Chapter 63. The risk for developing reduced glomerular filtration rate (GFR) varies with the type of stone, and this must be considered in planning management.

Medical Management

Patients who are seen by stone "specialists" often have a substantial decrease in stone recurrence even without pharmacologic intervention.[32] This phenomenon, termed the *stone clinic effect*, is likely a result of modifications in diet and fluid intake. These nonpharmacologic measures include an increase in fluid intake, which increases urine volume; restriction of dietary sodium, which leads to a reduction of urine calcium excretion; restriction of animal protein, which also leads to a reduction of urine calcium and uric acid excretion and an increase in excretion of the calcification inhibitor citrate; and ingestion of an age- and sex-appropriate amount of dietary calcium, which will bind oxalate in the intestine, preventing its absorption. Although dietary calcium restriction continues to be prescribed by many physicians, substantial evidence indicates that this is not beneficial and can actually increase the rate of stone formation (see later discussion of calcium stones) and can promote bone demineralization.[4,26]

Fluid intake. An increase in urine volume to more than 2 to 2.5 L daily has been proven to reduce the incidence of stones. Large urine volumes will reduce calcium oxalate supersaturation, as well as precipitation of other crystals. Increased fluid intake to augment urine volume is also a mainstay of therapy for patients with uric acid and cystine stones. The period of maximum risk for stone formation is at night, when urine concentration is physiologically increased. Patients should be encouraged to drink enough fluid in the evening to provoke nocturia and then drink further fluid before returning to bed. Patients should avoid calorie-containing beverages, such as sugar-sweetened beverages, which may lead to weight gain and are associated with a higher risk of stone formation.[27]

Salt intake. Urine sodium excretion correlated directly with urine calcium excretion;[2,3] thus, dietary salt restriction is associated with decreased urine calcium excretion. Patients should be instructed to limit daily sodium intake to a maximum of 2 g (87 mmol).

Dietary protein. Animal protein ingestion increases the frequency of kidney stone formation by a number of mechanisms. Metabolism of certain amino acids leads to generation of sulfate ions, which render urinary calcium ions less soluble.[33,34] The metabolic acidosis that results from excess protein ingestion causes calcium release from bone and a consequent increase in the filtered load of calcium.[33,34] Acidosis also decreases tubular calcium reabsorption, resulting in hypercalciuria. Urinary citrate excretion is also pH dependent, with acidosis leading to a decrease in citrate excretion. The result of increased animal protein intake is an increase in urinary calcium excretion that is rendered less soluble because of concomitant sulfate excretion and hypocitraturia. Low urine pH, coupled with increased uric acid excretion from the metabolism of animal protein, can result in uric acid lithiasis. Stone formers should be encouraged to consume a moderate protein intake. Dietary fructose may also increase uric acid lithiasis.

Dietary calcium. Despite conventional wisdom, several studies have demonstrated a decrease in stone incidence when people consume diets adequate, but not excessive, in calcium (>1500 mg/day of calcium).[35] This beneficial effect has been attributed to intestinal binding of ingested oxalate (which is highly lithogenic) by dietary calcium preventing oxalate absorption. Although women have reduced stone formation while ingesting an age-appropriate amount of dietary calcium, this benefit may not extend to those taking calcium in the form of calcium supplements.[36] The data are inconsistent as to whether calcium supplements increase the risk for nephrolithiasis. Some have postulated that any increased risk may be a result of timing the supplemental calcium ingestion apart from meals, which would enhance calcium absorption without reducing oxalate absorption. In addition, the calcium supplements may dissociate rapidly, leading to rapid absorption, increased filtered calcium load, and transitory hypercalciuria, leading to increased supersaturation.

We advise patients that it is best to obtain calcium from dairy products rather than supplements.

Women ingesting calcium supplements may be at increased risk for cardiovascular disease and death compared with those not taking supplements, perhaps by promoting vascular calcification.[37] In one long-term study of more than 60,000 Swedish women, those with a dietary calcium intake exceeding 1400 mg/day had an increased risk for cardiovascular mortality with an HR of 1.49 (95% CI, 1.09–2.02). The risk for all-cause mortality rose to 2.57 (95% CI, 1.19–5.55) when any calcium tablet supplements were added to this high dietary intake.[38] A review of cardiovascular mortality in over 15 studies involving calcium supplementation versus placebo showed increased risk for myocardial infarction in those randomized to calcium supplements with an HR of 1.31 (95% CI, 1.02–1.67), which rose to 1.85 (95% CI, 1.28–2.67) in patients already taking more than 805 mg of dietary calcium daily.[37] In a 10-year follow-up of 5448 adults free of clinically diagnosed cardiovascular disease, calcium supplements increased the risk for incident coronary artery calcification (relative risk 1.22 [95% CI, 1.07–1.39]).[39] The Institute of Medicine in the United States recently adjusted the recommended allowance of calcium to 1000 mg/day for adults older than 19 years and 1200 mg/day for women older than 50 years.[40] We recommend that women take the appropriate amount of calcium in the form of food with limited supplement intake, except in cases of severe osteoporosis with insufficient dietary intake.

Support for the use of an age- and sex-appropriate amount of dietary calcium was provided by a randomized prospective study comparing the rate of stone formation in men assigned a low-calcium diet with those assigned a normal-calcium, low-sodium, and low–animal protein diet.[26] The men assigned the low-calcium diet were twice as likely to have recurrent stones over 5 years compared with those on the normal-calcium, low-sodium, and low–animal protein diet. Urinary calcium oxalate supersaturation also diminished more rapidly in those on the higher-calcium diet and remained lower than that of men on the low-calcium diet for most of the 5-year study. This reduction in supersaturation was the result of a greater fall in urinary oxalate in the men eating the normal-calcium, low-sodium, and low–animal protein diet.[26,41]

Patients prescribed a low-calcium diet can avoid excessive hyperoxaluria when adequately instructed to also consume a low-oxalate diet.[42] Some contend that this approach may benefit patients with excessive intestinal absorption of calcium associated with severe hypercalciuria by allowing calcium restriction without the risk for significant osteopenia. We recommend, however, an age- and sex-appropriate calcium intake, best derived from a diet containing an adequate number of dairy products. Because stone formation can be reduced with normal calcium intake and there is a risk for bone demineralization and osteoporosis with calcium restriction, we consider the low-calcium diet to be obsolete.[24,38]

Vitamin D. Given the great degree of vitamin D deficiency and insufficiency in northern latitudes, vitamin D supplementation is very common.[43] There is concern that this might exacerbate nephrolithiasis, given the role of vitamin D in mineral metabolism. Active forms of vitamin D, such as calcitriol, may increase urinary calcium excretion.[44] However, studies have shown no association between vitamin D supplementation in the form of ergocalciferol, cholecalciferol, or levels of serum 25-hydroxyvitamin D and calcium excretion, nor an increased rate of stone formation in hypercalciuric patients on vitamin D supplementation. Thus, vitamin D therapy should not be withheld in patients with vitamin D deficiency (25-hydroxyvitamin D levels <20 ng/mL) on the basis of kidney stone disease.[45] If needed, we prefer cholecalciferol (D_3) to ergocalciferol (D_2) because of its more robust biologic activity and longer half-life.

SPECIFIC TYPES OF STONES

Calcium Stones

Calcium-containing kidney stones constitute approximately 70% of all stones formed. Most calcium stones are composed of calcium oxalate, either alone or in combination with calcium phosphate or uric acid. A small percentage of stones are composed entirely of calcium phosphate.[2] Most calcium stones do not exceed 1 to 2 cm in width. Surgical intervention is often required for stones larger than 5 mm.

Calcium-based stones most often develop as a result of hypercalciuria. Other causes of calcium stones are hyperoxaluria, hyperuricosuria, hypocitraturia, renal tubular acidosis, certain medications, and congenital abnormalities of the genitourinary tract (Fig. 60.6). Specific therapy for patients with calcium stones depends on the underlying metabolic abnormalities detected on evaluation. General therapy as outlined earlier always should be instituted; however, more definitive treatment is often required to significantly decrease the rate of recurrent stone formation.

Hypercalciuria

Etiology. Hypercalciuria for which a causative metabolic abnormality cannot be determined is called *idiopathic hypercalciuria.* Previously, hypercalciuric patients were divided into those with excessive kidney calcium excretion and those who absorbed excessive amounts of calcium via the gastrointestinal tract. However, hypercalciuric patients generally do not have a transport defect limited to a single site; they appear to have a systemic dysregulation of calcium transport at the major calcium transporting sites, the intestine, kidney, and bone. In both hypercalciuric rats and in humans placed on a low-calcium diet, there is a wide range of calcium excretion. Hypercalciuric patients may appear to have excessive excretion on one examination and excessive absorption on another.[2,3] Some patients excrete more calcium than they consume, indicating a negative total body calcium balance. This calcium must be derived from the mineral phases of bone, which contain by far the largest repository of calcium in the body. The cause of this systemic disorder in calcium transport has, in hypercalciuric stone–forming rats and perhaps in humans, been linked to an increased number of biologically active receptors for vitamin D in the major calcium transporting organs (intestine, kidneys, and bone).[46,47] Metabolic disorders leading to elevated levels of serum calcium, parathyroid hormone, or $1,25(OH)_2D$ (1,25-dihydroxyvitamin D) also may result in hypercalciuria.

Treatment. For hypercalciuria the first-line therapy is a thiazide diuretic, which acts to reduce urinary calcium. In the United States, chlorthalidone 25 to 50 mg is the drug of choice because it requires only once-daily administration. Indapamide 1.25 to 2.5 mg/day does not tend to raise serum lipids as much as other thiazides and may be preferred for patients with cardiac risk factors or elevated serum lipids. On commencing these medications, patients should be instructed to increase their dietary potassium intake, and a serum potassium level should be checked 7 to 10 days later. If serum potassium is low, oral potassium supplementation should be initiated. Potassium citrate is generally preferred over potassium chloride. However, most patients find potassium citrate liquid preparations unpalatable. A wax matrix tablet of potassium citrate is well tolerated and is available in some countries. In general, patients are able to maintain a normal serum potassium level with potassium citrate 20 to 40 mmol/day. The serum potassium and bicarbonate levels should be rechecked 7 to 10 days later for further dosage adjustment. Because citrate is a base, potassium citrate may excessively raise the serum bicarbonate level and urinary pH, which could promote calcium phosphate stone formation. Urinary pH and supersaturation must be carefully monitored, and a

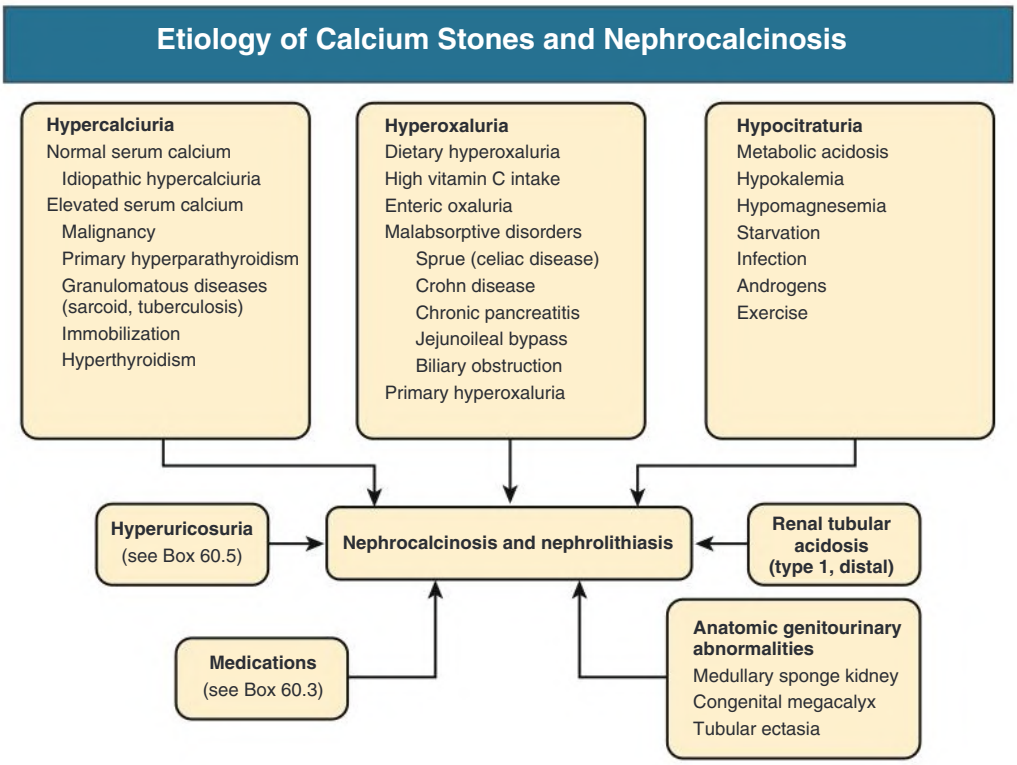

Fig. 60.6 Etiology of calcium stones and nephrocalcinosis.

change to potassium chloride may be required if supersaturation of calcium phosphate worsens with increasing urinary pH in a patient with primarily calcium phosphate stones.

The 24-hour urine calcium, sodium, and citrate should be rechecked after several weeks to months. If the calcium excretion remains elevated, the thiazide dose should be increased. However, if the sodium excretion also remains high (i.e., >100 mEq/day), patients should be encouraged to limit their sodium intake further because they will not have an adequate response to the diuretic on a high-sodium diet. If serum potassium remains low despite supplementation or the calcium excretion remains high despite increased thiazide dosing, addition of a potassium-sparing diuretic may be required to increase serum potassium. Amiloride with a starting dose 5 mg/day is the preferred treatment for thiazide-induced hypokalemia.[2,3] Triamterene should not be used because it can precipitate into stones.

Dietary recommendations. See the discussion of general treatment.

Hyperoxaluria

Etiology. Elevated urinary oxalate results from excessive dietary intake (dietary oxaluria), gastrointestinal disorders that can lead to malabsorption (enteric oxaluria), or an inherited enzyme deficiency that results in excessive metabolism of oxalate (primary hyperoxaluria) (see Fig. 60.6).[48]

Dietary excess of oxalate generally does not raise urinary oxalate above 60 mg/24 h (0.54 mmol/24 h). Enteric oxaluria may occur when malabsorption results in excessive colonic absorption of oxalate, as a result of sprue (celiac disease), Crohn disease, chronic pancreatitis, or short bowel syndrome or after bariatric surgery. The anion exchange transporter Slc26a6 appears responsible for intestinal oxalate secretion, and mice with targeted inactivation of this transporter have hyperoxaluria.[49] It is not yet known whether patients with enteric hyperoxaluria have mutations in Slc26a6. Urinary oxalate is generally more than 60 mg/24 h (0.54 mmol/24 h) and can exceed 100 mg/24 h (0.9 mmol/24 h). In primary hyperoxaluria, the tremendous oxalate production results in widespread calcium oxalate deposition throughout the body at an early age. This infiltration of calcium oxalate into organs can result in cardiomyopathy, bone marrow suppression, and kidney failure. Urinary oxalate values may range from 80 to 300 mg/24 h (0.72–2.70 mmol/24 h).

There are three types of primary hyperoxaluria with unique enzymatic defects in the liver glyoxylate pathway. In type 1, the defective enzyme is alanine–glyoxylate aminotransferase, encoded by the gene *AGXT* on chromosome 2; this accounts for approximately 80% of cases. Type 2 tends to be milder and is caused by mutations in the *GRHPR* gene on chromosome 9, which results in failure of glyoxylate reduction to glycolate; this accounts for approximately 10% of the cases. Type 3 is a result of mutations in the gene that encodes the mitochondrial 4-hydroxy-2-oxoglutarate aldolase enzyme, which catalyzes the cleavage of 4-hydroxy-2-oxoglutarate to pyruvate and glyoxylate and accounts for about half of the remaining cases.[50]

Treatment of dietary and enteric hyperoxaluria. Treatment of dietary oxaluria consists of dietary oxalate restriction. Patients should be given a list of foods that have high oxalate content to avoid or eat in moderation (see Box 60.4). Calcium-containing food may be included at each meal to bind intestinal oxalate and prevent its absorption. To evaluate the success of dietary modification, 24-hour urine oxalate and supersaturation of calcium oxalate can be used.

Specific therapy for the malabsorptive disorder, such as a gluten-free diet for patients with sprue, is the first-line treatment for enteric hyperoxaluria. More generalized therapy for steatorrhea, such as a low-fat diet, cholestyramine, and administration of medium-chain triglycerides, may reduce fat malabsorption as well as oxalate absorption and subsequent excretion. The low-oxalate diet and mealtime calcium carbonate prescribed for patients with dietary oxaluria is also helpful for these patients. The diarrhea associated with these disorders may result in low urine volumes, hypokalemia, hypocitraturia, and hypomagnesuria. Patients should therefore be advised to increase their fluid intake and take potassium citrate (in this case, the liquid, although

unpalatable, is better absorbed than the tablets), as well as a magnesium supplement. Magnesium also serves as a urinary stone inhibitor and can be given as magnesium gluconate 0.5 to 1 g once or twice a day or as magnesium oxide 400 mg every 12 hours.

Treatment of primary hyperoxaluria. Primary hyperoxaluria type 1 (PH1) is a severe disorder that until recently could be cured only with liver transplantation to replace the defective hepatic enzyme. Traditional treatments for PH1 have included pyridoxine (vitamin B_6) in doses ranging from 2.5 to 15 mg/kg/24 h in an attempt to reduce oxalate production. Efforts should be made to render the calcium and oxalate more soluble in the urine by raising the urinary pH (to at least 6.5) and giving supplemental citrate and magnesium. Orthophosphate is also an effective inhibitor of urinary calcium oxalate precipitation and can be safely administered in patients with a GFR greater than 50 mL/min/1.73 m^2. Because oxalate is poorly excreted in CKD and is not removed well by dialysis, kidney transplantation serves not only to improve kidney function but also to improve oxalate excretion and diminish systemic oxalosis.[16] Recently, a specific RNA interference therapeutic, lumasiran, has been approved in Europe and the United States for treatment of PH1. This therapy leads to decreased synthesis of glycolate oxidase, an enzyme upstream of the defect in PH1. Lumasiran leads to a prolonged and substantial reduction in urinary oxalate excretion and plasma oxalate concentration, both of which generally decrease to near normal levels in both children and adults.[51] Lumasiran promises to be the standard of care for all patients with PH1. Hopefully with this important therapeutic advance, the devastating clinical consequences of PH1 will be avoided, including kidney failure and systemic oxalosis. Similar strategies to treat PH2 and PH3 are being developed.

Oxalobacter formigenes primarily uses oxalate for cellular metabolism.[52] Calcium oxalate stone formers who are colonized with *O. formigenes* have lower urine oxalate levels than those who are not colonized.[53] A small clinical trial involving administration of *O. formigenes* resulted in a modest decrease in urinary oxalate in some patients.[52] Further studies with larger numbers of patients and assessing clinically relevant outcomes are required.

Hypocitraturia

Citrate inhibits stone formation. A number of conditions reduce urinary citrate excretion, predisposing to stone formation. Excessive protein intake, hypokalemia, metabolic acidosis, exercise, hypomagnesemia, infections, androgens, starvation, and acetazolamide have all been implicated in decreased urinary citrate excretion. Therapy involves treatment of the underlying condition and potassium citrate supplementation. The potassium salt is preferred to sodium citrate because sodium promotes kidney calcium excretion. Potassium citrate 15 to 25 mmol two to three times daily is required, and tablets are considered by most patients to be more palatable than the liquid preparation. In patients with reduced GFR, serum potassium should be monitored carefully, and dose reduction may be needed if hyperkalemia develops.[16]

Distal Renal Tubular Acidosis

Patients with distal (type 1) renal tubular acidosis have impaired distal tubular excretion of hydrogen ions with non–anion gap metabolic acidosis and alkaline urine. The acidosis causes calcium and phosphate to be released from bone with an ensuing increase in kidney excretion of these ions.[33,34] The acidosis also leads to an increase in citrate reabsorption by the proximal tubule. The end result is a high urinary pH, hypocitraturia (urinary citrate generally <100 mg/24 h [0.53 mmol/24 h]), and increased kidney excretion of calcium and phosphate, all of which increase the propensity for calcium phosphate precipitation. Nephrocalcinosis in this setting is not uncommon, because calcium precipitates with phosphorus in the alkaline tubular fluid. The metabolic acidosis and hypocitraturia should be treated with a combination of sodium citrate (or bicarbonate) and potassium citrate (or bicarbonate). Often large amounts (e.g., 1–2 mmol/kg/day in 2 or 3 divided doses) are required to neutralize the acidosis.[2] Citrate is generally preferred to bicarbonate by patients because it does not produce carbon dioxide on contact with stomach acid with resultant gastrointestinal bloating. However, citrate is usually more expensive than bicarbonate and promotes the absorption of aluminum.

Hyperuricosuria

Calcium oxalate crystals often nucleate around other crystal types such as uric acid. Hyperuricosuria contributes to nephrolithiasis in 10% to 15% of calcium stones. Patients with hyperuricosuric calcium oxalate nephrolithiasis may have hyperuricosuria with normal urinary calcium and oxalate, but often a higher urinary pH (>5.5) than patients with pure uric acid stones. Therapy for hyperuricosuria consists of increased fluid intake and reduced dietary purine intake. If uric acid excretion remains elevated, allopurinol should be initiated at 100 to 300 mg/day.[2]

Uric Acid Stones

Epidemiology

The prevalence of uric acid stones depends greatly on geographic location. In the United States, uric acid stones constitute 5% to 10% of all stones formed, whereas in Mediterranean and Middle Eastern countries, uric acid stones may constitute up to 75% of stones. The stones are radiolucent and therefore poorly visible on plain radiographs. They are detectable on ultrasound and CT and as filling defects on IVU (Fig. 60.7).

Etiology and Pathogenesis

Causes of hyperuricosuria include excessive dietary purine or protein intake, disorders associated with cellular breakdown (tumor lysis syndrome, myeloproliferative disorders, hemolytic anemia), gout, uricosuric medications, certain inborn errors of metabolism, and possibly excessive fructose intake.[54]

Three major factors influence uric acid stone formation: low urine pH, low urine volume, and elevated urinary uric acid levels (Box 60.5). Of the three, low urine pH is the principal metabolic disorder found in patients with uric acid nephrolithiasis. Uric acid is poorly soluble at pH below 5.5. Solubility increases with urine alkalinity such that at urine pH 6.5, urine can contain over 6 times the quantity of uric acid present at pH 5.3 without exceeding supersaturation. The rising incidence of obesity and insulin resistance in the United States led to a parallel increase in uric acid lithiasis. The urinary acidosis is likely a result of impaired ammoniagenesis, which results in excessive excretion of unbuffered acid and a very low urine pH.[9,55] The geographic and ethnic variations in the incidence of uric acid stones may be due to diet, caused by environmental factors, or the result of genetic susceptibility in some populations.[9]

Treatment

Treatment of uric acid stones involves increasing urine pH and volume, and decreasing uric acid excretion. Alkaline urine not only can prevent uric acid stone formation but also may result in stone dissolution. To raise urine pH, potassium citrate is recommended. Although sodium bicarbonate alkalinizes the urine and enhances uric acid solubility, the added sodium increases sodium urate formation, which

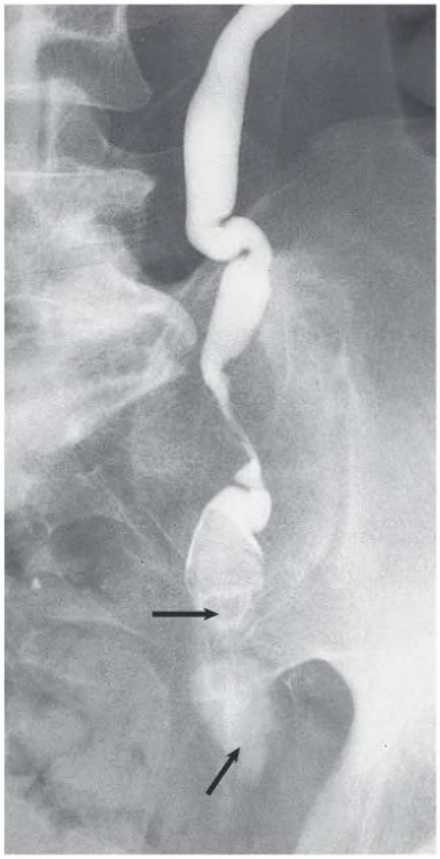

Fig. 60.7 Radiolucent Urate Calculi. Antegrade pyelogram showing multiple radiolucent uric acid stones *(arrows)* obstructing the lower ureter.

BOX 60.5 Factors Associated With Uric Acid Stone Formation

Low Urine pH (≤5.5)
- High–animal protein diet
- Diarrhea
- Insulin resistance (high body mass index, metabolic syndrome, type 2 diabetes)

Low Urine Volume
- Inadequate fluid intake
- Excessive extrarenal fluid losses
  - Diarrhea
  - Insensible losses (e.g., perspiration)

Hyperuricosuria
- Excessive dietary purine intake
- Hyperuricemia
  - Gout
  - Intracellular-to-extracellular uric acid shift
  - Myeloproliferative disorders
  - Tumor lysis syndrome
- Inborn errors of metabolism
  - Lesch-Nyhan syndrome
  - Glucose-6-phosphatase deficiency

Medications
- See Box 60.3

serves as a nidus for calcium oxalate precipitation. Potassium citrate 40 to 50 mmol/day in divided doses is given, increasing the dose as necessary to achieve a urine pH of 6.5 to 7.0. Patients should monitor pH with urine dipsticks at various times of the day and adjust the dosage accordingly. If urine pH remains low despite potassium citrate exceeding 100 mmol/day, or if that dose results in hyperkalemia, acetazolamide may be added. This carbonic anhydrase inhibitor produces an alkaline urine similar to that seen in renal tubular acidosis. Patients should be cautioned not to exceed urine a pH of 7.0 because this may result in calcium phosphate precipitation.

A low-purine and low–animal protein diet is also useful in raising urinary pH and decreasing uric acid excretion (see Box 60.4). If uric acid excretion remains high despite dietary intervention, as in patients with disorders of cellular catabolism, allopurinol should be prescribed, 100 mg/day increasing to 300 mg/day as needed to keep urinary uric acid excretion lower than 750 mg/24 h (4.5 mmol/24 h). See Box 60.4 for high-purine foods to avoid.

Struvite Stones

Struvite stones are also referred to as *infection stones* or *triple phosphate stones.* The stones grow rapidly to a large size, can reduce GFR in the affected kidney, and are difficult to eradicate. Because of the significant morbidity in patients with struvite stones, they also have been termed *stone cancer.* Most staghorn calculi, large stones that penetrate more than one renal calyx, are composed of struvite. Their formation requires the presence of urease-producing bacteria in the urine (Box 60.6).[56]

Etiology and Pathogenesis

Struvite stones are composed of magnesium ammonium phosphate and calcium carbonate apatite. They form when urease production by certain urinary bacteria breaks down urea to ammonium (NH_4^+) and a carboxyl (OH^-) group. The urine becomes quite alkaline; urinary phosphate becomes insoluble and forms a solid phase with magnesium, calcium, and the ammonium. Women are more prone to struvite nephrolithiasis than men because of an increased propensity for UTI. Others predisposed to developing struvite stones through infections or urinary stasis include patients with indwelling urinary catheters, neurogenic bladders, genitourinary tract anomalies, and spinal cord lesions. An alkaline urine (pH ≥7.0), urine culture of urease-producing bacteria, and large stones suggest the diagnosis of struvite nephrolithiasis.[56]

Certain gram-negative and gram-positive bacteria have been implicated in urease production and consequent struvite formation, with the most common being *Proteus* spp. (see Box 60.6). *Escherichia coli,* which is frequently present in urine cultures, is not a urease producer. If there is a strong suspicion for struvite stones but no organism is

  - *Ureaplasma*
- Elevated urinary pH

[a] Escherichia coli is not a urease producer.

detected in the urine, a specific culture request for *Ureaplasma urealyticum* should be considered, because it does not grow on routine culture media.

Treatment

Struvite stones require aggressive medical and surgical management. Antibiotic therapy is important to reduce further stone growth and for stone prevention. Bacteria will remain in the stone interstices, however, and stones will continue to grow unless chronic antibiotic suppression is maintained or the calculi are completely eradicated. Given the need for complete stone removal to effect a cure, early urologic intervention is advised. Stones smaller than 2 cm may respond well to ESWL; however, larger stones will likely require percutaneous nephrolithotomy, often in combination with ESWL (see Chapter 63). Any stone fragments retrieved should be cultured and culture-specific antibiotics continued.[57] Once the urine is sterile, usually approximately 2 weeks after initiation of therapy, the dose is halved. Monthly urine cultures should be obtained, and if they remain sterile for 3 consecutive months, antibiotics may be discontinued, although surveillance urine cultures should continue monthly for a full year.

Cystine Stones

Cystinuria is an autosomal disorder in which there is a tubular defect in dibasic amino acid transport, resulting in increased cystine, ornithine, lysine, and arginine excretion. It is also discussed in Chapter 50. The pattern of inheritance may be autosomal recessive or autosomal dominant with incomplete penetrance. The stone disease is usually clinically manifested by the second and third decades of life. Because of the high sulfur content of the cystine molecule, the stones are apparent on plain radiographs (see Fig. 60.4A) and often will manifest as staghorn calculi or multiple bilateral stones.

Cystine is poorly soluble, only approximately 300 mg/L (1.25 mmol/L) at a neutral pH. Normal cystine excretion of approximately 30 to 50 mg (0.12–0.21 mmol) per day is readily soluble in the usual daily urine output of approximately 1 L. However, homozygote cystinurics often excrete 250 to 1000 mg (1.04–4.20 mmol) of cystine per day, with heterozygotes excreting an intermediate amount. Treatment is directed at decreasing the urinary cystine concentration below the limits of solubility. Because the dietary precursor of cystine, methionine, is an essential amino acid, it is impractical to significantly reduce intake. Increasing urine volume so that cystine remains below the limits of solubility sometimes requires 4 L of urine per day. A low-sodium diet may reduce urine cystine excretion, although the mechanism by which this occurs is not clear.[58] Increasing urine pH greater than 7.5 will increase cystine solubility, but this is difficult to achieve on a long-term basis. Tiopronin 800 mg/day in 3 divided doses or D-penicillamine with a starting dose 250 mg/day and maximum dose of 2 g/day will both bind cystine and reduce urinary supersaturation; however, side effects may limit their use. The angiotensin-converting enzyme inhibitor captopril may be effective by forming a thiol-cysteine disulfide bond that is more soluble than cystine.[59]

Stones Associated With Melamine Exposure

By late 2008, more than 50,000 Chinese children aged 3 years or younger had developed kidney stones associated with contaminated milk products. Powdered milk and infant formulas were noted to contain melamine, a nitrogenous substance synthesized from urea that increases the apparent protein content of the product.[22] Risk factors for nephrolithiasis after melamine exposure may include volume depletion, small body size, uricosuria, and low urine pH.

Although affected children often presented with dysuria and hematuria, many children who were subsequently tested were asymptomatic despite kidney stones identified on ultrasound.[22] On urinalysis, some children exhibited fan-shaped crystals. The kidney stones formed were radiolucent and fragile. Many were composed of a combination of uric acid with melamine and were amenable to dissolution by hydration and alkalinization.

BOX 60.7 Causes of Nephrocalcinosis

Medullary

Disturbed Calcium Metabolism
- Hyperparathyroidism
- Sarcoidosis
- Milk-alkali syndrome
- Rapidly progressive osteoporosis
- Idiopathic hypercalciuria

Other Tubular Disease
- Distal (type 1) renal tubular acidosis
- Oxalosis[a]
- Dent disease (X-linked hypercalciuric nephrolithiasis)
- X-linked hypophosphatemic rickets
- Bartter syndrome
- Hypomagnesemia-hypercalciuria syndrome

Anatomic Disease
- Medullary sponge kidney
  - Papillary necrosis

Medications
- Acetazolamide
- Amphotericin
- Triamterene

Cortical
- Cortical necrosis
- Transplant rejection
- Chronic glomerulonephritis
- Trauma
- Tuberculosis
- Oxalosis[a]

[a] Oxalosis typically causes both cortical and medullary nephrocalcinosis.

NEPHROCALCINOSIS

Nephrocalcinosis refers to increased calcium content within the kidney and may be unilateral or bilateral.

Etiology and Pathogenesis

Medullary Nephrocalcinosis

Medullary nephrocalcinosis in which the calcification tends to occur in the area of the renal pyramids accounts for most cases of nephrocalcinosis. It is typically associated with elevated urinary calcium, phosphate, and oxalate, or it can occur with alkaline urine (Box 60.7). Any disorder that can lead to hypercalcemia and/or hypercalciuria may be implicated. Instead of stone formation, smaller parenchymal calcifications deposit in the medulla, and they are usually bilateral and relatively symmetric (Fig. 60.8). Some metabolic disorders, particularly oxalosis caused by primary hyperoxaluria, can result in both medullary and cortical nephrocalcinosis (Fig. 60.9).

In adults, the most common causes of medullary nephrocalcinosis are primary hyperparathyroidism, distal renal tubular acidosis, and

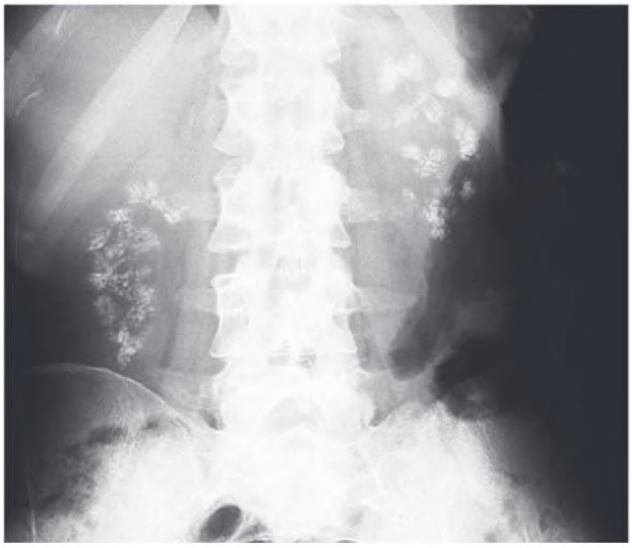

Fig. 60.8 Medullary Nephrocalcinosis. Plain radiograph showing bilateral metastatic medullary nephrocalcinosis in a patient with distal renal tubular acidosis.

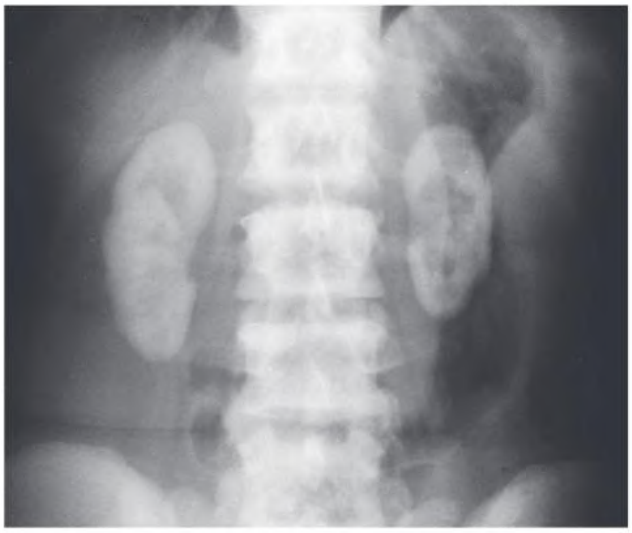

Fig. 60.9 Nephrocalcinosis. Dense cortical and medullary calcification in the shrunken kidneys of a patient with oxalosis and long-standing kidney failure.

medullary sponge kidney, as well as medications, including acetazolamide, amphotericin, and triamterene (see Box 60.3).

In children, a similar range of disorders can be seen, but the most common associations are with furosemide and the hereditary disorders associated with hypercalciuria.[24] Furosemide, when used in premature neonates and older infants with congestive heart failure, can result in nephrocalcinosis with or without apparent hypercalciuria. The lesions often resolve with discontinuation of therapy. A normal ratio of calcium to creatinine at the time of diagnosis of nephrocalcinosis (~0.40 mg/mg in premature infants) appears to be a good predictor of resolution.

There are many uncommon hereditary disorders associated with nephrocalcinosis, including Dent disease, X-linked hypophosphatemic rickets, hypomagnesemia-hypercalciuria syndrome, and Bartter syndrome.

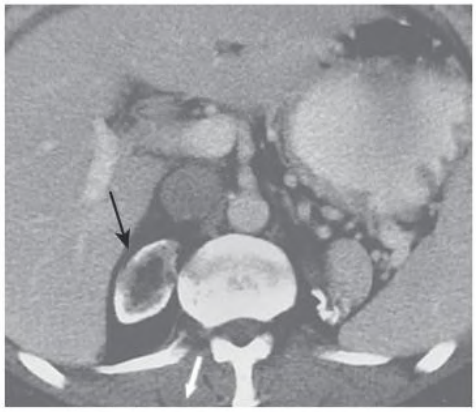

Fig. 60.10 Cortical Nephrocalcinosis. Noncontrast computed tomgraphy scan showing cortical nephrocalcinosis *(arrows)* in the right kidney after cortical necrosis.

Dent disease is an X-linked recessive disorder of proximal tubules characterized by low-molecular-weight proteinuria with hypercalciuria and nephrocalcinosis.[60] In most cases, it is due to mutations that inactivate a voltage-gated chloride transporter called *CLC-5*. A number of mutations affecting the *CLCN5* gene on the X chromosome have been identified that lead to inactivation of CLC-5. The result is a clinical syndrome typically affecting young boys and usually including hypercalciuria, nephrocalcinosis, nephrolithiasis, and hematuria, as well as low-molecular-weight proteinuria, glycosuria, aminoaciduria, hypophosphatemia, kidney failure, and rickets. Dent disease is further discussed in Chapter 50.

In X-linked hypophosphatemic rickets, the traditional treatment, with phosphate repletion and vitamin D, may itself result in hypercalcemia, hypercalciuria, and nephrocalcinosis. Recently, the monoclonal immunoglobulin antibody burosumab, which binds excess fibroblast growth factor 23, was approved for the treatment of this disorder. The drug normalized phosphorus levels in adults and children, and its use should prevent the calcific disorders caused by X-linked hypophosphatemic rickets.

Another cause of medullary nephrocalcinosis in children is primary hypomagnesemia-hypercalciuria syndrome.[3,61] This rare autosomal recessive condition results from defective production of the cellular tight-junction protein paracellin-1. This claudin family protein is necessary for adequate calcium and magnesium reabsorption in the thick ascending limb of the loop of Henle. Children typically present with symptoms of UTI (often with nephrolithiasis), polyuria, tetanic seizures (caused by hypomagnesemia), and muscle cramps and weakness. Hypercalciuria, hypermagnesuria, and a urinary concentrating defect also occur. Patients often have reduced GFR and may require kidney replacement therapy by the third decade of life. Sensorineural hearing disorders and ocular impairment may accompany the kidney manifestations in a subset of patients.

Cortical Nephrocalcinosis

Cortical nephrocalcinosis is usually the result of dystrophic calcification, which follows parenchymal tissue destruction, rather than the precipitation of excessive urinary constituents. It is secondary to infarction, neoplasm, and infection. It is typically asymmetric and is usually localized to the renal cortex (Fig. 60.10). Causes of cortical nephrocalcinosis include transplant rejection, cortical necrosis (mostly following hemorrhagic shock), tuberculosis, ethylene glycol toxicity, and chronic glomerulonephritis.

Clinical Manifestations

Patients who do not have nephrolithiasis associated with nephrocalcinosis are often asymptomatic. Ultrasound and CT scanning are sensitive diagnostic tests for both cortical and medullary nephrocalcinosis, demonstrating the parenchymal calcifications before they can be visualized on plain radiographs. The extent of calcification correlates poorly with GFR.

Treatment

Similar to nephrolithiasis, treatment of nephrocalcinosis relies on therapy for the underlying disease, as well as measures to reduce hypercalcemia, hyperphosphatemia, and oxalosis, if possible. The goal of treatment is usually to prevent further deposits, because therapy cannot eradicate existing calcium deposits.

SELF-ASSESSMENT QUESTIONS

1. A 49-year-old paraplegic man is referred for evaluation of nephrolithiasis. He has a suprapubic catheter and has had frequent urinary tract infections. He has reduced kidney function and is noted to have large staghorn calculi in both kidneys. On urinalysis, he has many white blood cells and bacteria. Urine culture grows *Proteus.* All statements regarding this patient's kidney stones are true *except:*
   - **A.** His current stones can be treated with a course of antibiotics.
   - **B.** Stone formation is facilitated by the effects of urease-producing bacteria.
   - **C.** His stones are formed by a combination of phosphate with three cations.
   - **D.** Stone formation is potentiated by an elevated urine pH.
   - **E.** His current stones require surgical management.
2. A 35-year-old woman presents with her fourth kidney stone. Her father and brother have had stones as well. She was informed that her stones are composed of calcium. She tries to drink as much fluid as possible. Urine calcium excretion is elevated, but serum calcium is normal. All of the following dietary measures may be recommended for kidney stone prevention in this patient *except:*
   - **A.** Low-sodium diet
   - **B.** Reduction in animal protein intake
   - **C.** Reduction in dietary calcium intake
   - **D.** Low-oxalate diet
3. A 52-year-old obese man presents with flank pain and gross hematuria. Computed tomography reveals an obstructing left kidney stone and two other nonobstructing kidney stones in the right kidney measuring 0.5 mm. He passes the left kidney stone, which is found on analysis to be a uric acid stone. He was recently started on metformin for diabetes mellitus, his body mass index is 33, and he has normal kidney function; 24-hour urine reveals urine pH 5.3, volume 1.5 L, and uric acid excretion of 500 mg. Which of the following is a *true* statement regarding this patient's kidney stones?
   - **A.** The patient's right kidney stones can be followed by serial abdominal radiographic examination of the kidneys.
   - **B.** The patient's insulin resistance may be contributing to his stone disease.
   - **C.** The patient should be treated with allopurinol.
   - **D.** Potassium citrate would not be beneficial.
   - **E.** The patient is drinking an adequate amount of fluid.

Urinary Tract Obstruction

Kevin M. Gallagher, Jeremy Hughes

DEFINITIONS

Obstructive uropathy refers to the structural or functional changes in the urinary tract that impede normal urine flow. *Obstructive nephropathy* refers to the kidney disease caused by impaired flow of urine or tubular fluid. *Hydronephrosis* refers to dilation of the urinary tract. *Hydronephrosis* is not synonymous with *obstructive uropathy* because the former can occur without functional obstruction to the urinary tract and can be absent in established obstruction. Obstructive uropathy and nephropathy frequently coexist, and their management requires close collaboration between nephrologists and urologists. Some surgical aspects of obstruction to the urinary tract are discussed in Chapter 63.

Obstructive uropathy is classified according to the site, degree, and duration of the obstruction. Acute or chronic obstruction can occur anywhere in the urinary tract and includes intrarenal causes (casts, crystals) and extrarenal causes. Acute or chronic obstruction is further subdivided into obstruction of the upper urinary tract (the urinary tract above the vesicoureteral junction, often unilateral) and the lower urinary tract (usually bilateral obstruction located below the vesicoureteral junction). Complete obstruction of the urinary tract is termed *high grade,* whereas partial or incomplete obstruction is termed *low grade.*

Unilateral obstruction in a patient with two normal kidneys will not result in significant reduction in glomerular filtration rate (GFR) because the contralateral kidney compensates. However, bilateral obstruction or the obstruction of a single functioning kidney will result in kidney failure. In acute urinary tract obstruction, changes are mainly functional, whereas structural damage to the kidney results from more chronic obstruction. The kidney with acute functional changes may recover after effective release of the obstruction, but structural changes may be permanent and lead to chronic kidney disease (CKD). Urinary tract obstruction is a major cause of acute kidney disease and CKD worldwide in children and adults.

ETIOLOGY AND PATHOGENESIS

The causes of obstructive uropathy affecting the upper and lower urinary tracts are summarized in Boxes 61.1 and 61.2.

Congenital Urinary Tract Obstruction

Congenital urinary tract obstruction occurs most frequently in males, most commonly because of posterior urethral valves (PUV) or pelviureteral junction (PUJ) obstruction. If obstruction occurs early during development, the kidney fails to develop and becomes dysplastic. If the obstruction is bilateral, there is a high mortality rate from kidney failure. If the obstruction occurs later in gestation and is low grade or unilateral, hydronephrosis and nephron loss will still occur, but kidney function may be sufficient to allow survival, and such patients may not present until later in childhood. Mild PUJ obstruction may not manifest until adulthood and in some patients may be an incidental finding (Fig. 61.1). However, with increased use and improved sensitivity of antenatal scanning, congenital abnormalities of the urinary tract are now frequently identified early, allowing prompt postnatal (and in some cases antenatal) intervention to relieve the obstruction and hence preserve kidney function. Congenital causes of obstruction are discussed further in Chapter 52.

Acquired Urinary Tract Obstruction

Acquired urinary tract obstruction may affect either the upper or lower urinary tract and can result from intrinsic or extrinsic causes. Intrinsic causes of obstruction may be intraluminal or intramural.

Intrinsic Obstruction

Intraluminal obstruction. Intrarenal intraluminal obstruction may result from tubular obstruction, such as the deposition of uric acid crystals after treatment of hematologic malignancies (tumor lysis syndrome), the precipitation of Bence Jones protein in myeloma, or the precipitation or crystal formation of certain drugs (e.g., sulfonamides, acyclovir, methotrexate, indinavir). Uncommonly, patients with glomerulonephritis such as immunoglobulin A (IgA) nephropathy may develop severe glomerular hematuria with tubular obstruction from erythrocytes and acute kidney injury (AKI) that typically resolves.

Extrarenal intraluminal obstruction in young adults is most commonly caused by urinary calculi (see Chapter 60). Calcium oxalate stones are the most common and typically cause intermittent acute unilateral urinary tract obstruction. Any stone formation is a significant and independent risk factor for CKD, although end-stage kidney disease (ESKD) because of urinary stones is rare.[1] Less common causes of urinary lithiasis, such as struvite stones, uric acid stones, and cystinuria are often bilateral and recurrent and therefore more likely to cause CKD. Kidney calculi lodge more commonly in the calyx, PUJ, or vesicoureteral junction and at the level of the pelvic brim. Surgical management of stones is discussed in Chapters 60 and 63. Intraluminal obstruction can also result from a sloughed papilla after papillary necrosis or blood clots after macroscopic hematuria ("clot colic"). Papillary necrosis may occur in diabetes mellitus, sickle cell trait or disease, analgesic nephropathy, amyloidosis, and acute pyelonephritis. Clot colic can occur with bleeding from kidney tumors (benign and malignant) or arteriovenous malformations, after kidney trauma or surgery, and in patients with polycystic kidney disease.

Intramural obstruction. Intramural obstruction can result from either functional or anatomic changes. Functional disorders include adynamic ureteral segments (usually at the junction of the ureter with the pelvis or bladder) and neurologic disorders. The latter may result in a contracted (hypertonic) bladder or a flaccid (atonic) bladder,

BOX 61.1 Causes of Lower Urinary Tract Obstruction[a]

Urethral Anatomic Causes
- Urethral strictures: trauma, *postinstrumentation,* infections such as gonococcal urethritis, nongonococcal urethritis, tuberculosis
- Posterior urethral valves
- Stones
- Blood clots
- Periurethral abscess
- Phimosis
- Paraphimosis
- Meatal stenosis

Urethral Functional Causes
- Anticholinergic drugs, antidepressants, levodopa

Prostate
- *Benign prostatic hypertrophy*
- *Prostatic carcinoma*

Bladder Anatomic Causes
- *Bladder cancer*
- *Schistosomiasis* (*Schistosoma haematobium* infection)
- Bladder calculi
- Bladder trauma, pelvic fracture

Bladder Functional Causes
- *Neurogenic bladder:* spinal cord defects or trauma, diabetes, multiple sclerosis, Parkinson disease, cerebrovascular accidents

[a]The most common causes are in italics.

BOX 61.2 Causes of Upper Urinary Tract Obstruction[a]

Intrinsic Causes

Intraluminal
- Intratubular deposition of crystals (uric acid, drugs)
- *Stones*
- Papillary tissue
- Blood clots
- Fungal ball

Intramural
- Functional: pelviureteral or vesicoureteral junction dysfunction
- Anatomic: tumors (benign or malignant)
- Infections, granulomas, strictures

Extrinsic Causes

Reproductive System
- Cervix: *carcinoma*
- Uterus: *pregnancy, tumors,* prolapse, endometriosis, pelvic inflammatory disease
- Ovary: tumor, cysts
- Prostate: *carcinoma*

Vascular System
- Aneurysms: aorta, iliac vessels
- Aberrant arteries: pelviureteral junction
- Venous: ovarian veins, retrocaval ureter

Gastrointestinal Tract
- Crohn disease
- Pancreatitis
- Appendicitis
- Diverticulitis
- Tumors

Retroperitoneal Space
- Lymph nodes
- Fibrosis: idiopathic, drugs, inflammatory or immunoglobulin G4–related disease
- Tumors: primary or metastatic
- Hematomas
- Radiation therapy

Other
- *Surgical disruption or ureteral ligation*

[a]The most common causes are in italics.

depending on whether the lesion affects upper or lower motor neurons, and may lead to impaired bladder emptying with vesicoureteral reflux. Bladder dysfunction is very common in patients with multiple sclerosis and after spinal cord injury and is also seen in diabetes mellitus, Parkinson disease, and after cerebrovascular accidents. Some drugs (anticholinergics, levodopa) can alter neuromuscular activity of the bladder and result in functional obstruction, especially if there is preexisting bladder outflow obstruction (e.g., prostatic enlargement).

Anatomic causes of intramural obstruction of the upper urinary tract include transitional cell carcinoma of the renal pelvis and ureter and ureteral strictures secondary to radiotherapy, previous stones or endoscopic stone surgery, or retroperitoneal surgery. Rarely, obstruction may result from ureteral valve malfunction, polyps, or strictures after therapy for tuberculosis. Intramural obstruction of the lower urinary tract can result from urethral strictures, which are usually secondary to instrumentation or previous urethritis, or malignant and benign tumors of the bladder. Infection with *Schistosoma haematobium* when the ova lodge in the distal ureter and bladder is a common cause of obstructive uropathy worldwide; up to 50% of chronically infected patients develop ureteral strictures and fibrosis, with calcifications and contraction of the bladder.

Extrinsic Obstruction

The most common cause of extrinsic compression in females is pressure from a gravid uterus on the pelvic rim; the right ureter is more commonly affected. It is usually asymptomatic, and the changes resolve rapidly after delivery. Rarely, bilateral obstruction and AKI may occur. Ureteral dilation frequently may be seen in pregnancy as a result of hormonal effects (especially progesterone) on smooth muscle, but this does not indicate functional obstruction (see Chapter 44). Carcinoma of the cervix also may cause extrinsic obstruction secondary to direct extension of the tumor to involve the urinary tract. Other pelvic pathologic processes that can cause ureteral compression include benign and malignant uterine and ovarian masses, endometriosis, and pelvic inflammatory disease. Compression of the ureters outside the bladder also may occur with uterine prolapse. Rarely, inadvertent ureteral ligation may occur during surgical procedures, particularly those related to obstetrics and gynecology and colorectal surgery. Unilateral ligation may go undetected, but AKI will result from bilateral ligation.

In males, the most common cause of extrinsic obstruction of the lower urinary tract is benign prostatic hypertrophy. Carcinoma of the prostate can result in obstruction either from direct tumor extension to the bladder outlet or ureters or from metastatic spread.

Fig. 61.1 Intravenous Urogram Demonstrating Pelviureteral Junction Obstruction. The study was performed in a previously asymptomatic adult to investigate nonspecific right loin pain. There is unilateral dilation of the pelvicalyceal system. The ureter has not been visualized.

Retroperitoneal pathology may result in extrinsic obstruction of the ureters, as can metastases or extension of tumors from the cervix, prostate, bladder, colon, ovary, and uterus. Primary tumors of the retroperitoneum, such as lymphomas and sarcomas, commonly cause obstruction. Obstruction can also result from inflammatory conditions affecting the retroperitoneum, such as Crohn disease and large bowel diverticulitis. In Crohn disease, the obstruction is usually right-sided as a result of ileocecal disease. Less common pathologic processes include retroperitoneal fibrosis, in which thick fibrous tissue encases the ureters and draws them medially (Fig. 61.2). Retroperitoneal fibrosis may be idiopathic but can result from inflammatory aortic aneurysms, certain drugs (e.g., β-blockers, bromocriptine, methysergide), previous irradiation, trauma or surgery, and granulomatous disease (e.g., tuberculosis, sarcoidosis). Retroperitoneal fibrosis is also associated with IgG4-related disease (see Chapter 65), which typically presents with autoimmune pancreatitis, and elevated serum IgG4 levels suggest this diagnosis.[2] IgG4-related disease may be diagnosed after retroperitoneal biopsy material with an IgG4-positive plasma cell infiltrate, fibrosis with a whorled (cartwheel) appearance, and an obliterative venous phlebitis evident.[3] The main differential diagnosis for idiopathic or benign retroperitoneal fibrosis is lymphoma or other malignant mimics and therefore consideration should be given to the need for biopsy. Computed tomography (CT) positron emission tomography (PET) can help with the distinction between benign retroperitoneal fibrosis and malignant disease.[4]

Ureteral compression may be a result of vascular abnormalities, including aneurysmal dilation of the aorta or iliac vessels, aberrant vessels such as an aberrant anterior crossing accessory renal artery causing PUJ obstruction in adults, and anatomic variations in the location of the ureter (retrocaval ureter).

Fig. 61.2 Retrograde Pyelogram Showing Idiopathic Retroperitoneal Fibrosis. Dilation of the pelvicalyceal system is clearly demonstrated. The ureters, however, are not dilated, and the left ureter can be seen displaced medially as a result of being encased in thick fibrous tissue.

Pathophysiology

Obstruction of the urinary tract causes profound functional and structural changes of the kidney. Initially, changes are predominantly functional and potentially reversible, but with time, chronic and irreversible structural changes occur. Our understanding of the consequences of urinary tract obstruction stems mainly from the study of animal models.[5] Although many studies have focused on the effects of complete ureteral obstruction in rodents, investigators have also examined models of chronic complete, partial, or reversible obstruction in adult and neonatal animals.[5] Available experimental data show little species-to-species variation in the response to acute obstruction, suggesting that similar changes are likely to occur in humans. The complex effects of urinary tract obstruction on the kidney affect both glomerular hemodynamics and tubular function.

Changes in Glomerular Function

GFR declines progressively after the onset of complete ureteral obstruction. After complete ureteral obstruction, there is an initial rise in proximal tubular pressure. This is accompanied by afferent arteriolar dilation as a result of the generation of vasodilatory prostaglandins. Although this increases glomerular capillary hydraulic pressure, it does not offset the rise in tubular pressure, and there is a decrease in the hydraulic pressure gradient across glomerular capillaries, resulting in a dramatic decline in GFR. The relative changes in ureteral pressure, renal plasma flow, and GFR are summarized in Fig. 61.3. With ongoing obstruction, there is a progressive fall in renal blood flow secondary to the generation of angiotensin II (Ang II) and thromboxane A_2, the release of vasopressin (antidiuretic hormone), and decreased nitric oxide production. An interstitial leukocyte infiltrate develops, predominantly macrophages, and promotes the late structural changes that occur after obstruction as macrophage depletion limits experimental interstitial fibrosis.[6]

The extent to which glomerular function recovers after the release of ureteral obstruction depends on the duration of the obstruction. Whole-kidney GFR may return to normal after short-term obstruction (days), whereas recovery may be incomplete after prolonged obstruction.

Changes in Tubular Function

Abnormalities in tubular function are common in urinary tract obstruction and manifest as altered kidney handling of electrolytes and changes in the regulation of water excretion. The degree and nature of the tubular defects after obstruction depend in part on whether the obstruction is bilateral or unilateral. These differences could result from the dissimilar hemodynamic responses, different intrinsic changes within the nephron, or differences in extrinsic factors (e.g., volume expansion and accumulation of natriuretic substances in bilateral obstruction) between the two states.

After ureteral obstruction, the ability to concentrate the urine is impaired with causative factors including a loss of medullary tonicity and reduced expression of sodium transporters. Also, the collecting duct is unresponsive to vasopressin because of reduced expression of kidney aquaporins.

Rats exhibit reduced expression of multiple acid-base transporters after ureteral obstruction,[7] and patients with urinary tract obstruction often have urinary acidification defects. These defects may be detected only by exogenous acid loading, but hyperchloremic acidosis caused by impaired distal acid secretion, hyporeninemic hypoaldosteronism (type 4 renal tubular acidosis), and a combination of these findings has been described. This acidifying defect results from a marked increase in bicarbonate excretion or from a distal acidification defect, possibly as a result of abnormalities of the H^+-ATPase activity of intercalated cells of the collecting duct after ureteral obstruction.

Obstruction also alters kidney potassium handling. In the presence of a normal functioning contralateral kidney, potassium excretion is reduced after relief of obstruction, either in proportion to or perhaps even greater than the fall in GFR (i.e., fractional excretion of potassium is unaltered or slightly reduced). There is a defect in the distal potassium secretory mechanism after unilateral obstruction that may be secondary to reduced responsiveness of that nephron segment to aldosterone. By contrast, after release of bilateral ureteral obstruction, there is a marked increase in both net and fractional potassium excretion. The major mechanism by which potassium losses occur in this setting is an increased delivery of sodium to the distal tubule, resulting in increased sodium-potassium exchange.

Recovery of tubular function after release of obstruction is slow and may remain abnormal even after whole-kidney GFR has returned to normal. In rats, acidification and potassium-handling abnormalities persist for at least 14 days and urinary concentrating ability is abnormal for up to 60 days after the release of 24 hours of unilateral ureteral obstruction. These observations are consistent with persistent alterations in distal tubular and collecting duct function or a loss in functioning juxtaglomerular nephrons after the release of the obstruction.

HISTOPATHOLOGIC CHANGES

The morphologic alterations in kidney architecture are similar irrespective of the cause of the obstruction. Initially, there is kidney enlargement and edema with pelvicalyceal dilation (Fig. 61.4). Tubular dilation that predominantly affects the collecting duct and distal tubular segments is seen microscopically with cellular flattening and atrophy of proximal tubular cells. Glomerular structures are usually preserved initially, although the Bowman space may be dilated and some periglomerular fibrosis may ultimately develop.

Inadequately treated urinary tract obstruction eventually causes irreversible structural changes. The renal pelvis becomes widely dilated, with the papillae either flattened or hollowed out. The cortex and medulla become grossly thinned, such that the kidney becomes a thin rim of kidney tissue surrounding a large saccular pelvis (Fig. 61.5). Histologic examination demonstrates tubulointerstitial fibrosis and profound nephron loss. Tubular proliferation and apoptosis, interstitial myofibroblast accumulation, increased extracellular matrix deposition, and tubular atrophy occur. Ischemia as a result of the decreased renal blood flow and the rarefaction of peritubular capillaries contributes to parenchymal damage after obstruction. In both genetic and interventional studies, an important pathologic role for Ang II and transforming growth factor-β (TGF-β) has been established.[5]

Infiltrating macrophages release profibrogenic factors (e.g., TGF-β, galectin-3) and play a pivotal role in the chronic tissue injury and fibrosis that result from prolonged ureteral obstruction[6,8] (Fig. 61.6). Local Ang II generation also may stimulate tubular cell production of TGF-β. Treatments shown to ameliorate chronic interstitial damage in experimental obstructive uropathy include angiotensin receptor

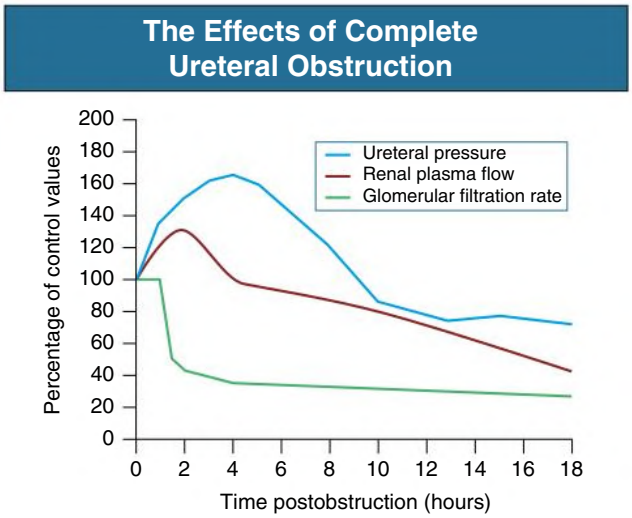

Fig. 61.3 Effects of Complete Ureteral Obstruction. The relative changes in ureteral pressure, kidney plasma flow, and glomerular filtration rate are shown using data from experimental studies of unilateral ureteral obstruction in rats.

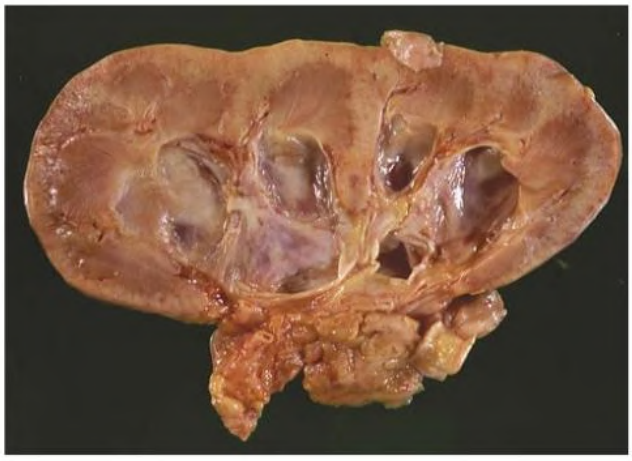

Fig. 61.4 Autopsy Specimen of a Kidney Showing the Early Effects of Ureteral Obstruction. The kidney is enlarged and edematous with pelvicalyceal dilation. There is good preservation of the kidney parenchyma.

Fig. 61.5 **Chronic Ureteral Obstruction.** Surgical specimen of a kidney showing gross dilation of the pelvicalyceal system and the reduction of the kidney cortex to a thin fibrotic rim of tissue. There would have been no prospect for any significant functional recovery in this kidney after the relief of the obstruction.

blockers (ARBs), pentoxifylline, simvastatin, and various growth factors with beneficial effects including reduced tubulointerstitial inflammation, tubular cell apoptosis, and fibrosis.[5] However, differences have been noted in the responses of adult and neonatal rodents to experimental therapeutic interventions, and it is unclear whether such differences might occur in humans.

EPIDEMIOLOGY

Obstructive uropathy is common and can occur at all ages, with the prevalence of hydronephrosis at autopsy being 3.5% to 3.8%, although this underestimates the true incidence because these figures exclude transient obstruction. The frequency and cause of obstruction vary in both sexes with age. Antenatal ultrasound has significantly increased the detection rate of lower urinary tract obstruction in the fetus.[9] In children aged younger than 10 years, obstruction is more common in males; congenital urinary tract anomalies, such as PUV and pelviureteral obstruction, account for most cases. In North America, obstructive uropathy is a common cause of ESKD in children and accounts for 11.4% of cases.[10] In addition, congenital obstructive uropathy accounts for 0.7% of all patients (median age, 31 years) treated with maintenance kidney replacement therapy,

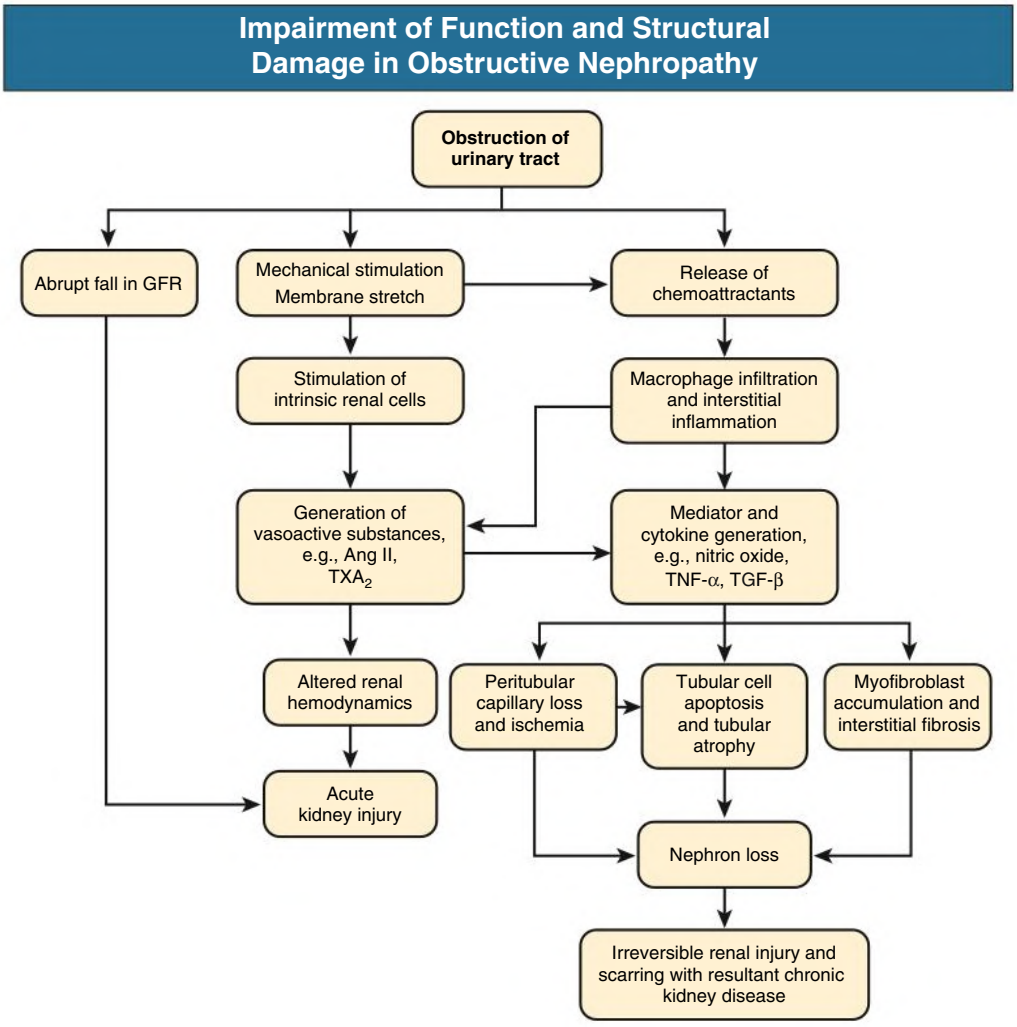

Fig. 61.6 Events leading to acute impairment of kidney function and chronic structural damage in obstructive nephropathy. *Ang II,* Angiotensin II; *GFR,* glomerular filtration rate; *TGF-β,* transforming growth factor-β; *TNF-α,* tumor necrosis factor α; *TXA_2,* thromboxane A_2.

demonstrating the continued impact of this disease into adult life.[11] In adults younger than 20 years, the frequency of urinary tract obstruction is similar in males and females. Beyond 20 years of age, obstruction becomes more common in females, mainly because of pregnancy and gynecologic malignancy. The peak incidence of kidney calculi occurs in the second and third decades of life, with a threefold increased incidence in males. After the age of 60 years, obstructive uropathy occurs more frequently in males secondary to benign prostatic hypertrophy and prostatic carcinoma. About 30% of males older than 50 years have some symptoms of bladder outflow obstruction and acquired urinary tract obstruction can lead to ESKD in elderly patients with most resulting from prostatic disease.[12] In the United States, 1.4% of prevalent patients with ESKD have kidney failure secondary to acquired obstruction.[11]

CLINICAL MANIFESTATIONS

Obstruction of the urinary tract can present with a wide range of clinical symptoms, depending on the site, degree, and duration of obstruction. The clinical manifestations of upper and lower urinary tract obstruction differ. Symptoms can be caused by mechanical obstruction of the urinary tract (usually pain) or can result from the complex alterations in glomerular and tubular function that may occur in obstructive nephropathy. The latter commonly manifests as alterations in urine volume and as kidney failure, which can be acute or chronic. For example, patients with complete obstruction present with anuria and AKI, whereas those with partial obstruction may present with polyuria and polydipsia secondary to acquired vasopressin resistance. Alternatively, there may be a fluctuating urine output, alternating from oliguria to polyuria. However, obstructive uropathy and hence obstructive nephropathy can occur without symptoms and with minimal clinical manifestations. Therefore, obstruction of the urinary tract must be considered in the differential diagnosis of any patient with reduced GFR.

Pain

Pain is a frequent complaint in patients with obstructive uropathy, particularly in those with ureteral calculi. The pain is believed to result from stretching of the collecting system or the renal capsule. The location of the pain may help determine the site of obstruction. With upper ureteral or pelvic obstruction, flank pain and tenderness typically occur, whereas lower ureteral obstruction causes pain that radiates to the groin, the ipsilateral testicle, or the labia. Acute high-grade ureteral obstruction may be accompanied by a steady and severe crescendo flank pain radiating to the labia, the testicles, or the groin (classic kidney colic). The acute attack may last less than half an hour or as long as a day. By comparison, patients with chronic slowly progressive obstruction may have no pain or minimal pain; in such patients, any pain that does occur is rarely colicky. In PUJ obstruction, pain may occur only after fluid loading to promote a high urine flow rate (often reported after drinking alcohol, for example).

Lower Urinary Tract Symptoms

Obstructive lesions of the urethra or bladder neck or bladder disease may cause a decrease in the force or caliber of the urine stream, intermittency, hesitancy, straining (voiding lower urinary tract symptoms), postmicturition dribbling, or nocturia. Urgency, frequency, and urinary incontinence can result from incomplete bladder emptying. Indeed, the development of nocturnal incontinence suggests chronic urinary retention and should be considered a red flag that may be associated with painless kidney failure. Such symptoms commonly result from prostatic hyperplasia (a histologic diagnosis; benign prostatic enlargement [BPE] is the preferred clinical term) and are frequently referred to as *prostatism.* The preferred clinical term is lower urinary tract symptoms (LUTS), caused by BPE, resulting in benign prostatic obstruction (BPE with evidence of bladder obstruction). However, lower urinary tract symptoms have many causes and are not pathognomonic of benign prostatic enlargement.

Urinary Tract Infections

Urinary stasis resulting from obstruction predisposes to urinary tract infections (UTIs), and patients may develop cystitis with dysuria and frequency or pyelonephritis with loin pain and systemic symptoms. Infection occurs more often in patients with lower urinary tract obstruction than in those with upper urinary tract obstruction.

UTI in males or young children of either sex, recurrent or persistent infections in females, infections with unusual organisms such as *Pseudomonas* or *Proteus spp.*, and a single attack of acute pyelonephritis require further investigation to exclude obstruction or stone disease. Also, the presence of obstruction makes effective eradication of the infection difficult. Infections of the urinary tract with a urease-producing organism such as *Proteus mirabilis* predispose to stone formation. These organisms generate ammonia, which results in urine alkalinization and favors the development of magnesium ammonium phosphate (struvite) stones. Struvite calculi can fill the entire renal pelvis to form a staghorn calculus that eventually leads to loss of the kidney if untreated. Thus, stone formation and papillary necrosis can be consequences of urinary tract obstruction and causes of obstruction.

Hematuria

Calculi may cause trauma to the urinary tract uroepithelium and result in either macrohematuria or microhematuria. Any neoplastic lesion that obstructs the urinary tract, especially uroepithelial malignancies, may bleed, resulting in macrohematuria. Urinary tract bleeding may result in obstruction, giving rise to clot colic when it is in the ureter, or clot retention when it is in the bladder. Clot obstruction of the ureter is usually (but not always) transient.

Changes in Urine Output

Complete bilateral obstruction or unilateral obstruction of a single functioning kidney such as a kidney transplant will result in anuria. However, in partial obstruction, the urine output may be normal or increased (polyuria). A pattern of alternating oliguria and polyuria or the presence of anuria strongly suggests obstructive uropathy.

Abnormal Physical Findings

Physical examination can be completely normal. Some patients with upper urinary tract obstruction may have flank tenderness. Longstanding obstructive uropathy may result in an enlarged palpable kidney in children. Lower urinary tract obstruction causes a distended, palpable, and occasionally painful bladder. However, in severe chronic bladder outflow obstruction (which is most likely to cause kidney failure), there may be no tenderness and no discrete palpable bladder because the bladder has stretched to such an extent that it is now "baggy." Ultrasound scan, or catheterization with careful documentation of residual bladder volume and subsequent urine output, may be required to clinch the diagnosis. A rectal examination and, in females, a pelvic examination should be performed because they may reveal a local malignancy, prostatic enlargement, or neurologic deficit suggesting cauda equina pathology.

Acute or chronic hydronephrosis, either unilateral or bilateral, may cause hypertension secondary to impaired sodium excretion with expansion of extracellular fluid volume or from the abnormal release

of renin. On occasion, in patients with partial urinary tract obstruction, polyuria and volume depletion lead to hypotension.

Abnormal Laboratory Findings

Urinalysis may show hematuria, bacteriuria, pyuria, crystalluria, and low-grade proteinuria, depending on the cause of obstruction. However, urinalysis may be completely negative despite advanced obstructive nephropathy. In the acute phase of obstruction, urinary electrolyte values are similar to those seen in a prerenal state, with a low urinary sodium concentration (<20 mmol/L), a low fractional excretion of sodium (<1%), and a high urinary osmolality (>500 mOsm/kg). However, with more prolonged obstruction, a decreased ability to concentrate the urine and an inability to reabsorb sodium and other solutes occur. These changes are particularly marked after the release of chronic obstruction and give rise to the syndrome commonly referred to as "postobstructive diuresis."

Increases in serum urea and creatinine are the most significant laboratory abnormalities in patients with obstructive uropathy. Electrolyte abnormalities may occur, including hyperchloremic hyperkalemic (type 4) metabolic acidosis or hypernatremia from acquired nephrogenic diabetes insipidus. The development of obstruction in patients with underlying CKD may accelerate the rate of progression. ESKD may occasionally be caused by chronic obstructive uropathy that had been asymptomatic.

Obstruction in Neonates or Infants

With the advent of routine antenatal scanning, the diagnosis of hydronephrosis and genitourinary abnormalities is now frequently made antenatally; however, unsuspected obstructive uropathy may present in the postnatal period with failure to thrive, voiding difficulties, fever, hematuria, or symptoms of kidney failure. Oligohydramnios at the time of delivery should raise the suspicion of obstructive uropathy, as should the presence of congenital anomalies of the external genitalia. Nonurologic anomalies such as ear deformities, a single umbilical artery, imperforate anus, or a rectourethral or rectovaginal fistula should prompt investigation for urinary tract obstruction. Any infant with neurologic abnormalities may have a neurogenic bladder with associated obstructive uropathy.

DIAGNOSIS

Prompt diagnosis of urinary tract obstruction is essential to allow timely treatment. Symptoms such as kidney colic may suggest the diagnosis and prompt appropriate investigation. However, urinary tract obstruction should be considered in any patient with unexplained acute or chronic kidney impairment. The diagnostic approach must be tailored to the clinical presentation (Fig. 61.7), but a careful history and thorough physical examination are mandatory in all patients.

Urinalysis may provide valuable diagnostic information. Hematuria suggests that the obstructing lesion is a calculus, sloughed papilla, or tumor. Bacteriuria suggests urinary stasis, especially in males or pregnant females, but it also may be a complication of chronic obstruction. The presence of crystals in the urine sediment (cystine or uric acid) may be an indication of the type of stone causing the ureteral obstruction or the intrarenal obstruction resulting in AKI. Laboratory studies must include assessment of GFR and serum electrolytes.

Imaging

Because the sites, causes, and consequences of obstruction to the urinary tract are so variable, no single imaging investigation can diagnose or exclude urinary tract obstruction with certainty. Therefore, if the clinical suspicion of obstruction is high, the patient may require investigation with multiple imaging techniques.

Ultrasound is the most widely used imaging modality, but CT scanning (with urographic phase) and magnetic resonance (MR) urography are increasingly used to accurately diagnose both the site and cause of obstruction. Although much less commonly used, older imaging techniques, such as intravenous urography (IVU), can be used to evaluate patients with obstructive uropathy. None of these modalities provides a functional kidney excretory or voiding profile, and where doubt still exists as to the existence of kidney obstruction (e.g., in cases of nonobstructive hydronephrosis ["baggy renal pelvis"], vesicoureteral reflux, or hypertonic bladder), functional investigations are required such as radioisotope excretory renography (mercaptoacetyltriglycine [MAG3] renogram), micturating cystoureterogram, or pressure-voiding studies (cystometrogram [CMG]), respectively. The role of imaging techniques is shown in Fig. 61.7 and discussed further in Chapters 5 and 6.

Ultrasound

Ultrasound can define kidney size and demonstrate calyceal dilation but depends on the expertise of the operator (Fig. 61.8). Although it is sensitive for detection of hydronephrosis, ultrasound often will not determine its cause. Pathologic change within the ureter is difficult to demonstrate, and tiny stones will not generate acoustic shadows. However, unilateral hydronephrosis suggests obstruction of the upper urinary tract by stones, blood clots, or tumors. Bilateral hydronephrosis is more likely to result from a pelvic problem obstructing both ureters or obstruction of the bladder outlet, in which case the bladder will also be enlarged. Ultrasound should be combined with radiographic examination of the kidneys, ureters, and bladder (KUB) to ensure that ureteral stones or small kidney stones are not overlooked.

Ultrasound produces false-negative results in cases of nondilated obstructive uropathy. Immediately after acute obstruction (within 24 hours), the relatively noncompliant collecting system may not have dilated, so ultrasound examination findings may be normal. Furthermore, if urine flow is low, as in severe dehydration or kidney failure, there may be little dilation of the urinary tract. Dilation also may be absent in slowly progressive obstruction when the ureters are encased by fibrous tissue (as in retroperitoneal fibrosis) or by tumor, and in some kidney transplants in which there is dense surrounding scar tissue. The acoustic shadow of a staghorn calculus also can mask dilation of the upper urinary tract. In view of this, it is advisable to repeat the kidney ultrasound if suspicion of obstruction is high. The sensitivity of ultrasound for diagnosis of obstruction can be improved by measuring the resistive index with color Doppler sonography. A resistive index above 0.7 reflects the increased vascular resistance present in obstruction and can assist discrimination between obstructed and nonobstructed kidneys, although the resistive index can be increased in other conditions.[13] Such ultrasound techniques are particularly useful when it is especially important to minimize radiation exposure, such as in pregnant patients and in children, and in the follow-up of patients requiring repeated imaging, such as after extracorporeal shock wave lithotripsy.

Even in experienced hands, ultrasound may have a significant false-positive rate, especially if minimal criteria are adopted to diagnose obstruction. In addition, the echogenicity produced by multiple kidney cysts may be mistaken for hydronephrosis.

Ultrasound scanning can be used to assess bladder emptying and should be undertaken in patients with lower urinary tract symptoms, being performed at the bedside if necessary. The normal postmicturition (postvoid) residual volume is less than 50 mL (<100 mL is usually acceptable in patients > 65 years), and a large postmicturition residual volume suggests bladder outflow obstruction or detrusor muscle failure, which should prompt further urologic investigation and treatment.

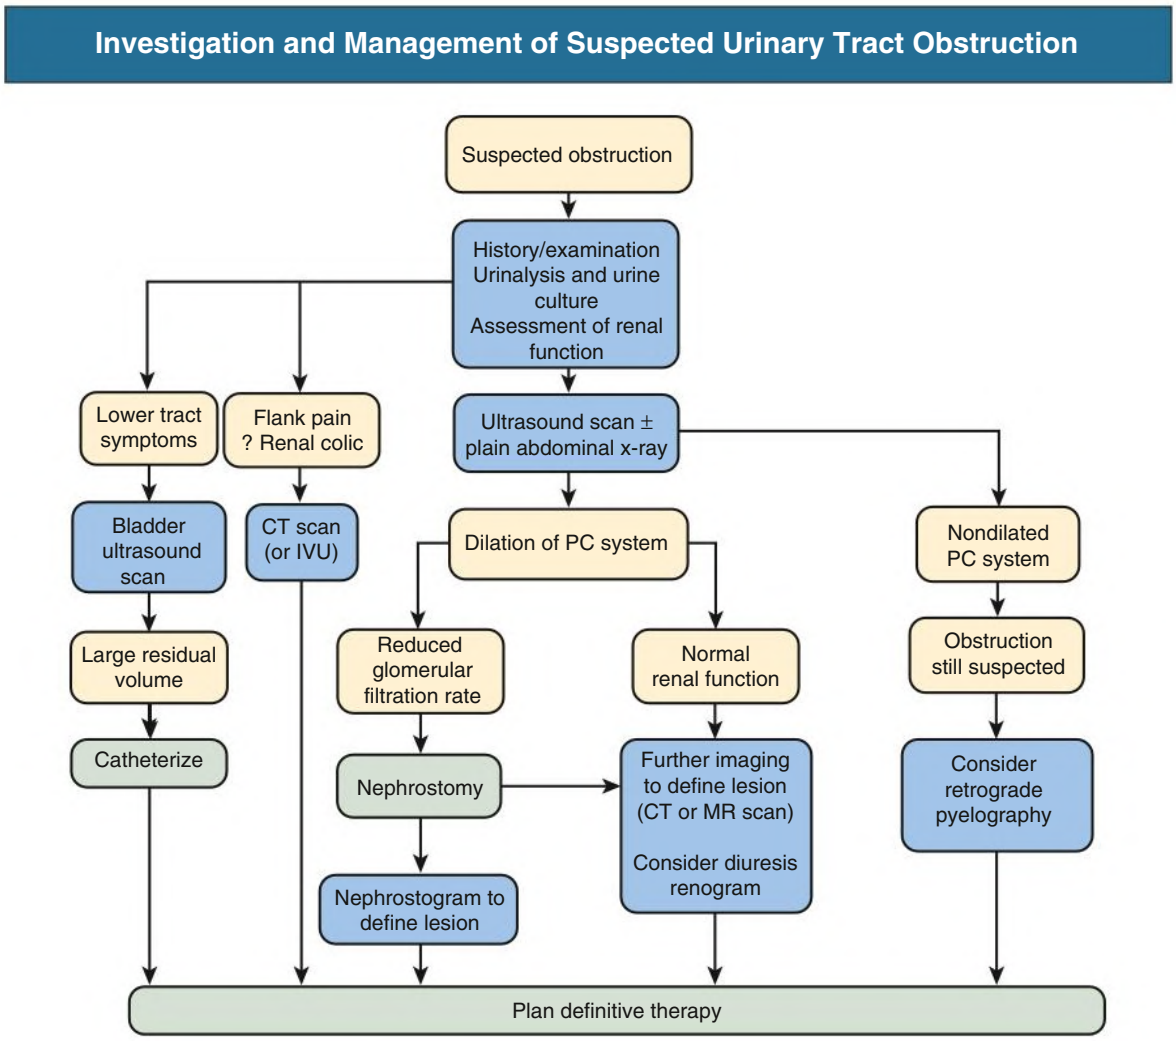

Fig. 61.7 Investigation and Management of Suspected Urinary Tract Obstruction. A full history and examination should be performed, together with urinalysis, urine microscopy and culture, and measurement of kidney function and serum electrolytes. Ultrasound is a useful first-line investigation for any patient with suspected urinary tract obstruction. Computed tomography (CT) is now the preferred imaging technique when kidney calculi are suspected. Either CT or magnetic resonance (MR) urography can accurately diagnose both the site and cause of obstruction in most cases. If there is reduced glomerular filtration rate, a nephrostomy or stenting allows the effective relief of the obstruction and time for kidney function to recover while definitive therapy is planned. *IVU,* Intravenous urography; *PC,* pelvicalyceal.

The investigation of neonates with hydronephrosis diagnosed antenatally depends on the grade of hydronephrosis identified. Neonates with grade 1 or 2 hydronephrosis (no calyceal dilation) undergo ultrasound scanning; neonates with grade 3 or 4 hydronephrosis (indicating increasingly severe pelvicalyceal dilation) require both ultrasound scanning and voiding cystourethrography.[14] This combination can distinguish megaureter resulting from obstruction or reflux and enable the diagnosis of PUV and UPJ obstruction. Measurements of both calyceal dilation and the anteroposterior diameter of the kidney pelvis at the first postnatal ultrasound may be able to distinguish those children who will require surgery, but this grading system will require further validation.[15]

Plain Abdominal Radiography

A plain abdominal radiograph (or KUB) allows an assessment of kidney size and contour and frequently demonstrates kidney calculi because about 90% of calculi are radiopaque.

Intravenous Urography

IVU was formerly the first-choice investigation for suspected upper urinary tract obstruction. In patients with normal GFR, it can usually define both the site and the cause of the obstruction. However, the excretion of contrast material may be poor or delayed in patients with low GFR because of a decreased filtered load of the contrast agent. IVU is no longer a first-line investigation to diagnose urinary tract obstruction, especially in patients with reduced GFR.

Computed Tomography

Non–contrast-enhanced spiral CT scanning is used increasingly as the primary imaging modality for the evaluation of patients with acute flank pain[16] and uses a low-dose protocol compared with conventional CT scanning of abdomen and pelvis. Stones are easily detected because of their high density; CT can provide an accurate and rapid diagnosis of an obstructing ureteral calculus, with a stone being found more commonly in males.[17] In addition, it provides useful information

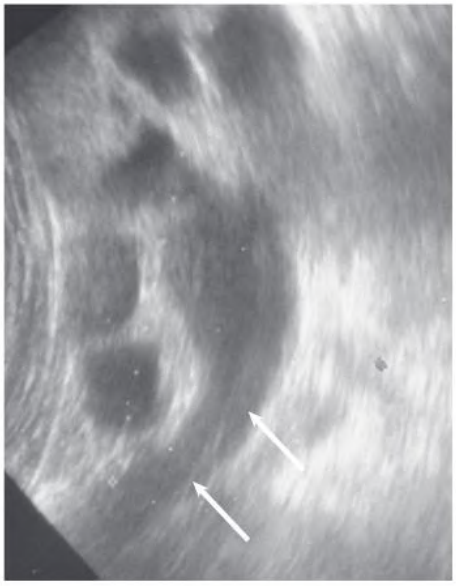

Fig. 61.8 Kidney Ultrasound Scan of a Patient with Obstruction of the Urinary Tract Causing Hydronephrosis. The kidney is hydronephrotic with dilation of the pelvicalyceal system; dilation of the upper ureter is also clearly seen *(arrows)*.

Fig. 61.9 Computed Tomography Scan of the Abdomen Showing a Grossly Hydronephrotic Kidney on the Left. *Arrows* mark dilated kidney pelvis. Dilated loops of small bowel are seen in the right hypochondrium. Sequential sections demonstrated that the ureter was dilated along its length and that there was a pelvic mass, which was responsible for both bowel and left ureteral obstruction. The mass was subsequently shown to be arising from a carcinoma of the colon.

about the site and nature of the obstructing lesion, especially when this is extrinsic to the urinary tract (Fig. 61.9), although a higher dose CT scan with intravenous (IV) contrast may be required for a full diagnostic study. CT demonstrates retroperitoneal disease, such as paraaortic and paracaval lymphadenopathy; retroperitoneal fibrosis is evident as increased attenuation within the retroperitoneal fat, with encasement of one or both ureters. Hematomas, primary ureteral tumors, and polyps are also detectable. The diagnostic potential of CT is enhanced by the administration of contrast material, but this may limit its use in patients with reduced GFR. CT urogram (IV contrast with delayed [usually 10 minutes] excretory phase images) is the gold standard imaging modality for diagnosis of intraluminal or intramural obstructing lesions such as upper tract urothelial malignancy. It should be noted that CT involves exposure to ionizing radiation, especially if patients require multiple CT scans over time.

Magnetic Resonance Urography

MR urography (combined with KUB) can enable the diagnosis of ureteral obstruction caused by kidney calculi with accuracy similar to that of spiral CT scanning but without exposure to contrast medium or ionizing radiation. The technique has less observer variability and is more accurate than CT in detecting indirect evidence of obstruction, such as perirenal fluid. MR urography can rapidly and accurately depict the morphologic features of dilated urinary tracts and provide information about the degree and level of obstruction[18] (Fig. 61.10). MR urography is a particularly attractive imaging modality for the evaluation of hydronephrosis in children because it provides both anatomic and functional data and can indicate whether the hydronephrosis is compensated (symmetric changes of signal intensity of the nephrogram) or decompensated.[19] Signs of decompensation (acute on chronic obstruction) include edema of the kidney parenchyma, a delayed and increasingly dense nephrogram, a delayed calyceal transit time, and a more than 4% difference in the calculated differential kidney function. MR urography is likely to be increasingly used in the future.

Retrograde Pyelography

Retrograde pyelography (Fig. 61.11; see also Fig. 61.2) usually requires a general anesthetic and cystoscopy but may be particularly useful to identify both the site and the cause of the obstruction because intervention (by stenting or dilation) and biopsy of a suspected tumor (by ureteroscopy) are both possible. It is also helpful when nondilated urinary tract obstruction is suspected or when there is a history of allergic reactions to contrast material.

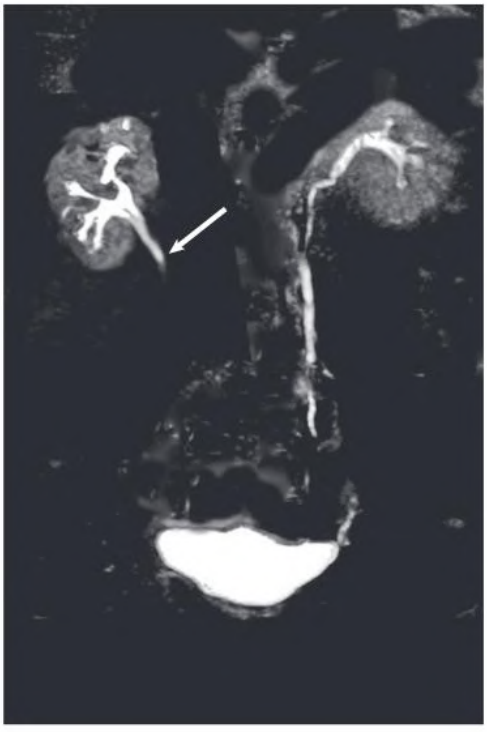

Fig. 61.10 Magnetic Resonance (MR) Urography Showing Obstructive Uropathy. T2-weighted MR image showing a proximal right-sided ureteric ureteral obstruction with an associated mild hydronephrosis. The obstruction was secondary to a ureteral calculus.

Diuresis Renography

A diuresis renogram using technetium-99m MAG3 (^{99m}Tc-MAG3), combined with IV furosemide administered 20 to 30 minutes after injection of the isotope (diuretic isotopic renography), can be used to distinguish between simple dilation of the collecting system and true

Fig. 61.11 Ureteral Obstruction by a Tumor. A retrograde pyelogram shows the tumor is within and obstructing the ureter *(arrows)*. Above the tumor, there is dilation of the ureter, but below it, the ureter is of a normal caliber.

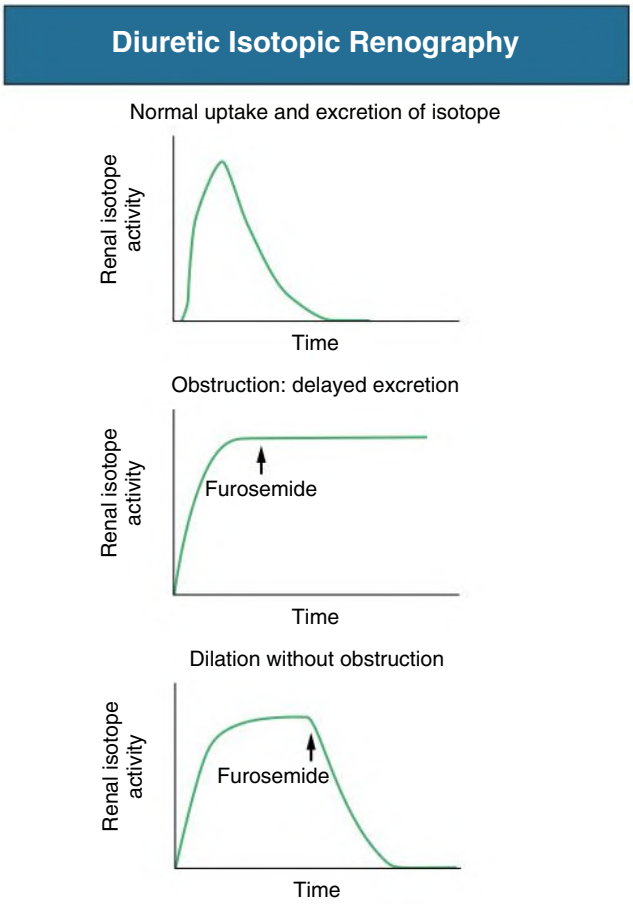

Fig. 61.12 Diuretic Isotopic Renography. Idealized tracings for normal, obstructed, and dilated kidneys without obstruction of the upper urinary tract. In obstruction, there is delayed excretion of technetium-99m mercaptoacetyltriglycine despite administration of furosemide. When there is dilation of the upper urinary tract without obstruction, the isotope is retained but is rapidly excreted after the administration of furosemide.

obstruction.[20] Normally, there is a rapid washout of the isotope from the kidney, and persistence of the isotope suggests a degree of obstruction (Fig. 61.12). Severely reduced GFR significantly limits the usefulness of renography because the diuretic response to furosemide may be absent. Diuresis renography also may be used for follow-up of patients who have undergone surgical procedures to relieve obstruction, such as a pyeloplasty.

Pressure Flow Studies

A pressure flow study (Whitaker test) involves puncture of the collecting system with a fine-gauge needle to perfuse fluid (at 10 mL/min) with concurrent measurement of the differential pressure between the bladder and the collecting system; a pressure greater than 20 cm H_2O indicates obstruction. Although this test is rarely required, it may be informative in patients with potential upper tract obstruction when other, less invasive tests have generated equivocal results.[21]

Other Evaluations

Lower urinary tract obstruction may be evaluated by cystoscopy, which allows a visual inspection of the entire urethra and the bladder. Urodynamic studies, also known as cystometrogram (CMG; see Chapter 50, Fig. 50.14), are most useful where the distinction between obstructive (e.g., BPE) and functional (e.g., detrusor muscle failure) impaired bladder emptying needs to be determined. High pressure voiding and vesicoureteral reflux can also be assessed with the use of fluoroscopy during urodynamics (known as video urodynamics).

DIFFERENTIAL DIAGNOSIS

Diagnostic uncertainty arises with nonobstructive dilation of the upper urinary tract, which may be seen with vesicoureteral reflux, diuretic administration, diabetes insipidus, congenital megacalyces, chronic pyelonephritis, and postobstructive atrophy. Diuresis renography or retrograde pyelography may be required to exclude obstruction.

NATURAL HISTORY

Obstructive uropathy is potentially curable but will result in progressive irreversible loss of nephrons and kidney scarring if left untreated (Fig. 61.13). ESKD will result if both kidneys are affected or if there is only a solitary kidney. Outcome data for obstructive uropathy are limited, but the exact prognosis will depend on the pathologic process responsible for the obstruction, the duration and grade of the obstruction (complete or partial), and the presence or absence of urosepsis. Relief of short-term obstruction (<1–2 weeks) usually results in an adequate return of kidney function. With chronic progressive obstruction (>12 weeks), there is often irreversible and severe kidney damage, and kidney functional recovery may be limited even after relief of the obstruction. A single-center study identified 104 patients who presented with obstructive nephropathy.[22] The mean GFR at presentation and at 3, 12, and 36 months was 9, 28, 29, and 30 mL/min, respectively

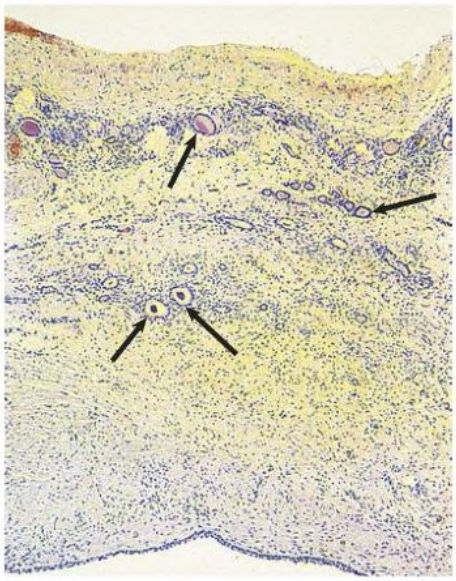

Fig. 61.13 Pathology of Chronic Ureteral Obstruction. Section of the rim of kidney tissue from the kidney shown in Fig. 61.7. The kidney capsule is at the *top,* the urinary space at the *bottom*. The cortex is considerably thinned, and only a few atrophic tubules remain *(arrows)* within an interstitium comprising dense fibrous tissue and a mononuclear cell infiltrate *(blue staining nuclei).* No glomeruli can be seen. This demonstrates why there would be no prospect for any significant functional recovery in this kidney even after the relief of the obstruction.

(patients on dialysis excluded), demonstrating significant but nonprogressive kidney impairment after relief of obstruction. It is likely that the prognosis for kidney functional recovery is better after earlier diagnosis and relief of the obstruction.

TREATMENT

General Considerations

Treatment is dictated by the location of the obstruction, the underlying cause, and the degree of any kidney impairment. If kidney impairment is present, the treatment of obstruction requires close collaboration between nephrologists and urologists to reduce the risks associated with the metabolic and electrolyte consequences of kidney failure and to optimize the chances for long-term recovery of kidney function. For example, complete bilateral ureteral obstruction (or obstruction of a single kidney) manifesting as AKI is a medical emergency and requires rapid intervention to salvage kidney function. Prompt intervention to relieve the obstruction should result in a rapid improvement in kidney function. Dialysis is rarely required in patients with AKI secondary to obstruction except to make the patient fit for intervention, such as by improving life-threatening hyperkalemia or severe fluid overload. The rapid relief of obstruction will limit permanent kidney damage, but kidney function may not recover immediately if acute tubular injury has resulted from obstruction or any accompanying sepsis.

Some surgical aspects of the management of obstructive uropathy are discussed in Chapter 63. The site of obstruction frequently determines the approach. If the obstruction is distal to the bladder, a urethral catheter or, if this cannot be passed, a suprapubic cystostomy will effectively decompress the kidneys. Placement of nephrostomy tubes or cystoscopy and passage of a retrograde ureteral stent will relieve upper urinary tract obstruction. Percutaneous nephrostomy (PCN) is generally the appropriate emergency treatment for upper urinary tract obstruction, especially in the setting of AKI. PCN can be achieved with local anesthetic and should allow for rapid recovery of kidney function in most patients (>70%), avoiding the need for dialysis. After relief of the obstruction by a nephrostomy, the exact site and nature of the obstructing lesion can be determined by an antegrade study infusing radiographic contrast material into the nephrostomy tube (nephrostogram), and time can be taken to plan definitive therapy (Fig. 61.14). The benefit of PCN insertion is that it can be achieved under local anesthetic, whereas ureteral stenting usually requires a general anesthetic. However, PCN is usually not possible where patients are therapeutically anticoagulated, potentially limiting its use where it is required urgently, and anticoagulation cannot be reversed. Major complications of nephrostomy insertion (abscess, infection, and hematoma) occur in less than 5% of patients. If both kidneys are obstructed, the nephrostomy should initially be placed in the kidney with the most preserved kidney parenchyma, although bilateral nephrostomies may be required to maximize the potential for the recovery of kidney function. If infection occurs above a ureteral obstruction (pyonephrosis), drainage of the kidney by PCN can play an important therapeutic role together with appropriate antibiotics.

A nephrostomy can be used to gauge the potential for functional recovery in patients with chronic obstruction. Failure of kidney recovery after several weeks of nephrostomy drainage strongly suggests irreversible structural damage and thus no likely benefit from undertaking a more definitive surgical correction of the obstructing lesion. Long-term nephrostomy or stenting may be used as a definitive therapy for patients who are unsuitable for major surgical intervention and those with incurable malignant disease, although patient selection is important in the latter[23] (see Chapter 63 for further discussion). Various types of stent are available, and there is some evidence that metallic stents may provide more durable functional decompression in patients with malignant ureteric obstruction.[24]

Where stents have failed or the ureters have become impassable because of disease, it is possible where expertise exists to insert "extra-anatomic stents." These stents are tunneled from the kidney to the bladder percutaneously in the abdominal wall, thus bypassing any intraabdominal pathology.[25]

Ureteral obstruction requiring intervention occurs in up to 3% of kidney transplant recipients.[26] It can be treated by nephrostomy and ureteral stenting, percutaneous incision or balloon dilation of the stricture, or open surgical repair (see Chapter 108).

Specific Therapies

Calculi are the most common cause of ureteral obstruction, and their treatment includes relief of pain, elimination of obstruction, and treatment of infection (see Chapters 60 and 63). Ureteral obstruction by papillary tissue, blood clots, or a fungus ball is treated by procedures similar to those used for calculi. When obstruction is caused by neoplastic, inflammatory, or neurologic disease, there is unlikely to be spontaneous remission of the obstruction, and some form of urinary diversion, such as an ileal conduit, long-term intermittent ureteral stenting, or extra-anatomic stenting should be considered. Some obstructing neoplastic lesions, such as lymphadenopathy from lymphoma, may respond to chemotherapy. A "realistic medicine" approach should be taken in management of ureteric obstruction because surgical management can reduce quality of life and carries risks of complications. Management of malignant urinary tract obstruction is discussed further in Chapter 59.

In idiopathic retroperitoneal fibrosis, ureterolysis (in which the ureters are surgically freed from their fibrous encasement) may be beneficial, especially if combined with corticosteroid therapy to prevent recurrence. The procedure can be performed minimally invasively using robotic technology in specialist centers and may represent a durable treatment preferable to long-term ureteric stents and steroids.[27]

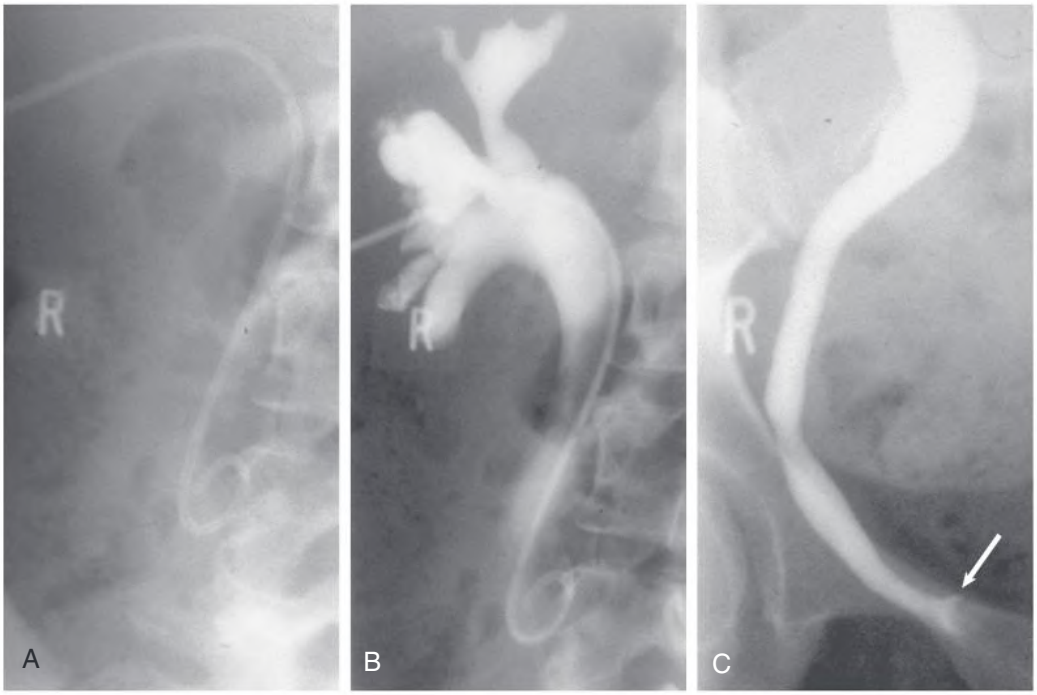

Fig. 61.14 Nephrostogram. A nephrostomy has been placed percutaneously into the dilated collecting system of the kidney under ultrasound control (A). After infusion of contrast material down the nephrostomy, the dilated pelvicalyceal system and upper ureter (B) and the lower ureter (C) are outlined. The ureter is dilated along its length but tapers abruptly at the vesicoureteral junction *(arrow)*. In this case the obstruction was caused by a radiolucent stone.

Although ureteral stent insertion and corticosteroids can provide relief of obstruction in idiopathic retroperitoneal fibrosis,[28] these treatments come with long-term adverse effects, whereas surgery may offer the chance of cure.[27,29] Retroperitoneal fibrosis complicating IgG4 disease may respond to corticosteroid treatment.[3] Although kidney obstruction per se results in kidney inflammation involving multiple immune cells irrespective of the underlying cause, there are no published trials of therapies that target the immune system in this patient cohort. Although pharmacologic blockade of the renin-angiotensin system is not instituted in the acute setting, it is reasonable to employ ARBs or angiotensin-converting enzyme inhibitors in patients with residual CKD.

Functionally significant PUJ obstruction should be corrected surgically; minimally invasive and robotic techniques have largely replaced the open (Anderson-Hynes) pyeloplasty. The laparoscopic approach results in significantly less morbidity and has good long-term outcomes that are comparable to those of the open procedure.[30] Balloon dilation of the abnormal segment of the ureter is also possible, but the recurrence rate is high. The severity of kidney fibrosis and atrophy as assessed on intraoperative wedge kidney biopsy in patients undergoing open PUJ surgery can be used to predict functional outcome.[31] There is increasing interest in the usefulness of urine proteomics to identify neonates with PUJ obstruction who require surgical intervention,[32] although a subsequent small study indicated that this approach was less specific and sensitive in older children.[33] Urinary biomarkers that show altered levels in children or adult patients with obstructive nephropathy include established well-studied AKI biomarkers (kidney injury molecule-1, neutrophil gelatinase–associated lipocalin, and liver-type fatty acid binding protein),[34] aquaporin-2, and TGF-β, as well as epidermal growth factor, monocyte chemotactic protein-1, and β_2-microglobulin.[35] Interestingly, a reduction in urinary epidermal growth factor is also seen in patients with CKD and is a predictor of CKD progression,[36] suggesting that urinary biomarkers may well facilitate the future stratification of patients with obstructive nephropathy and assist with predicting functional outcome after intervention.

Benign prostatic enlargement is the most common cause of lower urinary tract obstruction in males and may be mild and nonprogressive. Patients with minimal symptoms, no infection, and a normal upper urinary tract can continue with assessment until they and their physician agree that further treatment is desirable. Medical therapy with either α-adrenergic blockers (e.g., tamsulosin) or 5α-reductase inhibitors (e.g., finasteride) may be used in patients with moderate symptoms.[37] α-Blockers relax the smooth muscle of the bladder neck and prostate and decrease urethral pressure and outflow obstruction. 5α-Reductase inhibitors inhibit the conversion of testosterone to the active metabolite dihydrotestosterone and reduce prostatic hypertrophy. Combination therapy with these agents may be synergistic. Medical therapy is not appropriate for patients with outflow obstruction caused by BPE who have had upper urinary tract obstruction and loss of GFR. In these patients, definitive bladder drainage is mandatory and therefore will entail either long-term urethral catheter, intermittent self-catheterization, or definitive bladder outflow surgery according to individual patient risks and benefits. Surgical intervention for benign prostatic obstruction is generally required for failed medical treatment, debilitating symptoms, urinary retention, recurrent infection, or evidence of kidney parenchymal damage. A multitude of surgical modalities are available to treat benign prostatic obstruction, with transurethral resection of the prostate (TURP) still considered the gold standard; however, discussion with a urologist is recommended for all patients with significant BPE, even those who may traditionally have been considered "unfit for surgery."[38]

Urethral strictures in males can be treated by dilation or direct-vision internal urethrotomy before definitive urethroplasty, although urethral stenting is evolving. The incidence of bladder neck and

urethral obstruction in females is low and treatment rarely required. Suprapubic cystostomy may be necessary for bladder drainage in patients unable to void after injury to the urethra or in those who have an impassable urethral stricture.

When obstruction results from neuropathic bladder dysfunction, urodynamic studies are essential to guide therapy. The goals of therapy are to establish the bladder as a urine storage organ without causing kidney parenchymal injury and provide a mechanism for bladder emptying acceptable to the patient. Patients may have either a flaccid atonic or an unstable hypertonic bladder. Ureteral reflux and parenchymal damage may develop in both cases, although it is more common in patients with a hypertonic bladder. Asking the patient to void at regular intervals may achieve satisfactory emptying of the bladder. Patients with an atonic bladder and significant residual urine retention associated with recurrent urosepsis need to undertake clean intermittent self-catheterization. The aim should be to catheterize four or five times per day to ensure the amount of urine drained from the bladder on each occasion is less than 400 mL. In patients with a hypertonic bladder, improvement in the storage function of the bladder may be obtained with anticholinergic agents or intermittent detrusor injection with botulinum toxin. Occasionally, chronic clean intermittent self-catheterization is necessary.

Whenever possible, chronic indwelling catheters should be avoided in patients with a neurogenic bladder because they may lead to the formation of bladder stones, urosepsis, and urethral erosion, and they predispose to squamous cell carcinoma of the bladder. Patients who have chronic indwelling catheters for more than 5 years should have annual cystoscopic examinations. If deterioration in GFR occurs despite conservative measures or there is intractable incontinence or a small contracted bladder, an upper urinary tract diversion procedure such as an ileal conduit may be required or a bladder augmentation procedure such as a clam ileocystoplasty.

Management of Postobstructive Diuresis

Marked polyuria (postobstructive diuresis) is frequently seen after the release of bilateral obstruction or obstruction of a single functioning kidney. Indeed, a diuresis of greater than 7 L/day is associated with a good functional outcome.[39] Release of unilateral obstruction rarely results in a postobstructive diuresis despite the presence of tubular dysfunction and a concentrating defect. This is because of intrinsic differences in the tubular response to unilateral and bilateral obstruction and, more importantly, the salt and water retention and kidney impairment that occurred in bilateral obstruction (not evident in unilateral obstruction because of the contralateral normal kidney). The resultant increase in natriuretic factors (including atrial natriuretic peptide) and substances able to promote an osmotic diuresis, such as urea, promote an appropriate postobstructive diuresis to excrete water and electrolytes that were retained during the period of obstruction. However, the postobstructive diuresis also may be inappropriate because of tubular dysfunction and, if not managed correctly, may result in severe volume depletion and electrolyte imbalance with continued kidney dysfunction. The key to correct management is clinical fluid assessment because appropriate diuresis may not require treatment, whereas inappropriate diuresis requires treatment to prevent hypovolemia and electrolyte imbalance. IV and oral fluid replacement is usually required in cases of inappropriate diuresis with careful and regular assessment of the fluid balance and serum electrolytes to tailor the fluid replacement regimen appropriately. Once the patient is deemed euvolemic, urine losses plus an allowance for insensible losses should be replaced. Urine volume should be measured regularly (hourly) to facilitate fluid administration, and serum electrolytes should be measured at least daily and as frequently as every 6 hours when there is a massive diuresis. Daily weighing of the patient is also helpful. Replacement fluid regimens should include sodium chloride and a source of bicarbonate and potassium. Calcium, phosphate, and magnesium replacement also may be necessary.

If fluid administration is overzealous, the kidney will not recover its concentrating ability, and a continued "driven" diuresis will result. It may then be necessary to decrease fluid replacement to levels below those of the urine output and observe the patient carefully for signs of volume depletion.

Future Prospects

Understanding the pathophysiologic changes that follow ureteral obstruction has allowed the development of rational interventional therapies to hasten the recovery of kidney function and limit permanent kidney damage. Although the best treatment option in humans remains prompt and effective relief of the obstruction, development and implementation of improved imaging modalities that provide more sophisticated anatomic and functional information (including intrarenal oxygen content[40]) and future advances in urine proteomics will undoubtedly refine patient management and increase the data available for making key clinical decisions, such as whether and when surgical intervention is required.

SELF-ASSESSMENT QUESTIONS

1. Which of the following statements are correct?
   - **A.** The presence of hydronephrosis does not always indicate significant obstruction.
   - **B.** Despite the effective relief of urinary tract obstruction, the majority of patients slowly progress to ESKD.
   - **C.** Urinary tract obstruction is always associated with oliguria.
   - **D.** Patients with urinary tract obstruction typically exhibit microscopic hematuria on urinalysis.
   - **E.** Urinary tract obstruction is a risk factor for urinary infections.
2. Which of the following statements are correct?
   - **A.** The development of marked diuresis after relief of urinary tract obstruction is a poor prognostic indicator and is associated with the eventual development of ESKD.
   - **B.** Urinary tract obstruction may complicate neurologic disease.
   - **C.** Retroperitoneal disease may result in urinary tract obstruction.
   - **D.** Urinary tract obstruction leads to inflammation and scarring of the kidney.
   - **E.** Urinary tract obstruction may complicate IgA nephropathy.
3. Which of the following statements are correct?
   - **A.** Defective tubular function may persist after relief of urinary tract obstruction.
   - **B.** Urinary tract obstruction is associated with a reduction in the glomerular filtration rate but preservation of kidney blood flow.
   - **C.** Non–contrast-enhanced spiral CT scanning is now established as the first-line imaging investigation in patients with suspected urinary tract obstruction.
   - **D.** A diuresis renogram accurately assesses kidney function but is unlikely to indicate the presence of obstruction.
   - **E.** Urinary tract obstruction may occur in the absence of hydronephrosis.

Primary Vesicoureteral Reflux and Reflux Nephropathy

Ranjiv Mathews, Tiffany Damm, Tej K. Mattoo

INTRODUCTION

Vesicoureteral reflux (VUR) may be primary or secondary. Primary VUR is diagnosed mostly after a urinary tract infection (UTI) or during work-up for antenatal hydronephrosis. Secondary VUR results mostly from increased bladder pressure because of obstructive uropathy or neurogenic bladder. In this chapter, we discuss primary VUR only.

Prenatal kidney injury in the form of dysplasia has been noted with high-grade primary VUR. The presence of VUR increases the risk for postnatal upper tract infection (pyelonephritis), and the two together can cause kidney injury leading to scarring of the kidney termed *reflux nephropathy* (RN). RN may manifest as proteinuria, hypertension, preeclampsia, chronic kidney disease (CKD), and even end-stage kidney disease (ESKD). Some patients present with proteinuria as a result of secondary focal segmental glomerulosclerosis (FSGS).

CLASSIFICATION

VUR is classified by radiologic evaluation on voiding cystourethrography (VCU) into five grades as defined by the International Reflux Study in Children (Fig. 62.1 and Table 62.1).[1] An example of grade V reflux is shown in Fig. 62.2. Grades I and II are considered low-grade VUR, and grades III to V are considered high-grade VUR. Grading of VUR is necessary to standardize management strategies and compare clinical outcomes. Although widely used, there is interobserver variability in the application of the grading system.[2]

EPIDEMIOLOGY

The reported incidence of VUR depends on the age of presentation and sex. VUR is often first suggested by dilation of the fetal kidney during ultrasound examination. It is suspected when the fetal kidney pelvis is more than 5 mm in anteroposterior diameter; a diameter of more than 10 mm is suggestive of high-grade VUR. In neonates who had evidence of fetal kidney pelvis dilation, as many as 13% to 22% have VUR. Indeed, it is estimated that 1% to 2% of neonates have VUR, with a higher frequency in boys and premature infants.[3] The incidence of kidney dysplasia is also greater in male infants with VUR.[4] Although some studies show that there is a higher incidence of VUR in females compared with males, this may be attributable to the higher predisposition of UTIs in females, therefore leading to greater diagnosis of VUR in females.

VUR is identified in 30% to 40% of children presenting with UTI, predominantly in girls. VUR may also be identified in as many as 40% of siblings of index patients. When identified using sibling screening protocols, VUR was felt to be less likely to be associated with infection or long-term kidney injury.[5] VUR is less common and less severe in Black children.[6] Only about one-third as many Black girls as White girls with UTI have VUR, and no significant differences in age or mode of presentation exist between the two races.

EMBRYOLOGY AND PATHOLOGY

Primary VUR is a congenital anomaly of the ureterovesical junction caused by shortening of the intravesical submucosal length of the ureter, leading to an incompetent valve mechanism (Fig. 62.3). The formation of the ureteral bud from the mesonephric duct signals the initial development of the metanephric kidney, the final stage of kidney development. The ureteral bud interacts with the mesenchyme to give rise to the metanephric kidney. As the mesonephric duct is gradually absorbed into the enlarging urogenital sinus (the precursor of the developing bladder), the location of the ureteral bud on the mesonephric duct plays a role in the eventual location of the ureteral meatus within the bladder. If the ureteral bud reaches the urogenital sinus too early because of the absorption pattern of the mesonephric duct, it is eventually located more laterally and proximally in the bladder. This location is associated with reduction in the intravesical submucosal length of the ureter, leading to VUR.

The ureterovesical junction is designed to prevent free reflux of urine from the bladder to the kidney. The ureters pass into the bladder through the detrusor in an oblique path. The distal end of the ureter is located submucosally within the bladder. The length of the submucosal ureter is critical for preventing VUR. The muscles of the ureter extend into the trigone of the bladder and mesh with the fibers from the opposite ureter. This intermingling of fibers helps anchor the ureters into the trigone of the bladder. The distal submucosal segment is compressed against the muscular bladder wall with bladder filling, acting as an additional mechanism to prevent reflux. Because urine is propelled antegrade down the ureter, the tone of the ureter and the meatus in the bladder also help prevent reflux.

CLINICAL MANIFESTATIONS

Presentation of Primary Vesicoureteral Reflux

The three most common presentations are during follow-up for antenatal hydronephrosis, after a diagnosis of UTI, and on screening of siblings of a patient with VUR (Box 62.1).

Reflux Identified Secondary to Antenatal Hydronephrosis

Diagnosis of VUR may be suspected in utero with unilateral or bilateral hydronephrosis and confirmed after birth with VCU. There is a higher incidence of male infants diagnosed with VUR after identification of antenatal hydronephrosis.[7] Spontaneous resolution of the VUR occurs more commonly in boys with lower grades and unilateral reflux; infection rates are also lower in this cohort.[8] Female infants are more likely to have lower grades of VUR and are also less likely to develop kidney

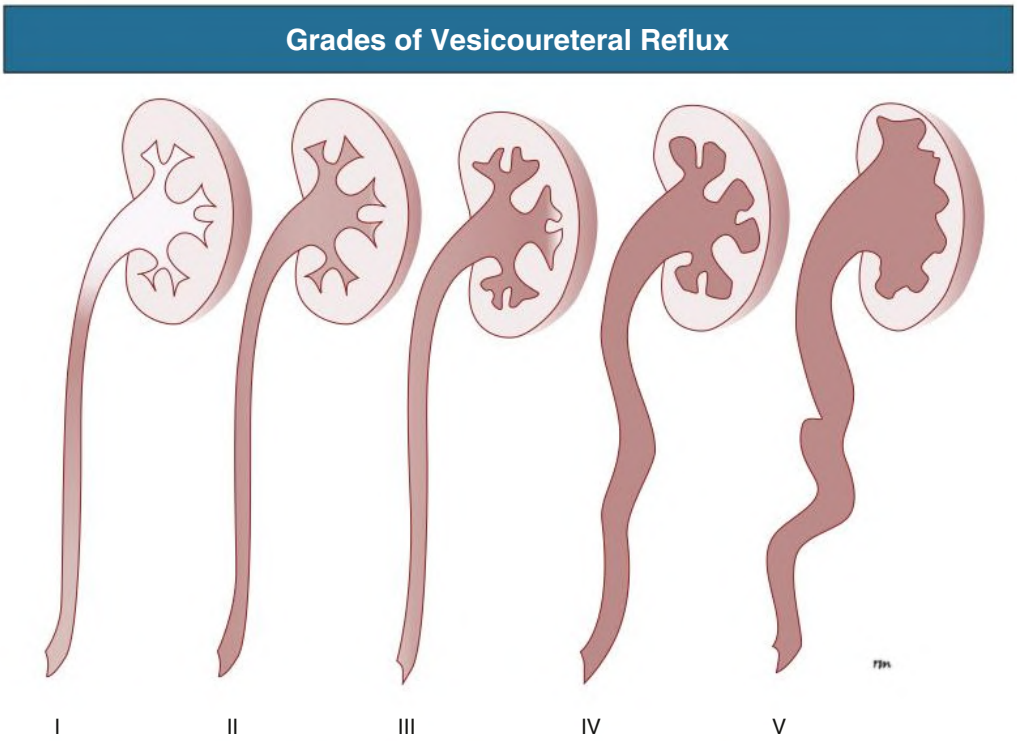

Fig. 62.1 Grades of vesicoureteral reflux.

TABLE 62.1 Classification of VUR[a]

Grade	Degree of VUR
I	Ureter only
II	Reflux into ureter, pelvis, and calyces with no dilation and with normal calyceal fornices
III	Mild or moderate dilation and/or tortuosity of the ureter and mild or moderate dilation of the pelvis; no or slight blunting of the fornices
IV	Moderate dilation and/or tortuosity of the ureter and moderate dilation of the pelvis and calyces; complete obliteration of the pelvis and calyces; complete obliteration of the sharp angles of the fornices but maintenance of the papillary impressions in the majority of the calyces (see Fig. 62.7C)
V	Gross dilation and tortuosity of the ureter, pelvis, and calyces; the papillary impressions are no longer visible in the majority of calyces (see Fig. 62.2)

damage compared with newborn males. Not all patients with antenatal hydronephrosis are investigated for the presence of VUR.

Reflux Identified After a Urinary Tract Infection

VUR is most commonly identified after UTI, particularly in a young child. The prevalence of VUR is higher in younger patients and decreases with age (Table 62.2). In neonates and toddlers, UTI may manifest as failure to thrive as opposed to typical symptoms of dysuria and frequency. VUR is more common in patients with complicated or upper tract UTI. Because VUR may potentiate the effect of UTI in children, the recommendations for evaluation of UTI have included ultrasound and VCU after resolution of symptoms. Current guidelines from the National Institute for Health and Care Excellence (NICE) and the American Academy of Pediatrics (AAP) do not recommend routine VCU in children after a first febrile UTI.[9] The AAP guidelines, which are meant for children aged 2 to 24 months old, suggest limiting the use of VCU to children identified as having complex UTIs or that have *any* abnormalities on ultrasound. We recommend beginning with an ultrasound of the kidneys and bladder once a febrile UTI has been confirmed, proceeding to evaluation with VCU if the ultrasound is abnormal or after a second febrile infection (Fig. 62.4). Other factors that may be considered as indications for VCU after the first febrile UTI include atypical causative pathogen, complex clinical course, known kidney scarring, or other congenital anomalies of kidney and the urinary tract.

Most children diagnosed with VUR after a UTI are younger than 7 years. UTI in these patients may be associated with modifiable host

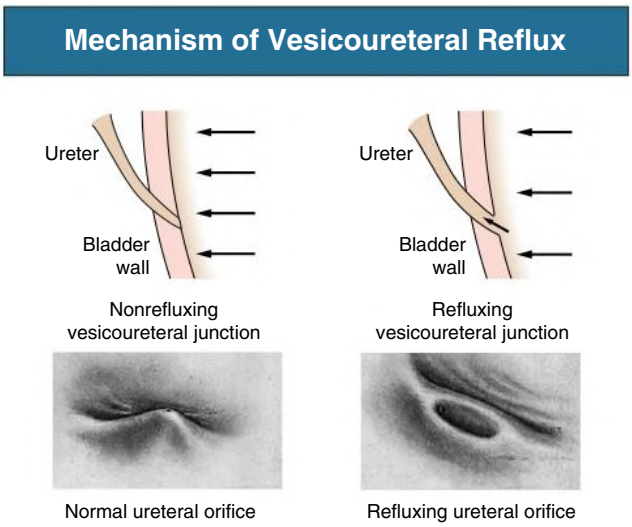

Fig. 62.3 Pathogenesis of Vesicoureteral Reflux. Competent *(left)* and incompetent *(right)* vesicoureteral junctions and ureteral orifices.

BOX 62.1 Clinical Presentations of Vesicoureteral Reflux

- Complicated urinary tract infection: usually acute pyelonephritis in infants and children
- Asymptomatic
  - Detected by fetal ultrasound
  - Detected in the workup of members of an affected family
  - Detected in pregnant persons with urinary tract infection
  - Detected during workup of kidney stones in children
  - Detected during assessment of other urologic congenital abnormalities

factors, such as bladder and bowel dysfunction (BBD). BBD is typically identified in toilet-trained children with urinary urgency, frequency, and/or incontinence in conjunction with constipation and is felt to be secondary to long-standing urine holding patterns. BBD is associated with development of UTIs that may be potentiated by the presence of VUR. Toilet-trained children with VUR identified after a UTI have a 43% incidence of dysfunctional voiding.[10]

Vesicoureteral Reflux in a Sibling

Approximately one-third of siblings of an index patient with VUR also have VUR.[5] There is a slightly higher incidence of VUR in female siblings of female index patients; 75% of children with VUR identified by evaluating siblings are asymptomatic, and siblings diagnosed with reflux have a better prognosis compared with the index patient with VUR, with lower risk of infection and long-term kidney injury.[5,11] The incidence of kidney damage is also lower in the siblings diagnosed with reflux compared with the index patient with VUR.[11] UTI with progression of scar was noted in only 5% of siblings with VUR observed for 3 to 7 years, and most of those with grades I and II VUR had spontaneous resolution.[11] The more benign course of sibling reflux compared with reflux identified after a UTI has led many to suggest limiting the testing of siblings. Currently, no routine testing for VUR is advised for siblings of a child with known VUR unless the sibling develops a UTI.

Other Presentations

An increased risk for kidney calculi has been reported in children with VUR. Recurrent infections with urease-splitting organisms can lead to staghorn calculi. VUR or RN may also be discovered in adults after recurrent lower or upper UTI; indeed, about 5% of sexually active females with UTI have VUR. VUR may first present as an infection in a pregnant person. In pregnant persons with active reflux, the risk for pyelonephritis is increased. A meta-analysis of 434 females with 879 pregnancies with RN showed that there was an increased risk of pregnancy-induced hypertension and pulmonary embolism.[12] Thus, it is likely that kidney scarring, not VUR itself, poses the greatest risk of morbidity in pregnant persons.[13]

TABLE 62.2 Prevalence of VUR in Patients With Urinary Tract Infection, According to Age

Age	Percentage With VUR
2–3 days	57
3–6 days	51
2–6 months	60
7–12 months	35
1–4 years	50
5–9 years	35

Reflux Nephropathy

RN may occur in patients with VUR and can be seen in those with or without proven UTI.[14,15] RN results from one of two processes (Table 62.3).[16] Prenatal kidney injury has been postulated to be secondary to the "water-hammer" effect of high-grade reflux and occurs in the absence of infection. This typically causes kidney dysplasia. This form of kidney scarring, which is also called *congenital RN,* is more commonly noted in infants with high-grade VUR, with a greater predominance of males. The second mechanism for development of kidney injury is the combination of VUR and repeated UTI, which is also

TABLE 62.3 Types of Kidney Damage Associated With VUR

	Congenital	Acquired
Time of occurrence	Often prenatal	Postnatal, sometimes in adulthood
Previous urinary infection	Not usually	Usually
Sex	Usually males	Usually females (particularly after infancy)
Grade of VUR	Usually grades IV and V	Grades IV and V less common
Kidney scarring	Often present	Present in minority[a]
Associated bladder dysfunction	Hypercontractile bladder common	Less commonly, high-capacity bladder with incomplete voiding

[a]Depends on unilateral versus bilateral involvement and the severity of kidney involvement.

BOX 62.2 Clinical Presentations of Reflux Nephropathy

- Complicated urinary infection: usually acute pyelonephritis in infants and children
- Hypertension: may be accelerated
- During pregnancy: urinary infection, hypertension, preeclampsia
- Proteinuria
- Chronic reduction in glomerular filtration rate
- Urinary calculi
- Asymptomatic
  - Detected in the workup of members of an affected family
  - Detected by fetal ultrasound
  - Detected during assessment of other urologic congenital abnormalities

called *acquired RN*. In these children, who are more commonly female, the combination of upper tract infection and reflux leads to kidney inflammation and permanent scarring. In one study, kidney cortical defects were seen on dimercaptosuccinic acid radionuclide scan (DMSA) in 45% of children with febrile UTI and VUR compared with 24% with UTI without VUR.[15] Scarring is more commonly located at the upper and lower poles of the kidney because of the anatomy of the kidney papillae in these regions.

The risk for kidney damage is greatest in the presence of high-grade VUR.[17] The Randomized Intervention for Vesicoureteral Reflux (RIVUR) trial also documented that the risk for new kidney scarring is higher in relatively older children and not in younger children as reported in the literature previously.[17] Other recent studies have also shown that older children may be at higher risk of kidney scarring.[18,19] One possible explanation for the higher incidence of kidney scarring in younger children is a lower threshold for diagnosing and investigating younger children with UTI compared with older children. Other risk factors for RN include duration of fever of longer than 72 hours before antibiotic initiation, recurrent UTI, and organisms other than *Escherichia coli.*

RN is diagnosed by using technetium-99m (^{99m}Tc)-labeled DMSA kidney scanning that demonstrates defects in the kidney outline.[20] As noted previously, high-grade prenatal reflux can lead to kidney injury in the absence of infection. Unfortunately, kidney scarring secondary to UTI is indistinguishable by DMSA kidney scan from that caused by prenatal kidney dysplasia. In addition, kidney injury can be noted after febrile UTI in the absence of identified VUR. Kidney scarring as shown by ^{99m}Tc DMSA scan correlates more closely with the severity of VUR than with a history of UTI.[21] The clinical manifestations of RN are varied and may include complicated UTI, hypertension, proteinuria, and various manifestations of CKD (Box 62.2).

The process of kidney scarring may take several years; in one study, the mean time from discovery of VUR to the appearance of a kidney scar was 6.1 years.[22] Injury is seen more at the kidney poles and is associated with clubbed calyces with medullary and cortical damage. The injury results from the local inflammatory response that may persist with chronic inflammation, tubular injury, local fibroblast activation, and interstitial collagen deposition (Fig. 62.5).[23] The loss of nephrons is associated with hyperfiltration and hypertension that can result in proteinuria and progressive loss of kidney function. This also can lead to the development of FSGS (Fig. 62.6).

Hypertension

Hypertension occurs in 10% to 30% of children and young adults with RN,[24,25] and according to one study, hypertension may take 8 years to develop from the time of diagnosis.[22] The exact cause of hypertension resulting from kidney scarring is not known, but it is thought to be caused by impaired sodium excretion resulting from the kidney injury and loss of kidney function. Hypertension is relatively uncommon in children with VUR, with an estimated probability of 2%, 6%, and 15% at 10, 15, and 21 years of age, respectively. However, hypertension increases in proportion to the degree of kidney injury.[26] Kidney scarring (noted by DMSA scans) was reported in 20% of newly diagnosed hypertension in children and adolescents.[27]

Proteinuria

Patients also may present with mild to moderate or (rarely) nephrotic-range proteinuria. Severe or nephrotic range proteinuria may suggest a histologic diagnosis of secondary FSGS, which can be confirmed by kidney biopsy if kidney size is normal and diagnosis is uncertain (see Fig. 62.6).[28] Proteinuria is commonly associated with hypertension and kidney dysfunction. CKD progression often occurs gradually over 5 to 10 years.

Chronic Kidney Disease

According to the North American Pediatric Renal Transplant Cooperative Study annual report of 2008, 3.5% of the 6491 children on dialysis had RN, which makes it the fourth most common cause of ESKD in children after FSGS; kidney aplasia, hypoplasia, or dysplasia; and obstructive uropathy.[29] The number of children with RN who present with ESKD as adults is not clear. According to one study of 123 adults with VUR diagnosed in childhood, the estimated glomerular filtration rate (eGFR) in those with nondilating VUR averaged 75 mL/1.73 m^2 and in the dilating group, the average was 72 mL/1.73 m^2; four patients (9%) in the nondilating group and 13 (17%) in the dilating group had an eGFR of less than 60 mL/1.73 m^2.[30] In a study that evaluated the clinical course of 735 children with primary VUR between 1970 to 2004, the probability of CKD was reported as 5% at

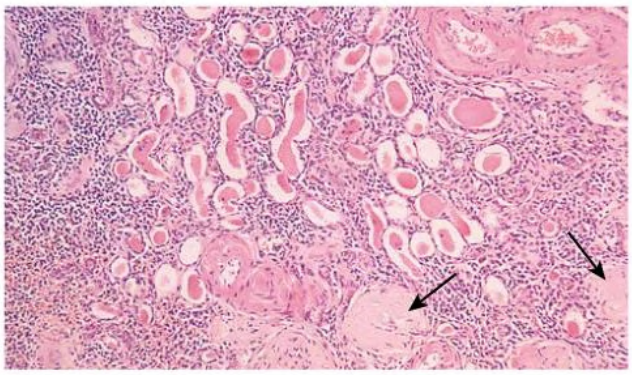

Fig. 62.5 Histologic Changes in Reflux Nephropathy. Sclerosed glomeruli *(arrows),* chronic inflammatory cell infiltration, and atrophic tubules with eosinophilic casts are present. (H&E stain; original magnification ×40.)

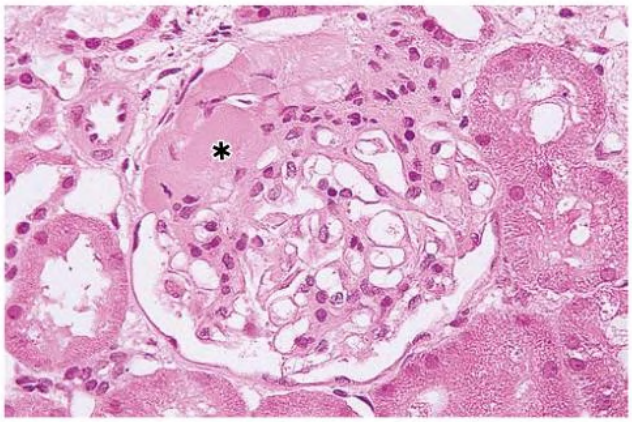

Fig. 62.6 Focal Segmental Glomerulosclerosis (FSGS) in Reflux Nephropathy. Light microscopy of a glomerulus from a patient with reflux nephropathy shows FSGS with the scarred area marked by an *asterisk.* (H&E stain; original magnification ×400.)

10 years after diagnosis of VUR. For children diagnosed after 1990, the probability of CKD was only 2%, indicating that the prognosis for patients diagnosed with VUR may be improving over time. Another study by the same group evaluated independent predictive factors of CKD in children with severe bilateral grades III to V VUR. The authors found that the probability of CKD for patients with bilateral severe reflux was 15% by 10 years after VUR diagnosis. The three variables that were independently associated with CKD were age at diagnosis of greater than 24 months, VUR grade V, and bilateral kidney damage.[26]

Diagnosis of Vesicoureteral Reflux and Reflux Nephropathy

An algorithm for diagnosis of VUR after the discovery of UTI is shown in Fig. 62.4. However, this is not followed by all practitioners, partly because of other published guidelines and the possible usefulness of antimicrobial prophylaxis in VUR, as reported by the RIVUR study.[31] An example of the various tests in a child with UTI and VUR is shown in Fig. 62.7.

Kidney Ultrasound

Ultrasound is the initial modality for the evaluation of postnatal hydronephrosis and UTI in children. Ultrasound is also used in siblings of children with VUR to determine whether kidney dilation suggestive of high-grade reflux is present. Although ultrasound can suggest the possibility of high-grade VUR, it is not sensitive for diagnosis of acute pyelonephritis. In patients with acute pyelonephritis, abnormalities compatible with the diagnosis were reported in 20% to 69% by ultrasound compared with 40% to 92% by DMSA scintigraphy.[32]

Kidney ultrasound is not diagnostic for VUR and is not a sensitive method for diagnosis of kidney scars. Nonetheless, a kidney ultrasound is useful to diagnose congenital anomalies of kidney and urinary tract and to detect complications of acute pyelonephritis such as kidney abscess or pyonephrosis.

Voiding Cystourethrography

VCU is the primary diagnostic modality for identification of VUR. It requires catheterization. The grading of VUR is based on radiographic appearance by VCU (see Fig. 62.1). In children with UTI, VCU should be performed as soon as the child has completed antibiotic therapy.

The results of VCU can be affected by size, type, and position of the catheter; rate of bladder filling; height of the column of contrast media; state of hydration of the patient; and volume, temperature, and concentration of the contrast medium. These parameters are not currently measured in the grading system. Durability of grade also appears to be hampered by the variability of a radiologist interpretation of VCU images. In an analysis comparing the interpretation of two blinded RIVUR radiologists with a local radiologist's interpretation, all three radiologists agreed on VUR grade in only 59% of ureters.[2] Ureteral dilation may be present without calyceal dilation, leading to discrepancies with grading.[33]

Nuclear cystography has been used to reduce the radiation exposure for children during follow-up of VUR. Nuclear cystography, although more sensitive, does not permit specific grading of VUR or reveal other anatomic defects, such as ureterocele and diverticulum. Therefore, nuclear cystography is typically not the primary study performed for identification of VUR, but it is useful in determining improvement or resolution of reflux during follow-up or after surgical correction.

DMSA Kidney Scintigraphy

DMSA scintigraphy is currently the gold standard for diagnosis of acute pyelonephritis and kidney scarring with a high rate of sensitivity. Single-photon emission computed tomography (SPECT) DMSA scintigraphy is superior to planar imaging for detection of kidney cortical damage.[34,35] The sensitivity of DMSA scintigraphy in experimentally induced acute pyelonephritis in a pig model was reported to be 92% when correlated with histologic findings.[35] By use of standardized criteria for its interpretation, high levels of intraobserver and interobserver agreement were reported.[36,37]

An abnormal DMSA scan during a febrile UTI allows for the identification of children with kidney inflammation who are at risk for development of kidney scars. For acute pyelonephritis, DMSA scintigraphy can be performed within 2 to 4 weeks after the onset of UTI symptoms; however, it is not encouraged because it usually does not change clinical management. Some have suggested the use of DMSA scanning as an initial modality to identify children with abnormalities that may suggest the need for evaluation for VUR. DMSA scintigraphy to identify kidney scarring should be performed 6 months after acute infection to allow reversible lesions to resolve.[38]

Dysplasia secondary to congenital reflux will appear similarly to kidney scarring after postnatal infections. In a child presenting with VUR, obtaining a baseline DMSA kidney scan allows identification of kidney dysplasia and scarring, which can then be observed over time.

Magnetic Resonance Imaging

Magnetic resonance imaging (MRI) can be used for the diagnosis of kidney scars because it discriminates swelling from scarring, both of which would be interpreted by DMSA scintigraphy as kidney scarring.

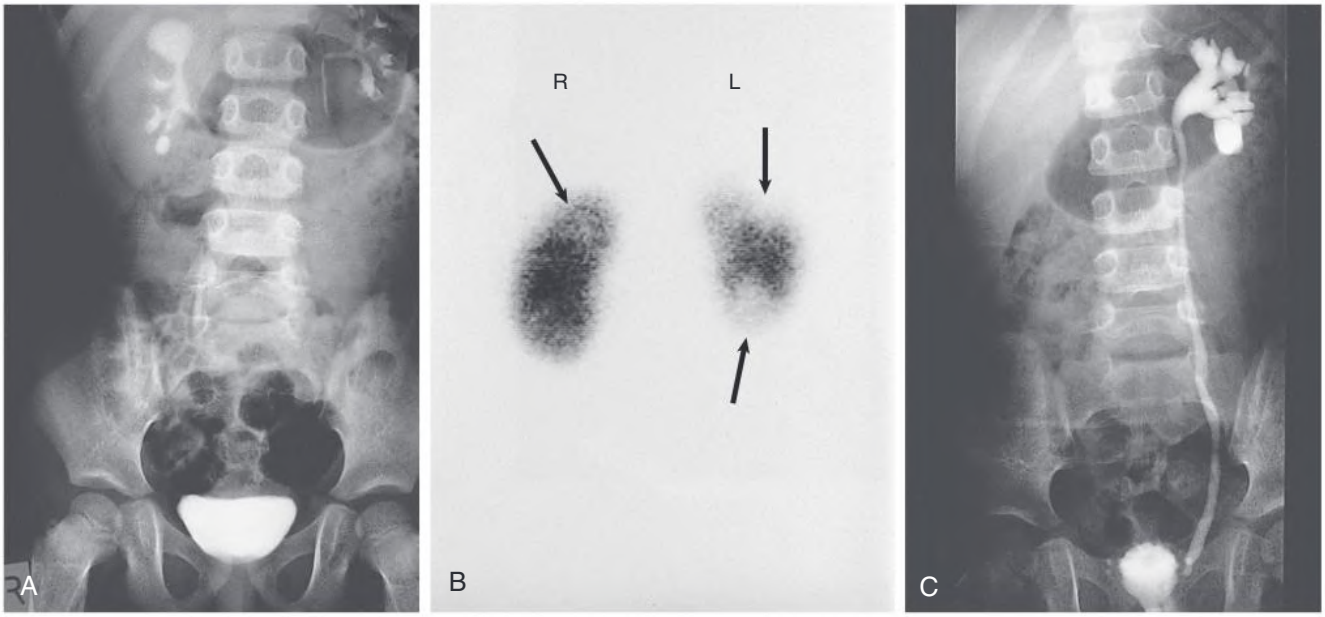

Fig. 62.7 Investigation of Reflux Nephropathy in a 3-Year-Old Child With Urinary Tract Infection. (A) Intravenous urogram showing calyceal diverticulum in the upper pole of the right kidney and kidney scarring in the upper pole and, probably, the lower pole of the left kidney. (B) Dimercaptosuccinic acid scintigraphy (posterior view) demonstrating upper and lower pole scarring *(arrows)* in the left kidney and scarring of the right upper kidney in association with the calyceal diverticulum *(arrowhead).* (C) Voiding cystourethrogram showing grade IV vesicoureteral reflux on the left.

MRI may diagnose other coexisting conditions, such as nephrolithiasis,[39] which is not diagnosed by DMSA scintigraphy. Newer imaging methods that show promise in diagnosis of kidney scarring include dynamic contrast-enhanced MRI and MRI using a gadolinium-enhanced short tau inversion recovery (STIR) sequence. However, routine use of MRI is less practical because of limited availability, especially for infants, need for prolonged sedation, and high cost. Gadolinium must be used with caution in the presence of significantly reduced glomerular filtration rate (< 30 mL/min/1.73 m^2).

Proteinuria as a Marker for Reflux Nephropathy

Proteinuria predicts CKD progression because of RN.[40] Persistent albuminuria is helpful in diagnosis of glomerular damage at an early stage. Albuminuria increases with increasing severity of VUR and kidney scarring.[41] In children with bilateral VUR with kidney scarring and normal creatinine clearance, mild albuminuria was detected in 54% of cases.[42] Evaluation for albuminuria offers the possibility of early intervention, such as the use of angiotensin-converting enzyme (ACE) inhibitors, aimed at retarding CKD progression. Severe albuminuria is usually associated with FSGS.

NATURAL HISTORY OF VESICOURETERAL REFLUX AND REFLUX NEPHROPATHY

Primary VUR, especially grades I to III, generally improves with time. This is likely the result of growth and lengthening of the submucosal segment of the ureter. Spontaneous resolution of VUR is more common with non-White race, lower grades of reflux, absence of kidney damage, and lack of voiding dysfunction. Primary VUR diagnosed before 1 year of age has a high likelihood of resolution[18,43]; however, after 1 year of age, the initial grade of reflux at presentation may be more useful to predict resolution. One retrospective study found spontaneous resolution rates to be 72% and 61% for grade I and II, compared with 32% for grade IV/V.[43] According to some studies, the resolution of VUR occurs more slowly in children with bilateral VUR compared with a unilateral VUR. The mean time until spontaneous resolution in Black children was 15 months versus 21 months in White children.[6] Increasing age at presentation and bilateral VUR decrease the probability of resolution, and bilateral grade IV or grade V VUR has a particularly low potential for spontaneous resolution.

The natural history of VUR in adults has been reported in few studies. In one study of adults (mean age of 24 years) with gross VUR diagnosed in infancy, proteinuria and CKD were present in 3 of the 13 patients with unilateral RN and 2 of the 4 patients with bilateral RN.[44] In another study of 127 adults (mean age of 41 years) with VUR diagnosed during childhood, 35% had unilateral kidney scarring, 24% had bilateral kidney scarring, 24% had albuminuria, and 11% had hypertension. Of the patients with bilateral kidney scars, 83% had reduced GFR.[45] In a study in VUR patients who were operated on, those with mild to moderate VUR and minimal kidney scarring were likely to maintain a normal GFR in adult life, whereas patients with high-grade VUR and severe scarring were likely to develop progressive CKD.[46] This suggests that the degree of kidney scarring rather than VUR grade after surgical management had the greatest correlation to progressive CKD.

Males with RN have worse outcomes compared with females. This difference has previously been attributed to a delayed diagnosis in males because of an insidious onset of proteinuria and kidney failure. In contrast, the diagnosis may be discovered earlier in females because of recurrent UTI and pregnancy-related complications. However, it is quite possible that the sex differences in adults may be because males are more likely to have congenital RN with kidney dysplasia, which may lead to greater kidney damage than acquired RN, which is seen more in females.[16]

TREATMENT

The management of VUR is based on the premise that VUR predisposes children to the development of recurrent UTI and kidney parenchymal

TABLE 62.4 American Urologic Association Guidelines for Management of Vesicoureteral Reflux

Grade of VUR	I	II	III	IV	V

injury but also has the potential for spontaneous resolution. Various treatment strategies have been used with the ultimate objective of preventing kidney injury. The two main treatment modalities are long-term antimicrobial prophylaxis and surgical correction. Surgical correction of VUR was common until antimicrobial prophylaxis for childhood UTI was introduced in 1975.[47] The International Reflux Study in Children ($n = 306$ patients) showed no significant difference in outcome between medical and surgical management in terms of the development of new kidney lesions or the progression of established kidney scars, although there was a lower incidence of pyelonephritis in the surgical arm.[48]

Medical Management

Medical management involves prompt antibiotic treatment of UTI, long-term antimicrobial prophylaxis, appropriate management of BBD if present, and follow-up VCU to assess the resolution of VUR and the potential development of kidney injury.

Antimicrobial Prophylaxis

The RIVUR trial revealed that trimethoprim-sulfamethoxazole (TMP/SMZ) prophylaxis reduced the risk of UTI recurrence by 50%.[31] Similar results were reported by another placebo-controlled double-blind (PRIVENT study) trial.[49] However, some other randomized studies have shown no beneficial effect with prophylaxis. Systematic reviews and meta-analyses have also reported mixed results. These variations in results have been attributed to significant differences in study designs, including patient inclusion and exclusion criteria.[50] No study has demonstrated any beneficial effect of antimicrobial prophylaxis for the prevention of kidney scarring. However, none of these studies were powered to evaluate kidney scarring as the primary outcome.

The antimicrobial agents most appropriate for prophylaxis include trimethoprim-sulfamethoxazole, trimethoprim alone, nitrofurantoin, and cephalexin. During the first 2 months of life, it is advisable to avoid TMP-SMZ because it may worsen hyperbilirubinemia and promote neurotoxicity.

Antibiotic resistance is a major risk of long-term prophylaxis and hence should be used selectively. In cases with febrile UTI and VUR, the American Urological Association (AUA) recommends continuous antibiotic prophylaxis in children less than 1 year of age and a selective approach in older children based on patient age, severity of VUR, recurrence of UTI, presence of BBD, and kidney cortical anomalies[51] (Table 62.4). The other factors that should be considered before initiating long-term antimicrobial prophylaxis include status of toilet training, risk of antibiotic resistance, anticipated compliance with daily medication administration, and the parental choice. In some cases, preemptive antimicrobial prophylaxis may be necessary to lower the risk of first UTI, such as in those with high-grade VUR diagnosed during workup for antenatal hydronephrosis.

Follow-up of patients with VUR and UTI requires rapid evaluation with stringent techniques for collection of urine specimens for culture (within 48 hours of the onset of fever) to allow early detection and prompt treatment of UTI. The timing of follow-up VCU is not well defined, but studies have suggested time intervals of 12 to 24 months.

Some studies have challenged the benefit of long-term antimicrobial prophylaxis in the prevention of recurrent infection and kidney injury in patients with VUR[52,53] and have alternatively suggested surveillance only. Concerns have also been raised regarding the potential risks for long-term antibiotic use, including the possibility of development of resistance or allergy. These studies have been used as the basis for the 2011 AAP recommendations, suggesting that evaluation for identification of VUR be limited.

The 2011 AAP guideline has affected the diagnosis and decreased surgical management of VUR by resulting in fewer VCUs ordered overall in patients 2 to 24 months old, with significant decline in VCU performed in patients with UTI.[54] The incidence of VUR has also paralleled the decrease in rate of VCU performance.[55] In a retrospective study of children age 0 to 24 months who were evaluated with both kidney ultrasound and VCU, 17% of patients in the cohort had grade IV reflux with a normal kidney ultrasound.[56] Use of the 2011 guideline may have resulted in high-grade reflux being missed in this cohort of patients.

Management of Bladder and Bowel Dysfunction

The management of bladder and bowel dysfunction may include the use of laxatives and timed frequent voiding every 2 to 3 hours. Pelvic floor exercises, behavioral modification, or anticholinergic medication have also been successfully used. A combined conservative medical and computer game–assisted pelvic floor muscle retraining decreases the incidence of breakthrough UTI and may facilitate VUR resolution in children with both BBD and VUR. Treatment of constipation by dietary measures, behavioral therapy, and laxatives helps to reduce UTI recurrence and may resolve enuresis and uninhibited bladder contractions.

TABLE 62.5 Surgical Techniques for Vesicoureteral Reflux

Technique	Success Rate (%)	Pros	Cons
Open reimplantation	95	High success rates Limited requirement for follow-up VCU Reduction in hospital stays	Surgical incision Hospitalization required Catheters needed during postoperative management Need for pain control
Endoscopic injection of dextranomer and hyaluronidase (Deflux)	70–80	Reasonable success rates Outpatient management Minimal pain	Expensive Lower success rates Need for repeated procedures Need for follow-up VCU
Laparoscopic or robotic reimplantation	70–90	Reasonable success rates Small incisions Less discomfort	Lower success rates Requires hospitalization Need for follow-up VCU Long procedure Expensive equipment Significant surgical learning curve

VCU, Voiding cystourethrography.

Surgical Management

Surgical management of VUR is now reserved for patients in whom medical management with antimicrobial prophylaxis has failed to prevent UTIs. Current indications for surgical management of VUR are recurrent infections despite compliance with a prophylactic antibiotic regimen, worsening of kidney scars as judged by DMSA scanning, and failure to comply with prophylaxis. The recent introduction of minimally invasive surgery for VUR management has made some clinicians reconsider the benefits of surgical correction as a potential first-line therapy: immediate correction could potentially avoid the need for antibiotic prophylaxis in children. Although most surgical techniques have high success rates for the correction of reflux and have been shown to reduce the risk of pyelonephritis, lower tract infections have been shown to occur in 20% of children that have had successful surgical management.[57] A review of surgical techniques is presented in Table 62.5.

Prevention of Kidney Injury

Although prevention of kidney injury remains the focus for the management of VUR, no modality has been shown to be able to consistently prevent scarring. Even the large multi-institutional studies were unable to show benefit of prophylactic regimens for prevention of scarring[17,53] because this was not a primary study endpoint and follow-up was short. Surgical ablation of VUR has also not been shown to impact the incidence of kidney scarring even with reduction in upper tract infection.

Hypertension and Proteinuria

Appropriate management of hypertension and proteinuria includes the use of ACE inhibitors or angiotensin receptor blockers (ARBs) as in other kidney diseases (see Chapter 82). Combinations of ACE inhibitors and ARBs may allow further reductions in proteinuria compared with monotherapy.[58] However, although the blood pressure control has been shown to have a beneficial effect on slowing CKD progression, the role of antiproteinuric effect in doing so is not well established. Because of the side effects of ACE inhibitors and ARBs, particularly hyperkalemia in CKD patients, we recommend monotherapy with appropriate monitoring. Combination therapy may be considered in CKD patients with poorly controlled blood pressure on monotherapy and a low risk of hyperkalemia. Historically, some patients also occasionally had their poorly functioning scarred kidney removed to help control hypertension, provided the contralateral kidney was healthy. However, this is exceptionally rare in recent times because of the availability of many potent antihypertensive agents.

SELF-ASSESSMENT QUESTIONS

1. Which imaging modality is used to diagnose vesicoureteral reflux?
   A. Ultrasound
   B. Voiding cystourethrogram
   C. DMSA kidney scan
   D. Magnetic resonance imaging
   E. Computed tomography scan
2. Which of the following patients diagnosed with VUR would have the *least* likelihood of spontaneous resolution?
   A. 2-year-old female with grade II reflux
   B. 2-year-old female with grade IV reflux
   C. 2-year-old male with grade II reflux
   D. 6-year-old female with grade IV reflux
   E. None of the above
3. Which of the following antibiotics would be an appropriate choice of prophylaxis for a 1-month-old female diagnosed with grade IV reflux?
   A. Trimethoprim-sulfamethoxazole
   B. Trimethoprim and amoxicillin
   C. Nitrofurantoin
   D. Cefalexin
   E. All of the above
4. Complications of reflux nephropathy include which of the following?
   A. Hypertension
   B. Proteinuria
   C. Progressive kidney failure
   D. Pregnancy-related complications
   E. All the above

Urologic Issues for the Nephrologist

Ross M. Warner, J. Kilian Mellon

Close interaction between nephrologists and urologists is crucial to the optimal management of several common clinical problems. A proper understanding of urologic strategies helps the nephrologist to ensure that patients with these problems are given clear information and are optimally managed. Areas in which such coordinated work is most important include the management of stone disease, the surgical approach to urinary tract obstruction, the investigation of hematuria, and the management of urinary tract malignant neoplasms.

ADVANCES IN MANAGEMENT OF KIDNEY STONES

Medical management of nephrolithiasis is discussed in Chapter 60. The surgical management of urinary tract stones has been transformed by the introduction of extracorporeal shock wave lithotripsy (ESWL), percutaneous nephrolithotomy (PCNL), and ureteroscopy. These advances mean that open stone surgery is now a final resort when other modalities have been exhausted or are contraindicated. Table 63.1 details the use of different treatment modalities over time since the introduction of newer techniques.[1] As familiarity with the available techniques and technology has developed, standardized treatment strategies have evolved and guidelines have been introduced.[2,3,4] However, the optimal treatment for certain patients with kidney stones remains controversial, especially lower pole stones.

Improvements in Imaging

Unenhanced computed tomography (CT) scanning of the abdomen and pelvis has replaced intravenous urography (IVU) as the standard imaging modality for stone diagnosis (Fig. 63.1). CT is readily available, quicker to perform, offers increased sensitivity compared with IVU (99% vs. 70%), and avoids the need for intravenous (IV) contrast. An additional advantage is that CT can demonstrate radiolucent stones (mainly uric acid and xanthine stones) and detect concomitant lesions and/or alternative diagnoses. CT requires an increased radiation dose, but this is less of an issue with modern equipment and newer radiation protocols. Comparative doses are 2.5 mSv for IVU, 5 mSv for standard non–contrast-enhanced CT, and 2 mSv for low-dose non–contrast-enhanced CT.

Conservative (Nonsurgical) Management

Spontaneous stone passage can be expected in up to 80% of patients with stones smaller than 4 mm. Conversely, for stones with a diameter of more than 7 mm, the chance of spontaneous stone passage is very low. Recent data from the MIMIC study, a multicenter retrospective cohort study of 4170 patients in 71 institutions across four countries, suggests a chance of just 29%.[5] The location is also important; up to 70% of distal ureteral stones pass spontaneously, in contrast to only 45% of midureteral and 25% of proximal ureteral stones. Intervention is recommended when there is persistent pain (>72 hours) despite adequate analgesia, persistent obstruction with risk for impaired kidney function (e.g., with preexisting kidney impairment or in a single kidney), bilateral obstruction, or associated urinary tract sepsis.

In the absence of an acute indication for surgical management, medical expulsive therapy (MET), such as tamsulosin (an alpha blocker) 400 μg once daily or nifedipine (calcium channel blocker) 30 mg once daily, is sometimes used to aid stone passage, particularly for distal ureteral stones, although the data on the efficacy of this are mixed. A recent U.K. study (the largest randomized controlled trial [RCT] of MET) demonstrated no significant benefit of this therapy.[6] This was supported by the MIMIC study.[5] In contrast, data from several meta-analyses of RCTs suggest that MET is beneficial for management of distal ureteral stones less than 10 mm.[4,7,8] Therefore, MET for small distal ureteral stones is still recommended in most guidelines.[2,3,4] Opinion among urologists remains divided.

Another conservative approach is chemolysis because several stone types are, in principle, amenable to dissolution by oral medications or by direct instillation of chemical solutions. However, chemolysis is only effective for uric acid stones and some drug-induced calculi, which can be readily dissolved by alkalization of the urine, usually with oral potassium citrate, or with sodium bicarbonate solution instilled directly into the urinary tract via a percutaneous nephrostomy (PCN) tube.

Acute Surgical Intervention

The goals of acute surgical intervention are to relieve obstruction and, if feasible, to remove the calculus. If the patient is well enough for general anesthesia, ureteroscopic stone destruction using laser lithotripsy can be attempted. Alternatively, a double-J stent (a ureteral stent with two coiled ends) can be inserted to relieve obstruction until definitive treatment is performed (Fig. 63.2). Acute ESWL is increasingly being used for ureteral stones in stable patients with adequate pain relief and without superimposed infection. However, in the setting of uncontrolled urinary tract infection (UTI) resulting from an obstructing stone, decompression of the urinary tract and free drainage of urine are the priorities. Evidence suggests little difference in the outcomes whether an antegrade (i.e., PCN) or retrograde (i.e., double-J stent) is used.[9] However, PCN is generally the preferred option (when not contraindicated) because it can be performed with local anesthesia and is less likely than endoscopic surgery to cause bacteremia (Fig. 63.3).

Elective Surgical Intervention

Extracorporeal Shock Wave Lithotripsy

During ESWL, acoustic shock wave energy is delivered to a stone under fluoroscopic and/or ultrasound guidance. Treatment sessions typically last about 30 minutes, during which 1500 to 2500 shock waves are delivered. Treatment is given to outpatients under analgesia or IV sedation and can be repeated at intervals of 10 to 14 days. Stones up

to 20 mm in size can be treated effectively, and stone-free rates of 60% to 98% have been reported. However, ESWL is operator dependent, and outcome is influenced by the size, composition, and location of the stone and the type of lithotripter used. Cystine and calcium oxalate monohydrate stones are especially resistant. Targeting of the stone may be impossible in the presence of obesity and skeletal deformities (increased skin-to-stone distance), and ESWL is contraindicated in patients with aortic or renal artery aneurysm, uncontrolled UTI, coagulation disorders/receiving anticoagulation treatment, pregnant persons, and obstruction distal to the stone being treated.

A double-J ureteral stent is sometimes placed endoscopically before ESWL treatment to prevent stone fragments from obstructing the distal ureter (*Steinstrasse,* literally "stone street"; Fig. 63.4). Other acute complications of ESWL include hemorrhage or hematoma, infection, and injury to adjacent organs. The risk for hypertension or reduced glomerular filtration rate (GFR) as sequelae of ESWL is controversial.

Percutaneous Nephrolithotomy

During PCNL, a tract through the kidney parenchyma is created between the skin and the collecting system of the kidney. A sheath within this tract is used as a working channel to remove stones under direct vision using a nephroscope. Preoperatively, CT imaging is used to localize calculi and neighboring organs (e.g., spleen, liver, large bowel, pleura, or lungs) and to plan access. The most frequently used access site is the dorsal calyx of the lower pole, and stone fragmentation is undertaken by ultrasound, pneumatic, or laser devices. With technologic advances, performing this procedure through smaller access sheaths (<18 Fr compared with standard 30 Fr sheaths) with fewer complications and equivalent stone clearance rates is becoming feasible.[10] The PCNL technique is modified for special circumstances, usually by altering the site of puncture (e.g., directly into a calyceal diverticulum) or, if there are ureteral stones, by using a higher placed puncture to permit antegrade ureteroscopy. The percutaneous puncture may be facilitated by the preliminary placement of a retrograde ureteral catheter to dilate and opacify the collecting system, which is then punctured under fluoroscopy with or without ultrasound

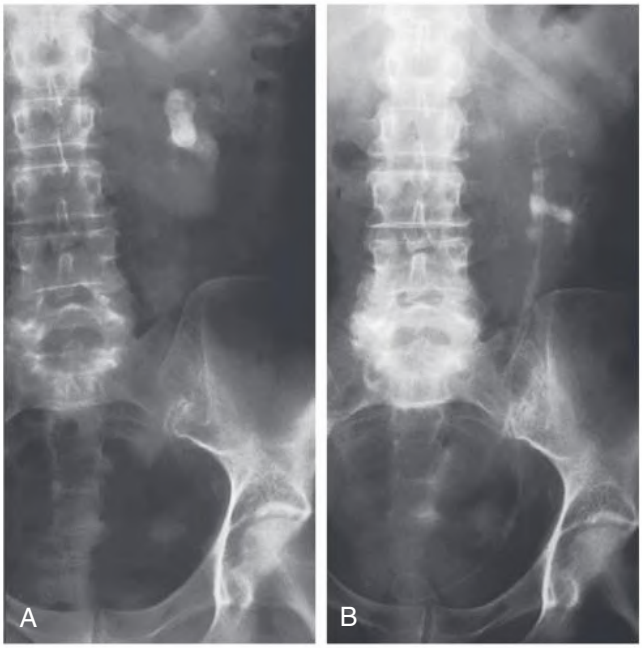

Fig. 63.4 Extracorporeal Shock Wave Lithotripsy (ESWL) Complicated by Stone Fragments Obstructing the Distal Ureter. (A) Preoperative plain radiograph showing stones in the left kidney pelvis. (B) After ESWL, note the disappearance of the pelvic stone, the string of stone fragments throughout the length of the ureter, and the double-J ureteral stent placed to facilitate their passage.

TABLE 63.2 Indications for Percutaneous Nephrolithotomy

Composition[a]	Struvite stones	Complete removal necessary to eliminate infection and minimize stone recurrence
	Calcium oxalate monohydrate stones	Difficult to pulverize by ESWL
	Cystine stones	Difficult to pulverize by ESWL
Stone position	Lower pole stones	Fragments less easily evacuated from dependent lower pole calyces, especially if collecting system dilated
Anatomic abnormalities	PUJ obstruction Calyceal diverticula	Prevent passage of fragments after ESWL
Patient characteristics	Morbid obesity Ureteral obstruction	Stone cannot be placed in focal point of ESWL machine

ESWL is the first choice for stone intervention, except in those circumstances that may favor PCNL.

[a]Stone composition can be defined with certainty only by direct stone analysis, but advances in imaging may ultimately provide a means to accurately assess stone composition in situ before treatment, thus allowing the urologist to select the treatment most likely to be successful.

ESWL, Extracorporeal shock wave lithotripsy; *PCNL,* percutaneous nephrolithotomy; *PUJ,* pelviureteral junction.

guidance. After completion of PCNL, there are a number of options to aid urinary drainage. These include ureteral stents (placed antegradely or retrogradely), "pig-tail" nephrostomy tubes, or a self-retaining balloon nephrostomy tube to tamponade the tract and provide further access if needed. Hemorrhage can complicate PCNL (from intrarenal or, rarely, intercostal/subcostal arteries) and usually can be treated conservatively or by selective angiographic embolization. Other complications include sepsis; fluid overload (similar to transurethral resection syndrome); injury to spleen, pleura, or colon; and extravasation. PCNL usually results in minimal parenchymal injury, averaging only 0.15% of the total kidney cortex.[11]

Indications for PCNL are shown in Table 63.2. These continue to evolve and are being challenged by developments in ureteroscopic techniques, which are allowing more upper ureteral and renal pelvic stones to be dealt with by a retrograde approach.

ESWL is the first-line treatment for more than 75% of stone patients that require an intervention. Table 63.2 shows circumstances in which ESWL is less effective and PCNL becomes the preferred approach or a combination of the two modalities is used. For lower pole stones in particular, ESWL may not provide optimal clearance because of problems with the drainage of residual fragments. An RCT has shown that for lower pole stones greater than 10 mm, PCNL has much better clearance rates than ESWL (92% vs. 23%).[12]

Open Stone Surgery

Open surgery still has a place in the treatment of stone disease. Approximately 2% of stone patients are now treated with open surgery, mainly when anatomic factors preclude the use of minimally invasive methods or when these techniques have failed. Other indications include complex stone burden, the presence of intrarenal anatomic abnormalities (e.g., pelviureteral junction [PUJ] obstruction), and stones within a nonfunctioning kidney where nephrectomy may be more appropriate. During surgery the kidney pelvis and the parenchyma can be opened along avascular planes, and clamping of the kidney vessels and hypothermia of the kidney may be needed. In selected patients a laparoscopic or robot-assisted approach can be used for the treatment of stone disease.

Ureteroscopy

Continued advances in the design of endoscopes for ureteronephroscopy have rendered the entire urinary tract accessible to endoscopic examination and manipulation. Ureteroscopes may be semirigid or flexible, the latter allowing access to the renal pelvis and calyces. Stone fragmentation is achieved ideally by laser but also by ultrasound or pneumatic devices (lithoclast). Laser use is equally effective for all types of stones and has the additional advantages of a flexible fiber (allowing intrarenal stone fragmentation), low tissue penetration, and minimal stone displacement during use. Success rates for laser fragmentation of ureteral stones are approximately 80%. Fig. 63.5 highlights the increasing use of ureteroscopy in stone disease and also the increasing proportion of procedures in which a laser rather than ultrasound or a lithoclast is used to achieve stone fragmentation.

For lower pole kidney stones, although flexible ureteroscopes can access the lower pole to facilitate treatment, the stone-free rate in comparative studies is similar to that of ESWL.[13,14] Furthermore, patients often prefer ESWL as the initial therapy compared with flexible ureterorenoscopy and lasertripsy. In the event of failed stone clearance after ureteroscopy, PCNL is commonly used next and is likely to remain an essential treatment for lower pole stones. Complications of ureteroscopy, particularly with use of graspers and baskets, include ureteral avulsion, perforation, extravasation, mucosal damage, hematuria, infection, and stricture. Advances in laser technology now enable stones to be reduced to dust-like particles, reducing the need for graspers and baskets and hence reducing complications.

A summary of the elective surgical management of nonobstructing kidney stones is shown in Table 63.3.

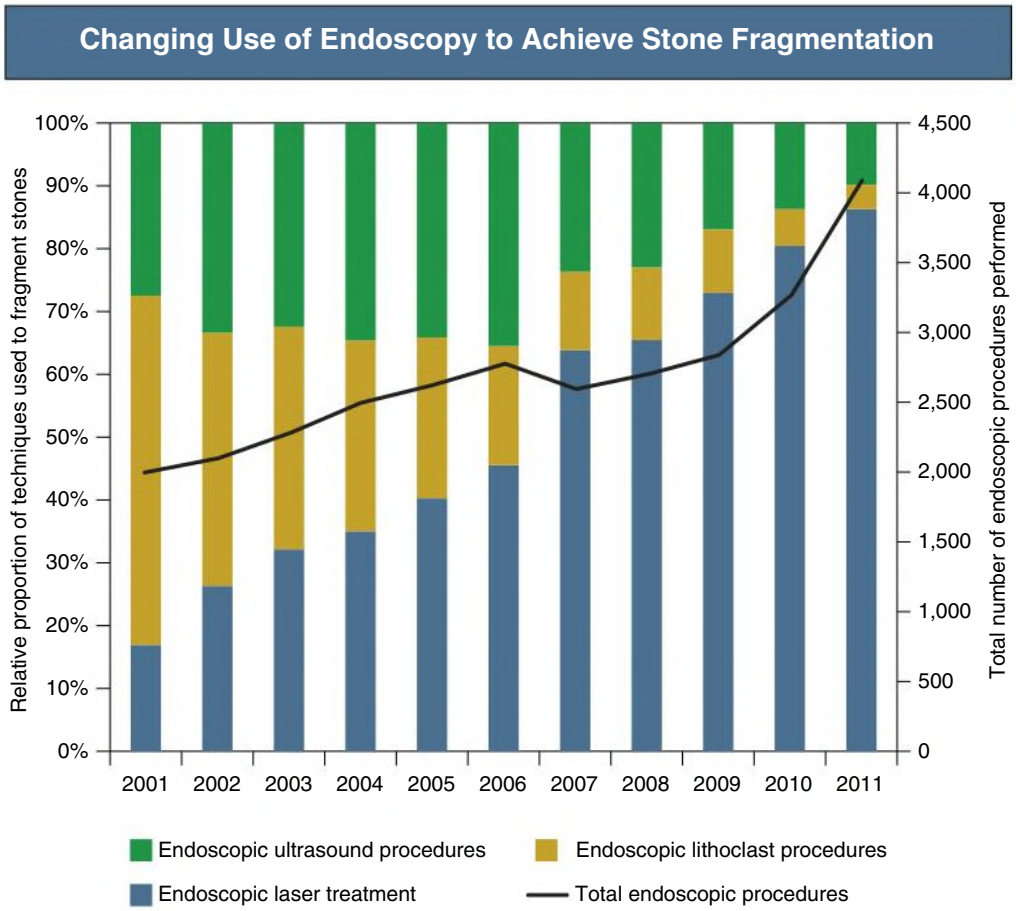

Fig. 63.5 Changing Use of Endoscopy to Achieve Stone Fragmentation. Chart showing the increasing use of endoscopy in stone surgery in addition to the increasing proportion of cases using lasers to achieve stone fragmentation. (Data from UK Hospital Episode Statistics dataset, http://www.hscic.gov.uk/hes.)

TABLE 63.3 Surgical Management of Intrarenal Stones

Stone Characteristic	First-Line Treatment Modality
Nonlower pole stone <20 mm	ESWL or URS
Nonlower pole stone >20 mm	PCNL
Lower pole stone <10 mm	ESWL or URS
Lower pole stone >10 mm	PCNL or URS

ESWL, Extracorporeal shockwave lithotripsy; *PCNL,* percutaneous nephrolithotomy; *URS,* ureteroscopy.
Data from Assimos D, Krambeck A, Miller N, et al. American Urological Association/Endourological Society Guideline: Surgical management of Stones, 2016. https://www.auanet.org/guidelines/kidney-stones-surgical-management-guideline.

Management of Staghorn Calculus

A staghorn calculus usually should be managed by intervention because reports of conservative therapy show a high rate of eventual nephrectomy (up to 50%) and an increase in associated morbidity (mainly kidney failure) and mortality (up to 28%). Patient age and GFR heavily influence treatment decision making. The primary treatment option for staghorn calculi in a patient with preserved kidney function is PCNL. For a staghorn calculus in a nonfunctioning kidney, partial or total nephrectomy may be indicated. ESWL or ureteroscopic stone removal alone are rarely effective for large staghorn calculi but can be used as an adjunct to PCNL to achieve total stone clearance. The advantage of a multimodal approach is the reduced need for additional access to the kidney and secondary PCNL. Consequently, endoscopic combined intrarenal surgery (ECIRS; i.e., retrograde flexible ureterorenoscopy and PCNL) is becoming more commonplace. Very rarely, open surgical removal of the stone may be indicated.

Stones in Transplanted Kidneys

The management of stone disease in a transplanted kidney is challenging because of the solitary kidney, the anatomic location within the pelvis, and the difficulty with retrograde access to the ureter and kidney. Early active intervention is indicated; prophylactic stenting, ureteroscopy, and PCNL are preferred to ESWL because stone targeting may not be possible. Open surgery may be needed in selected cases.

URINARY TRACT OBSTRUCTION

General Aspect

The causes of upper tract obstruction are listed in Chapter 61 (see Box 61.2), as is a summary of the management of obstruction (see Fig. 61.7). Upper tract obstruction caused by malignancy can be a result of direct tumor invasion, external compression by metastatic lymph node involvement or, rarely, true metastasis to the ureter. About 70% of tumors causing ureteral obstruction are genitourinary (cervical, bladder, prostate) in origin; breast and gastrointestinal carcinomas and lymphoma constitute the majority of the remainder.[15] The

presentation of a patient with obstruction may vary significantly, and hydronephrosis may develop progressively and insidiously and remain unrecognized until the patient develops anuria and uremia. Upper tract obstruction from malignancy rarely manifests with classic acute ureteral colic, which is typically seen with a benign cause such as a stone. Therefore, these patients often present first to a nephrologist because of an asymptomatic decline in GFR.

Bladder outflow obstruction may be acute and dramatic or chronic with few or no symptoms. To aid in understanding of the immediate needs and longer-term prognosis of these patients, the acute and the definitive management of the most common urologic diseases associated with obstruction and reduced GFR are outlined.

Acute Management

Relief of obstruction is crucial to reverse kidney impairment and preserve remaining kidney function. In cases of bladder outflow obstruction, a urethral or suprapubic catheter is indicated, whereas in upper tract obstruction, a double-J stent stent is preferable, when possible. The most straightforward approach is endoscopic retrograde placement under fluoroscopy, with PCN reserved for patients in whom the procedure fails. Bilateral stents should be placed if technically possible. However, tumor infiltration can distort trigonal anatomy, making identification of ureteral orifices for double-J stent insertion impossible at the time of cystoscopy. Furthermore, it has been suggested that stents fail to relieve obstruction in 40% to 50% of cases of external ureteral compression. Thus, these patients need to be closely monitored to ensure resolution of the obstruction. Alternatives include placing two stents within each obstructed ureter[16] and a metallic, self-expanding stent, used alone or in conjunction with double-J stents, which has had good initial results in maintaining ureteral patency and avoiding PCN, in malignant ureteral obstruction.[17]

A stable patient with obstruction but without signs of sepsis is a candidate for attempted retrograde stent placement with use of general anesthesia. However, in a patient with sepsis, endoscopic manipulation can lead to bacteremia and septic shock. Furthermore, such patients may not be fit for general anesthesia, in which case the preferred initial approach is PCN, which can then be followed, after an interval, with antegrade ureteral stenting. The success rate of this combined approach is high (>90%).[18] In patients with bilateral ureteral obstruction, it is not always necessary to insert bilateral PCN tubes. Significant palliation and return to nearly normal GFR can be accomplished by drainage of the kidney with the better-preserved parenchyma as determined by CT scan or ultrasound. Once they have been placed, PCN tubes or double-J stents need to be replaced every 3 to 6 months. If they are left for a longer period, they become increasingly brittle and encrusted and are liable to block or fracture under manipulation. Complications of ureteral stents include migration, obstruction with proteinaceous material, infection, fragmentation, and, rarely, erosion through the urinary tract.[19] As many as 70% of patients with stents report lower urinary tract symptoms, mainly urgency, frequency, and nocturia, as well as pain along the urinary tract.

Morbidity after stenting or PCN is similar.[20] The main problem with indwelling stents is the increased risk for recurrent obstruction (11% for stents vs. 1% for PCN). PCN may have an increased infection rate, and there may be psychological issues relating to the need for an external drainage bag. They are also more liable to displace. An alternative to attempt to offset this is the nephroureteral stent (otherwise referred to as a nephroureterostomy).[21] Placed antegradely, a single stent with a coil in the bladder and further coil in the kidney pelvis then continues and exits percutaneously to drain into an external nephrostomy bag.

Fig. 63.6 Extraanatomic Stenting for Malignant Ureteral Obstruction. Plain radiograph showing placement of an extraanatomic stent for malignant obstruction of the right ureter. The upper end of the double-J stent has been placed in the right kidney pelvis *(arrow)*. The stent then runs through a subcutaneous tunnel before the lower end enters the bladder *(arrowhead)*.

Extra-anatomic stents are an alternative for patients in whom conventional stent insertion has failed or for whom permanent nephrostomy drainage is unacceptable. An extra-anatomic stent is placed by an initial percutaneous puncture and insertion of the upper end of a long (50-cm) double-J stent into the kidney. A subcutaneous tunnel is then created to bring the stent to the level of the iliac crest. Another tunnel is fashioned to bring the lower end of the stent out suprapubically, followed, finally, by suprapubic puncture of a full bladder and insertion of the lower end (Fig. 63.6).[22] Extra-anatomic stents are usually changed at 6-month intervals, and preliminary experience confirms their value in maintaining ureteral patency and avoiding PCN. Because of the effectiveness of minimally invasive methods, open surgery today is rarely indicated in the acute setting.

SPECIFIC TYPES OF OBSTRUCTION

Pelviureteral Junction Obstruction

Surgical management of PUJ obstruction is aimed at obliterating the redundant (aperistaltic) portion of the ureter, allowing normalization of drainage from the affected kidney. The need for treatment is heralded by the onset of pain, infection, calculus formation, decline in GFR, or proven impaired excretion on mercaptoacetyltriglycine (MAG3) renography. The gold standard treatment is now laparoscopic or robotic pyeloplasty, although traditional open techniques are still used. Endoscopic (endopyelotomy) treatments are also performed in some centers. However, in treatment-naïve patients, endopyelotomy has inferior outcomes compared with pyeloplasty.[23,24]

Retroperitoneal Fibrosis

Retroperitoneal fibrosis can be treated medically or surgically. A causative factor should be excluded (see Chapter 61). There are reports of favorable outcomes after immunosuppression with high doses of corticosteroids or azathioprine/mycophenolate mofetil/rituximab. Alternatively, surgery, consisting of ureterolysis (freeing the ureters

from the fibrotic plaques) and omentoplasty (transposition of the ureters into the peritoneal cavity in omental wraps), can have good long-term results.

Malignant Obstruction

For upper tract transitional cell carcinoma, acute obstruction is best treated by internal stenting. PCN is avoided because of the risk of tumor seeding. Upper tract transitional cell carcinoma is an aggressive tumor and necessitates prompt extirpative surgery.

Bladder cancer can lead to hydronephrosis by invading the ureteral orifices and intramural ureters. In the absence of metastatic disease, radical cystectomy is indicated, although temporary ureteral decompression may normalize GFR if neoadjuvant chemotherapy is planned. In selected cases, bladder preservation strategies combining systemic chemotherapy and radiotherapy can offer long-term control of the disease.

Prostate cancer causes obstruction by occluding the urethra or invading the ureteral orifices. Hormonal treatment can shrink prostatic tissue and malignant deposits and offer long-term remission of symptoms. Limited resection of the prostate may sometimes be indicated.

The decision to offer ureteral decompression for upper tract obstruction caused by cancer is not straightforward and requires input not only from the urologist but also from colleagues in radiation and medical oncology and the palliative care team. There must also be careful discussion of the options with the patient and family.

Ureteral decompression is justified when radiotherapy and systemic chemotherapy remain therapeutic options after improvement in GFR but also may be justified for palliation of pain or ongoing renal tract sepsis.

A review of patients undergoing PCN for obstructive uropathy secondary to pelvic malignancy identified a subset with very poor survival in whom ureteral decompression is usually not justified (Table 63.4).[25] Patients with gastric or pancreatic cancer survive a median of only 1.4 months after ureteral decompression.[26] In another report, the average survival of patients with advanced malignant neoplasms undergoing endourologic diversion was only 5 months, half of which time was spent in the hospital.[27] A more recent review suggests a median survival of 6.4 months for all-cause malignant ureteral obstruction and a complication rate as high as 41%.[28]

TABLE 63.4 Percutaneous Nephrostomy for Malignant Obstructive Uropathy[a]

	Median Survival (wk)	5-Year Survival Rate (%)
Group I: primary untreated malignancy	27	10
Group II: recurrent malignancy with further treatment	20	20
Group III: recurrent malignancy with no further treatment	6.5	None survived >1 year
Group IV: benign disease as a result of previous treatment	Not stated	64
Overall	26	22

[a]Outcome in 77 patients undergoing percutaneous nephrostomy for obstructive uropathy secondary to pelvic malignant disease.

Benign Ureteral Strictures

These can be secondary to stone disease, iatrogenic, or caused by various benign diseases. The treatment of choice is endoscopic balloon dilation or ureterotomy. Open surgical repair or major reconstructive surgery may be needed in cases of recurrent strictures.

Hydronephrosis of Pregnancy

Hydronephrosis occurs in the majority of pregnant persons, typically seen from 6 to 10 weeks of gestation onward. It is caused by both mechanical obstruction from the gravid uterus and dilated ovarian venous plexus and a reduction in peristalsis caused by increasing levels of progesterone leading to smooth muscle relaxation. Resolution typically occurs within a few weeks of delivery but can take up to 3 months. Females are usually asymptomatic with little or no impact on GFR, but they can provide a diagnostic dilemma if presenting with loin pain. Differentiating between a physiologic hydronephrosis and one caused by ureteral obstruction secondary to a stone can be a challenge because the use of ionizing radiation is to be avoided.

Bladder Outflow Obstruction

Bladder outflow obstruction in males is most frequently caused by either benign or malignant prostatic enlargement. Common presentations of both conditions include the onset of lower urinary tract symptoms and acute (painful) or chronic (painless) retention of urine.

Chronic retention can be considered as the maintenance of voiding with incomplete bladder emptying. It is further classified into low- and high-pressure chronic retention. Low-pressure chronic retention occurs in the absence of upper tract compromise, whereas high-pressure chronic retention is associated with hydronephrosis and kidney injury.

In acute retention, low-pressure chronic retention, and lower urinary tract symptoms caused by bladder outflow obstruction, treatment with 5α-reductase inhibitors (finasteride, dutasteride) or α-adrenergic receptor blockers (tamsulosin, alfuzosin) is usually indicated before surgery is offered.[29] Given the risk for worsening kidney failure if medical therapy fails, it is not a safe management option in high-pressure chronic retention. Surgical management is reserved for patients who either derive no benefit from or are not willing to pursue medical therapy, those with acute and low-pressure chronic retention, and those with high-pressure chronic retention. Before surgery, evaluation of likelihood of success is essential. Patients with very high postvoid residual volumes of urine (>1 L) are less likely to benefit from surgery because of the chronicity of their symptoms and consequent detrusor muscle weakness. These patients are often treated best with intermittent clean self-catheterization or a permanent urethral or suprapubic catheter.

The number of surgical management options available for bladder outflow obstruction is continually increasing. Although transurethral resection of the prostate (TURP) has been the gold standard procedure for decades, the development of laser technology is challenging this. Holmium laser enucleation of the prostate (HoLEP) and vaporization of prostatic tissue (Green light laser) are being increasingly performed in specialist centers with superior results with respect to reduced patient stay, bleeding, and duration of postoperative catheterization. Unlike standard TURP, laser prostatectomy also can be routinely performed safely in patients with large gland size (>100 mL) and on anticoagulation therapy. A recently published 7-year follow-up study comparing TURP with HoLEP reported no significant difference in quality of life, maximum urinary flow, incontinence, or erectile dysfunction, with a reduced need for reoperation in the HoLEP arm of the study.[30] More novel techniques aimed at being less invasive and reducing the impact on sexual function and continence are becoming more commonplace. Examples include, but are not limited to, UroLift

(urethrally placed implants that tack the occluding prostate out of the lumen),[31] Aquablation (robot-assisted waterjet),[32] and Rezum (water vapor treatment).[33]

Neurologic Diseases of the Lower Urinary Tract

Diseases of the central or peripheral nervous system can manifest with bladder underactivity, bladder overactivity, and/or detrusor-sphincter dyssynergia and lead to bilateral hydroureteronephrosis. Diabetes mellitus also can produce a flaccid denervated bladder through destruction of the peripheral nerves and can cause chronic retention and kidney failure. Of diabetics who develop peripheral neuropathy, 75% to 100% will develop some neurogenic lower urinary tract dysfunction.

The goal of treatment in patients with neurogenic bladder dysfunction is to maintain low intravesical pressures to protect the kidneys. This can be achieved in a number of ways including clean intermittent self-catheterization, long-term suprapubic catheterization, anticholinergics, cystoscopic injection of intradetrusor onabotulinum toxin-A, or surgery, including augmentation cystoplasty.

INVESTIGATION OF HEMATURIA

Macrohematuria is perhaps the most important symptom in urologic practice, and apart from being alarming to the patient, it can be the first presenting sign of an underlying malignant urologic condition (most often a transitional cell tumor of the bladder). Studies show that 15% to 22% of patients with visible hematuria have an underlying genitourinary tract malignant neoplasm.

Patients with visible hematuria must be distinguished from those who have been found to have microhematuria (dipstick), in whom the risk for malignant change is significantly lower (2%–11%).

The outcome of full evaluation of a large group of patients attending a hematuria clinic is shown in Table 63.5.[34] In addition to a small but important group of patients in whom malignant disease was identified, there was a significant pickup rate of parenchymal kidney disease (~10%) presenting with both visible and nonvisible hematuria. It is also important to note the sizable proportion of patients in whom a definitive diagnosis could not be reached.

TABLE 63.5 Outcome of Evaluation in a Hematuria Clinic: Cases Investigated

Diagnoses Found	All (%)	Microscopic Hematuria (%)	Macroscopic Hematuria (%)
No diagnosis	63	69	53
Kidney cancer	0.6	0.3	0.9
Upper tract transitional cell carcinoma	0.1	0.1	0.1
Bladder cancer	12	5	19
Prostate cancer	0.4	0.2	0.6
Stone disease	4	4	3
Urinary tract infection	13	13	13
Kidney parenchymal disease	10	9	10
Likelihood of Finding Malignancy			
Male, age >40 yr		8	24
Male, age <40 yr		2	7
Female, age >40 yr		5	19
Female, age <40 yr		0	0

Data from Khadra MH, Pickard RS, Charlton M, et al. A prospective analysis of 1,930 patients with hematuria to evaluate current diagnostic practice. *J Urol*. 2000;163:524–527.

Evaluation of Visible Hematuria

All adults with a single episode of visible hematuria require full urologic evaluation, including kidney imaging and cystoscopy. The only exception to this rule occurs when an adult younger than 40 years gives a history characteristic of glomerular hematuria, such as is typically seen in immunoglobulin A (IgA) nephropathy, in which dark brown hematuria lasting 24 to 48 hours coincides with intercurrent mucosal infection, usually of the upper respiratory tract. This hematuria may be painless, or there may be bilateral loin ache. These young adults should be referred first for nephrologic assessment.

Evaluation of Microhematuria

Perhaps the greatest degree of overlap in practice between urologists and nephrologists occurs in the initial assessment of patients with microhematuria. Concurrent UTI will cause microhematuria and should be treated before further evaluation. Furthermore, features such as menstruation, vigorous exercise, viral illness, and trauma can themselves account for microhematuria. In the presence of a transient or treatable underlying cause other than UTI, repeat urinalysis should be performed 2 days later. Further urinalysis should be deferred until 6 weeks after treatment of confirmed UTI. If microhematuria resolves, no further investigation is required.

The 2012 American Urological Association (AUA) guidelines on the assessment and management of asymptomatic microscopic (nonvisible) hematuria (AMH) defined AMH by the presence of three or more red blood cells (RBCs) per high-power field (HPF) on microscopic examination of one properly collected, noncontaminated urine sample. In addition to the benign causes listed, pyuria and bacteriuria also should be excluded with either dipstick or microscopy.

The most notable departure from previous guidance is the recommendation of urologic investigation after one episode of AMH, rather than waiting for two of three positive samples as previously suggested. No studies directly compare the diagnostic yield of investigating the first episode of AMH rather than reserving investigation for patients with more than one episode. However, indirect comparison reveals a diagnostic yield of urinary tract malignancy of 1.8% and 3.6% in patients with one or more than one episode of AMH, respectively.[35] Dipstick-positive hematuria may still herald significant disease in the absence of RBCs on microscopy because RBCs may lyse in alkaline or hypotonic urine before reaching the laboratory for analysis.[36]

Complete evaluation of microhematuria includes a history and physical examination, laboratory analysis, and radiologic imaging of the upper urinary tract, followed by cystoscopy (Fig. 63.7). The 2020 update to the AUA guidelines introduces risk stratification to the workup of patients with microhematuria. This provides guidance as to what imaging modality of the upper tract should be performed.[37] In females, urethral and vaginal examinations should be performed to exclude local causes of microhematuria. In uncircumcised males, the foreskin should be retracted to expose the glans penis, if possible. If phimosis is present, a catheter specimen of urine may be required. An assessment of GFR should be made (serum creatinine, estimated GFR [eGFR]) because intrinsic kidney disease may have implications for consequent imaging and treatment. The remaining laboratory investigations are guided by specific findings of the history, physical examination, and urinalysis. Multiphase CT urography, which allows evaluation of kidney parenchyma and also the collecting system, has been shown to have the highest sensitivity and specificity for imaging the upper tracts. If CT urography is unavailable, then ultrasound is an alternative imaging strategy. The 2020 guidelines recommend cystoscopy for all patients with AMH who are at least AUA intermediate risk

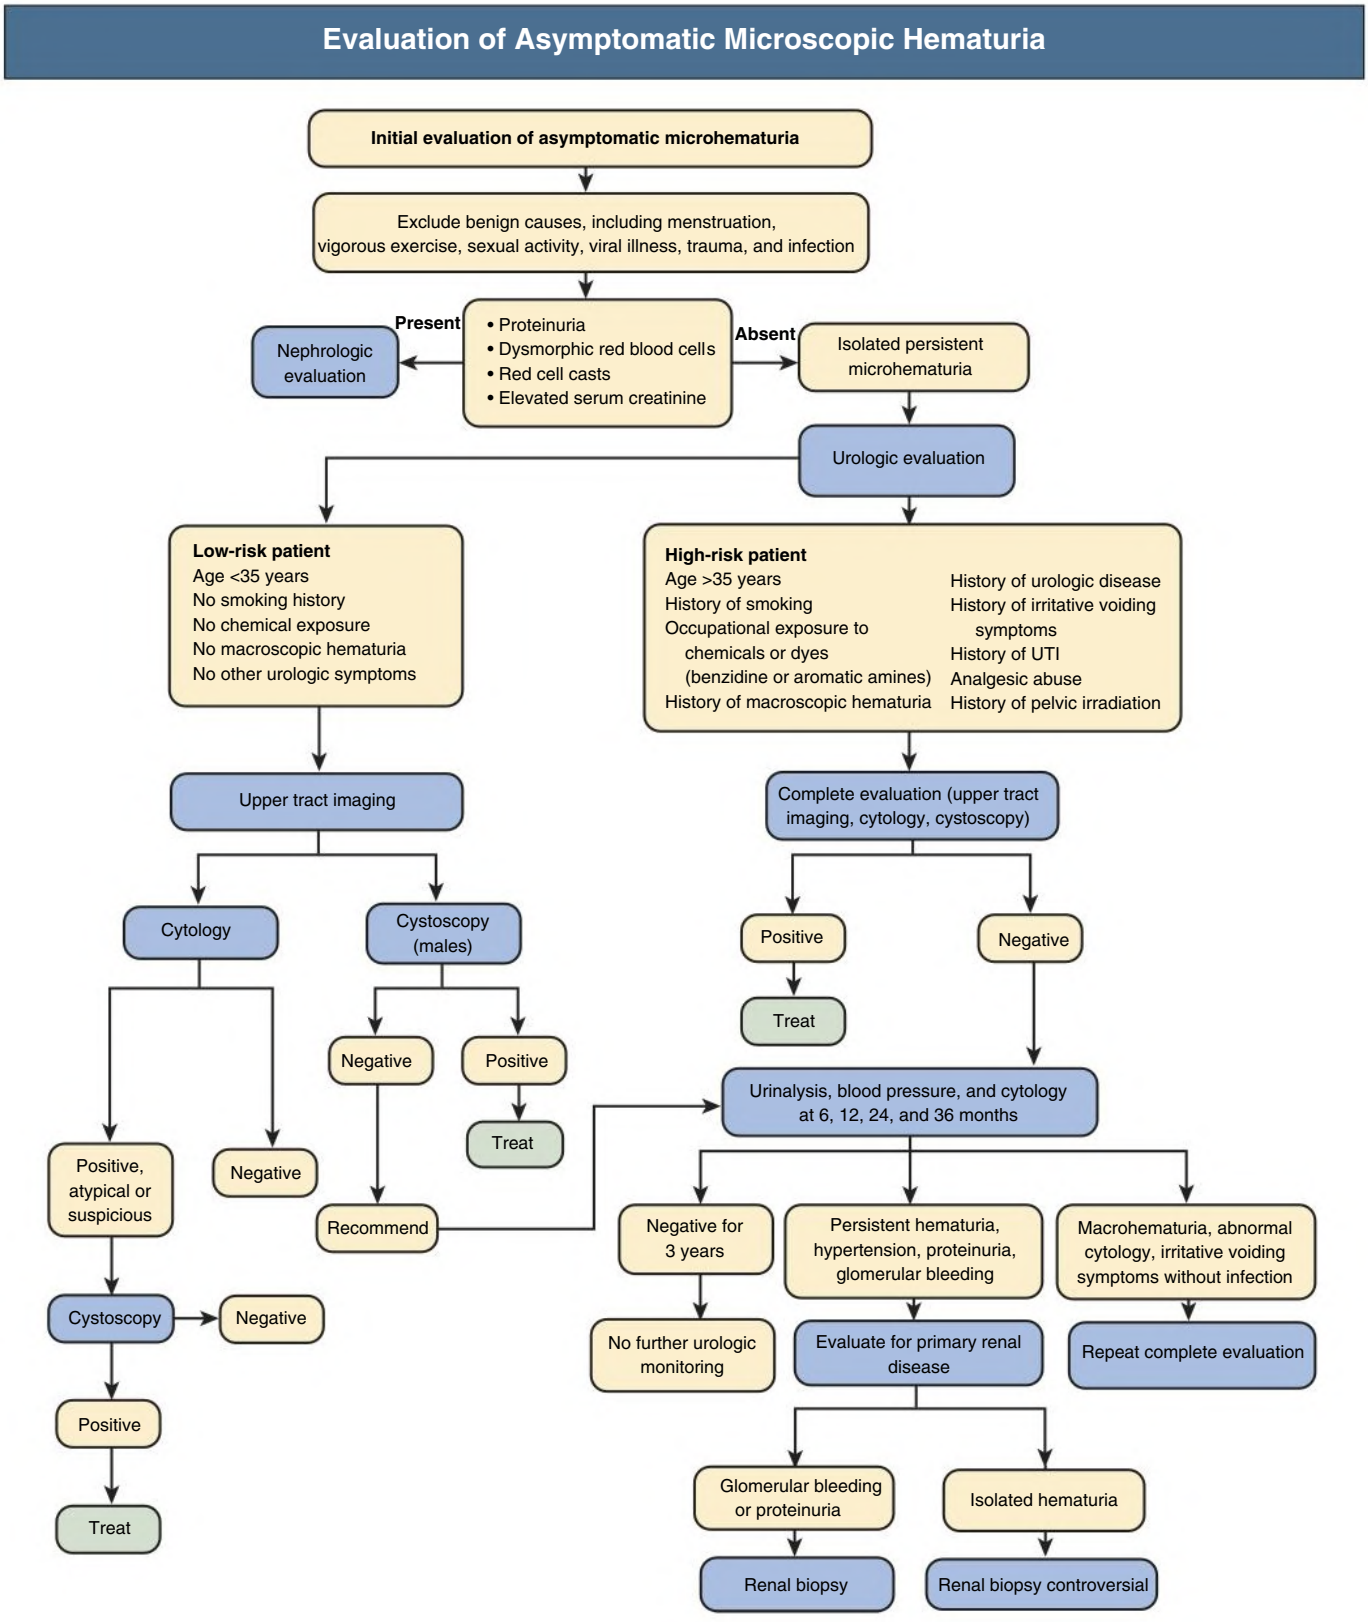

Fig. 63.7 Evaluation of asymptomatic microscopic hematuria. *UTI,* Urinary tract infection.

for a urologic malignancy (i.e., females >50 years old, males >40 years old, those with a more than 10 pack per year smoking history, >11 RBCs per HPF, recurrent AMH, or with specific risk factors for urologic malignancy or clinical suspicion of malignancy) (Box 63.1). The use of adjuncts to AMH workup such as urine cytologic examination and other urine biomarkers is no longer advocated.[37]

Significant proteinuria (>0.3 g/24 h), RBC casts, predominance of dysmorphic RBCs in the urine, or reduced GFR should prompt

BOX 63.1 Common Risk Factors for Urinary Tract Malignancy in Patients With Microhematuria

- Male sex
- Age (>35 years)
- Past or current smoking
- Occupational or other exposure to chemicals or dyes (benzenes or aromatic amines)
- Analgesic abuse
- History of visible hematuria
- History of urologic disorder or disease
- History of irritative voiding symptoms
- History of pelvic irradiation
- History of chronic urinary tract infection
- History of exposure to known carcinogenic agents or chemotherapy such as alkylating agents
- History of chronic indwelling foreign body

referral to a nephrologist and evaluation for parenchymal kidney disease. When present, RBC casts are virtually pathognomonic of glomerular bleeding, but they are often absent in low-grade glomerular disease. Accurate determination of RBC morphology requires inverted phase-contrast microscopy. In general, glomerular bleeding is associated with more than 80% dysmorphic RBCs, and lower urinary tract bleeding is associated with more than 80% normal RBCs.[38] This assessment is operator dependent (urine microscopy is further discussed in Chapter 4). An alternative is to assess urinary RBC size by Coulter counter analysis because dysmorphic RBCs are smaller than normal RBCs, but this method is not useful when RBC numbers in the urine are small. Even in the absence of features of glomerular bleeding, many patients with isolated microhematuria have glomerular disease, most commonly IgA nephropathy or thin basement membrane nephropathy.[39] Because there is a low risk for progressive loss of GFR, kidney biopsy in this setting is not usually recommended. Nevertheless, one study showed that microhematuria unexplained by urologic evaluation carries a twofold risk for eventual development of kidney failure,[40] so these patients should be observed for the development of hypertension, reduced GFR, or proteinuria.

Cyclophosphamide

Past treatment with cyclophosphamide increases the risk of bladder cancer up to ninefold, probably in a dose- and duration-dependent manner. Tumors have been reported 6 to 13 years after cyclophosphamide exposure and are often of high grade. Hematuria is also common after cyclophosphamide in the absence of cancer. If full evaluation does not identify a cause of hematuria, there is no agreed surveillance protocol; it is not clear whether routine follow-up by cystoscopy and urine cytology is valuable, although a high index of suspicion should be maintained.

INVESTIGATION AND MANAGEMENT OF A KIDNEY MASS

The incidence of renal cell carcinoma (RCC) has more than doubled in the last 30 years, now accounting for 3% of all cancers. It is the third most common tumor of the urinary tract but the most lethal. The apparent increased incidence is partly attributed to the widespread use of cross-sectional and ultrasound imaging; more than 50% of new cases are incidental findings on CT, magnetic resonance imaging (MRI), or ultrasound scan.

The primary goal in investigating a kidney mass is to diagnose or exclude malignancy. Ultrasound is 79% sensitive for the detection of kidney parenchymal masses but does not detect lesions that are less than 5 mm. Contrast enhancement with ultrasound also can identify malignancy and improve sensitivity. However, CT scanning before and after contrast administration is the most common modality used to characterize kidney masses. MRI, especially with T2-weighted and diffusion-weighted imaging, may be superior to CT in the correct characterization of benign lesions,[41] but distinguishing an RCC from a benign lesion (i.e., oncocytoma, fat-free angiomyolipoma) is occasionally not feasible radiologically. The choice of imaging techniques and their interpretation are discussed further in Chapters 5 and 6.

Because of the limitations of radiologic evaluation, percutaneous biopsy of a kidney mass is increasingly used to obtain a histologic diagnosis before treatment. Up to 30% of small kidney masses (<3 cm) are nonmalignant. Traditional fears regarding tumor seeding after percutaneous biopsy are not supported by recent studies. Biopsy of a kidney mass is recommended for diagnostic uncertainty despite imaging, before systemic therapy for metastatic RCC and in kidney tumors managed with surveillance or ablative modalities.[42] Many clinicians also perform a biopsy before embarking on surgery in high-risk or elderly surgical candidates, those who will require technically challenging surgery, and patients with small kidney masses. In a recent systematic review evaluating 57 studies investigating more than 5000 patients, percutaneous biopsy was shown to have a high diagnostic yield, sensitivity (>98%), and specificity (>98%) for kidney cancers, with a low associated complication rate.[43]

The management of mixed cystic and solid masses is more problematic. Table 63.6 shows the Bosniak classification of cystic kidney masses.[44] This classification, based on CT appearances, provides the basis for management according to risk for malignancy. The evaluation of multiple cystic lesions in the kidney is discussed further in Chapters 46 and 47.

Tumor size is important; in a large retrospective study of 2935 patients with surgically treated solid kidney tumors, 46% of lesions that were less than 1 cm were benign compared with 22% and 10% of tumors 1 to 2 cm and 4 to 5 cm, respectively. Furthermore, only 2.3% of cancers smaller than 1 cm were of high grade, whereas for tumors greater than 7 cm, the percentage was 58%.[45] Surveillance studies of small kidney tumors have shown a median growth rate of 0.28 cm per year; about 30% of these lesions will not increase in size.

Traditionally, radical nephrectomy was the gold standard treatment for localized kidney cancers. However, nephron-sparing surgery (NSS) is now recommended in all tumors that are less than 7 cm where technically feasible.[42] Comparison of these two approaches for T1a (<4 cm) and T1b (4–7 cm) lesions has shown equivalent tumor clearance and a reduction in long-term kidney complications with partial nephrectomy.[46] Radical nephrectomy therefore should be reserved for larger kidney cancers (≥T2), those technically not amenable to partial nephrectomy, and for patients unlikely to benefit from NSS.[42]

The last two decades have also seen a shift from open to minimally invasive surgery. Laparoscopic radical nephrectomy and robotic-assisted partial nephrectomy (particularly for small exophytic tumors) have now superseded open approaches for these techniques in most large centers. Minimally invasive treatment modalities give equivalent long-term cancer control, while reducing perioperative blood loss, postoperative analgesic requirement, and hospitalization.

Cryosurgery and radiofrequency ablation via laparoscopic or percutaneous approaches have emerged as treatment options for small localized kidney cancers. There is no consensus on the maximum size of lesions amenable to these techniques, but they are usually

TABLE 63.6 Bosniak Classification and Management of Cystic Kidney Masses[a]

Bosniak Class	Features on Imaging	Comment	Management
Class I: simple benign cyst	Round or oval Uniform density <20 HU Unilocular No perceptible wall No contrast enhancement	Majority of asymptomatic cystic lesions	No further intervention required
Class II: benign cyst	One or two nonenhancing septa Calcifications in the wall or septum Hyperdense lesions (50–90 HU, resulting from the presence of blood, protein, or colloid) <3 cm No contrast enhancement		No further intervention required
Class II F: probable benign cyst	Multiple hairline septa "Perceived" enhancement Nodular calcification Hyperdense lesions >3 cm	"Perceived" enhancement resulting from contrast within capillaries of septa	Surveillance with CT scans every 6–12 months
Class III: indeterminate cystic lesions	One or more of the following: Thick, irregular borders Irregular calcifications Thickened or enhancing septa Multilocular form Uniform wall thickening Small nonenhancing nodules	About 40% are neoplastic Magnetic resonance imaging may improve characterization	Surgical exploration
Class IV: presumed malignant cystic masses	Appear malignant Heterogeneous cysts Shaggy, thickened walls or enhancing nodules	Appearances result from necrosis and liquefaction of a solid tumor or a tumor growing in the wall	Surgical exploration

All patients with symptomatic kidney masses should be referred for urologic assessment.
[a]Approach to kidney mass found incidentally by ultrasound or CT scanning.

reserved for tumors that are less than 4 cm. Such treatments offer the advantages of NSS, especially in patients with high surgical risk. Case series evaluating these modalities individually have reported promising results. However, there are no RCT data on either modality and nonrandomized studies have not shown any significant oncologic or survival benefit when comparing these modalities to partial nephrectomy, although several studies have reported reduced efficacy in terms of local recurrence, metastatic progression, and survival.[47–49] Further disadvantages of both techniques include absence of histologic confirmation of complete tissue destruction and potential for more difficult salvage surgery for local recurrence.

Adjunctive Therapy for Kidney Cancer

The 5-year survival for patients diagnosed with localized RCC is approximately 80% to 90%. However, in the United States, up to 20% of patients with RCC present with metastasis. The 5-year survival falls to 60% and 10% in the presence of regional and distant metastasis, respectively. Metastatic RCC is resistant to commonly used chemotherapeutic agents, and cytokine therapy with either interleukin (IL)-2 or interferon-α (IFN-α) was standard treatment for metastatic RCC in the United States and Europe until 2005. Although more effective than traditional chemotherapy, it produced only modest response rates with significant toxicity.[50] Identification of the molecular pathways implicated in the etiology of RCC has led to the development of targeted tyrosine kinase inhibitors and monoclonal antibodies directed against the vascular endothelial growth factor (VEGF) pathway (sorafenib, sunitinib, bevacizumab, pazopanib, axitinib, cabozantinib) and mammalian target of rapamycin (mTOR) (temsirolimus, everolimus). In randomized studies, many of these agents, compared with standard existing therapy, have improved both progression-free and overall survival when used as first- or second-line therapy.[51–56] Further development of immune checkpoint inhibitors including nivolumab and pembrolizumab (IgG4 monoclonal antibodies blocking PD-1 [programmed cell death protein 1]) and ipilimumab (CTLA4 [cytotoxic T-lymphocyte-associated protein 4] inhibitor) within the last 5 years have developed treatment further. Landmark trials have demonstrated superior progression-free and overall survival with combination immune check point treatment compared with single VEGF-targeted therapy that had been the first-line treatment only a few years ago.[57,58] The European Association of Urology has made recommendations on the sequence in which these agents should be used (Table 63.7).[59] Nephrologic aspects of cancer therapy are further discussed in Chapter 67.

Natural History of Reduced Glomerular Filtration Rate After Surgical Treatment of Kidney Cancer

Normal GFR is usually preserved in the long term after donor transplant nephrectomy. Donors are highly selected to minimize comorbidities and generally are younger than patients treated for kidney tumors. However, emerging long-term evidence suggests those undergoing donor nephrectomy do have increased long-term cardiovascular complications and reduced survival.[60] Similarly, after surgery for kidney cancer, when the residual functioning kidney tissue is reduced, there is significant risk for late sequelae, including proteinuria, glomerulosclerosis, and progressive kidney failure resulting in increased cardiovascular complications and reduced survival. These risks are

TABLE 63.7 Evidence-Based Recommendations for Targeted Therapy in Metastatic Renal Cell Carcinoma

Prognosis Risk Group[59]	Standard of Care	Alternative if Unable to Receive/Tolerate Standard of Care
Favorable	Pembrolizumab + axitinib	Sunitinib Pazopanib
Intermediate/ poor	Pembrolizumab + axitinib *or* Ipilimumab + nivolumab	Cabozantinib Sunitinib Pazopanib

Based on 2020 European Association of Urology Guidelines for renal cell carcinoma.
Data modified from Ljungberg B, Bensalah K, Bex A, et al. European Association of Urology guidelines on Renal Cell Carcinoma, 2020. www.uroweb.org/guideline/renal-cell-carcinoma/.

thought to be greater when radical rather than partial nephrectomy is performed. A recent systematic review of 21 nonrandomized comparative studies (11,204 patients) evaluating partial nephrectomy versus radical nephrectomy demonstrated superiority for NSS.[61] Partial nephrectomy was associated with greater perioperative blood loss and postoperative complications, affirming that it is a more challenging procedure. However, NSS was associated with a lower long-term decline in eGFR and reduced risk for chronic kidney disease. NSS also provided a more favorable cancer-specific survival. The one RCT to compare partial nephrectomy versus radical nephrectomy also has demonstrated that fewer patients undergoing NSS develop reduced GFR (<60 mL/min/1.73m^2), but survival and cancer outcomes are similar with either modality.[46]

Renal Cell Carcinoma in von Hippel–Lindau Disease

Von Hippel–Lindau disease (VHL) is a rare autosomal dominant condition with a predisposition to the development of RCC. The genetics, clinical manifestations, and general management of VHL are discussed in Chapter 47. The incidence of RCC in patients with VHL is about 45%. On histologic examination, the tumors are of the clear cell type, often multifocal and bilateral, and can be solid or cystic. The mean age at diagnosis is 39 years, and there is a 30% to 35% risk for tumor progression, metastasis, and death.

Longitudinal imaging studies have described the natural history of VHL kidney lesions. In one study, multifocal lesions were frequent[62] (on average, 8 per patient), of which 74% were classified as simple cysts, 8% as complex cysts with solid components, and 18% as solid masses. The solid components of VHL lesions almost always contain RCC. During a mean 2.4-year follow-up, most cysts remained the same size (71%) or enlarged (20%), and 9% became smaller. On the contrary, 95% of solid masses increased in size. Although it is generally thought that the cysts are premalignant, the transformation of a simple cyst to a solid lesion was observed in only two patients. Patients with VHL require multidisciplinary management. Surgical intervention is not used for tumors that are less than 3 cm because metastasis is rare below this threshold. In addition, bilateral nephrectomy should be avoided, if possible, because of the substantial morbidity associated with kidney replacement therapy. The standard of care for these patients is partial nephrectomy, and a 10-year survival rate of 81% has been reported.

The results of NSS for VHL appear less satisfactory than for sporadic RCC because of a high risk for local tumor recurrence. Repeated surgery may be needed for new or growing lesions, and for this reason the use of minimally invasive methods is being investigated. Repeated ablation of tumors with radiofrequency and cryotherapy is possible with minimal morbidity; however, the long-term effectiveness of these methods has not yet been established.

SELF-ASSESSMENT QUESTIONS

1. A 50-year-old man presents with right-sided ureteral colic and on subsequent investigation is found to have a 4-mm distal ureteral calculus with no hydronephrosis. He has normal eGFR. In the absence of ongoing pain or sepsis, what is the most appropriate management option?
   - **A.** Acute endoscopic lasertripsy
   - **B.** Decompression with ureteric stenting
   - **C.** Trial of medical expulsive therapy
   - **D.** Discharge from care of urologist
   - **E.** Percutaneous nephrostomy
2. A 70-year-old man is seen in an outpatient clinic with a 2-month history of intermittent hematuria. He takes warfarin for atrial fibrillation but is otherwise healthy. His eGFR is in the normal range. What urologic investigations does he require?
   - **A.** Clotting screen to exclude overanticoagulation as the sole cause of his hematuria
   - **B.** Clotting screen; proceed to urologic workup only if INR is within therapeutic range
   - **C.** Clotting screen, flexible cystoscopy, and CT urogram
   - **D.** Clotting screen, serum creatinine (eGFR), flexible cystoscopy, and CT urogram
3. A 60-year-old man with diabetic nephropathy is referred with a 3-cm lower pole kidney lesion suspicious for malignancy on routine ultrasound scan. These findings are confirmed on CT scan. Despite his comorbidity, he is deemed fit for surgery. What is the most appropriate procedure to consider?
   - **A.** Open radical nephrectomy to achieve maximum oncologic benefit
   - **B.** Laparoscopic cryosurgery
   - **C.** Laparoscopic partial nephrectomy
   - **D.** Laparoscopic radiofrequency ablation

Acute Interstitial Nephritis

Robert MacGinley, Jérôme A. Rossert

DEFINITION

Acute interstitial nephritis (AIN) is an acute, often reversible disease characterized by inflammatory infiltrates within the kidney interstitium. AIN is a relatively rare cause of acute kidney injury (AKI), but it should not be overlooked because it usually requires specific therapeutic interventions.

PATHOGENESIS

Most studies suggest that AIN is an immunologically induced hypersensitivity reaction to an antigen that is classically a drug or an infectious agent. Evidence for a hypersensitivity reaction in drug-induced AIN includes the following: it occurs only in a small percentage of individuals; it is not dose dependent; it is often associated with extrarenal manifestations of hypersensitivity; it recurs after accidental reexposure to the same drug or to a closely related one; and it is sometimes associated with evidence of delayed-type hypersensitivity reaction (kidney granulomas). Similarly, AIN secondary to infections can be differentiated from pyelonephritis by the relative absence of neutrophils in the interstitial infiltrates and the failure to isolate the infective agent from the kidney parenchyma, again suggesting an immunologic basis to the disease.

Experimental models of AIN have identified three major types of antigens that induce the condition.[1] Antigens may be tubular basement membrane (TBM) components (e.g., the glycoproteins 3M-1 and TIN-Ag/TIN1), secreted tubular proteins (e.g., uromodulin), or nonrenal proteins (e.g., from immune complexes).

Although human AIN may be secondary to an immune reaction directed against a kidney antigen, most cases of AIN are probably induced by extrarenal antigens, being produced in particular by drugs or infectious agents. These antigens may induce AIN by a variety of mechanisms, including binding to kidney structures ("planted antigen"); acting as haptens that modify the immunogenicity of native kidney proteins; mimicking kidney antigens, resulting in a cross-reactive immune reaction; and precipitating within the interstitium as circulating immune complexes.

Experimental models have identified both cell-mediated immunity and antibody-mediated immunity in the pathogenesis of AIN (Fig. 64.1). In humans, most forms of AIN are not associated with antibody deposition, which suggests that cell-mediated immunity plays a major role. This hypothesis is reinforced by the fact that interstitial infiltrates usually contain numerous T cells, and these infiltrates sometimes form granulomas. Nevertheless, deposition of anti-TBM antibodies or of immune complexes can be observed occasionally in kidney biopsy specimens, and antibody-mediated immunity may play a role in the pathogenesis of the disease in these cases.

Formation of immune complexes within the interstitium, or interstitial infiltration with T cells, will result in an inflammatory reaction. This reaction is triggered by many events, including activation of the complement cascade by antibodies and release of inflammatory cytokines by T lymphocytes and phagocytes (see Fig. 64.1). Although the interstitial inflammatory reaction may resolve without sequelae, it sometimes induces interstitial fibroblast proliferation and extracellular matrix synthesis, leading to interstitial fibrosis and chronic kidney disease (CKD). Cytokines such as transforming growth factor-β appear to play a key role in the latter process.

EPIDEMIOLOGY

AIN is a relatively uncommon cause of AKI, although its incidence may be increasing.[2] It accounts for 2% to 3% of all kidney biopsies, 10% to 15% of biopsies performed for unexplained AKI, and up to 25% of those performed for drug-induced AKI.[2] Of kidney biopsies done in children with AKI, 3% to 7% show AIN.[3]

Before antibiotics were available, AIN was most commonly associated with infections such as scarlet fever and diphtheria. Drug-induced AIN now appears to account for about 70% to 90% of all cases.

DRUG-INDUCED ACUTE INTERSTITIAL NEPHRITIS

Clinical Manifestations

In the 1960s and 1970s, most cases of drug-induced AIN were caused by methicillin, and the clinical manifestations of methicillin-induced AIN were considered the prototypical presentation of AIN. Since then, many other drugs have been implicated in the induction of AIN (Box 64.1), of which antimicrobial agents (in particular, β-lactam antibiotics, sulfonamides, fluoroquinolones, and rifampin), nonsteroidal antiinflammatory drugs (NSAIDs) (especially fenoprofen), and proton pump inhibitors (PPIs) have been most commonly involved.[4,5] In a large case series of biopsy-proven AIN, drug-induced AIN was because of antibiotics in 49% of cases, NSAIDs in 11%, and PPIs in 14%.[4] There has been a rising incidence of AIN in the current decade. In a large single-center Spanish

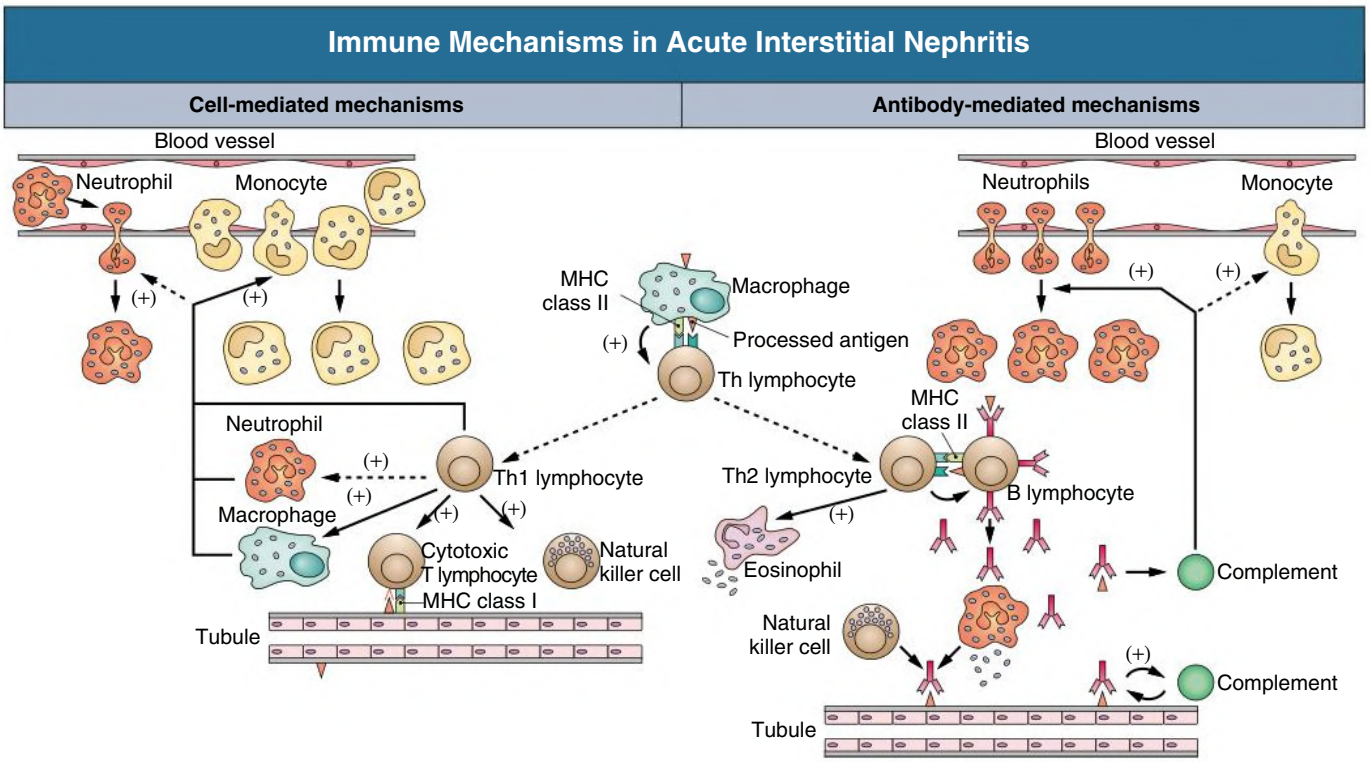

Fig. 64.1 Immune Mechanisms That Can Be Involved in Acute Interstitial Nephritis. Both cell-mediated and antibody-mediated mechanisms occur. The cell-mediated mechanism is primarily associated with macrophages and T cells. The antibody-mediated mechanism is frequently associated with neutrophil or eosinophil infiltration and with local complement activation. *MHC,* Major histocompatibility complex.

study of 182 patients, the most common offending drugs were NSAIDs (27%), antibiotics (22%), and PPIs (4%), but 30% of cases had no identified offending drug.[6] Other antiulcer agents, diuretics, phenindione, phenytoin, allopurinol, highly active antiretroviral therapy (HAART), and anticancer agents such as tyrosine kinase inhibitors, pemetrexed, and ifosfamide also have been reported to cause AIN.[7,8] In addition, AIN can be caused by immune checkpoint inhibitors (e.g., programmed death 1 [PD-1], PD ligand 1 [PD-L1], and cytotoxic T-lymphocyte–associated antigen 4 [CTLA-4] inhibitors), as shown in meta-analysis and now confirmed by a large single-center study of 1016 patients to occur about 3% of the time.[9,10] Most other drugs only rarely have been linked with AIN (see Box 64.1). AIN also has been reported after snake or wasp envenomation, and the pathogenic mechanism is likely to be similar to that in drug-induced AIN.

The clinical characteristics of drug-induced AIN are now recognized as much more varied and nonspecific than the spectrum seen in classic methicillin-induced AIN (Fig. 64.2).[2,11,12]

Kidney Manifestations

Symptoms of AIN usually develop a few days to a few weeks after the inciting drug is started, although cases have occurred months after initial exposure to the drug. In particular, AIN induced by NSAIDs or PPIs is often diagnosed several months after treatment initiation, and a recent paper suggests an average time of 4 months with immune checkpoint inhibitors.[11] The typical presentation is sudden impairment in kidney function, associated with mild proteinuria (<1 g/day) and abnormal urinalysis, in a patient with flank pain, normal blood pressure, and no edema. Clinical presentation is often incomplete (see Fig. 64.2), and AIN should be considered in any patient with unexplained AKI.[2] Kidney dysfunction may be mild or severe, and dialysis is required in about one-third of patients. Hematuria and pyuria are present in a little more than half of the patients, and although leukocyte casts are common, hematuria is almost never associated with red blood cell casts. Flank pain (reflecting distention of the kidney capsule) is observed in about one-third of the patients and can be the main complaint on hospital admission. Some patients have low fractional sodium excretion.

Standard imaging procedures show kidneys normal in size or slightly enlarged. Ultrasound usually discloses an increased cortical echogenicity (comparable to or higher than that of the liver).

Extrarenal Manifestations

Extrarenal symptoms consistent with a hypersensitivity reaction are occasionally observed, including low-grade fever, maculopapular rash (Fig. 64.3), mild arthralgia, and eosinophilia. However, each of these symptoms is typically present in fewer than half of the patients (see Fig. 64.2), and these symptoms are all present in less than 10% of patients.[2] With some drugs, other manifestations of hypersensitivity, such as hemolysis or hepatitis, can be present. Serum immunoglobulin E (IgE) levels also may be elevated.

The association of AKI with clinical signs suggestive of hypersensitivity or eosinophilia should lead to consideration of AIN. However, signs of hypersensitivity can be observed in patients with AKI that is

BOX 64.1 Drugs Responsible for Acute Interstitial Nephritis

Antimicrobial Agents

Penicillins

Amoxicillin
Ampicillin[a]
Aztreonam
Carbenicillin
Cloxacillin
Flucloxacillin
Methicillin[a]
Mezlocillin
Nafcillin
Oxacillin[a]

Fenoprofen[a]
Flurbiprofen
Ibuprofen[a]
Ketoprofen
Naproxen

Acetic Acid Derivatives

Indometacin[a] **(indomethacin**[a]**)**
Alclofenac
Diclofenac
Fenclofenac
Sulindac
Zomepirac

Enolic Acid Derivatives

Meloxicam
Piroxicam[a]

Fenamic Acid Derivatives

Mefenamic acid

Coxibs

Celecoxib
Rofecoxib

Other

Azapropazone
Mesalamine (mesalazine, 5-ASA)
Phenazone
Phenylbutazone
Sulfasalazine
Tolmetin

Antalgics

Aminopyrine
Antipyrine

Anticonvulsants

Carbamazepine[a]
Diazepam
Lamotrigine[a]
Levetiracetam
Phenobarbital (phenobarbitone)
Phenytoin[a]
Valproic acid (valproate sodium)

Diuretics

Chlorthalidone
Etacrynic acid (ethacrynic acid)
Furosemide[a] (frusemide[a])
Hydrochlorothiazide[a]
Indapamide
Triamterene[a]

Antiulcer Agents

Histamine-2 Receptor Antagonists

Cimetidine[a]
Famotidine
Ranitidine

Proton Pump Inhibitors

Esomeprazole
Lansoprazole
Omeprazole
Pantoprazole
Rabeprazole

Immune Checkpoint Inhibitors

Ipilimumab[a]
Nivolumab
Pembrolizumab

Other Anticancer Agents

Adriamycin
Bevacizumab
Bortezomib
Carboplatin
Cytosine arabinoside
Gemcitabine
Ifosfamide
Interleukin-2
Lenalidomide
Methotrexate
Pemetrexed
Sorafenib
Sunitinib

Others

Allopurinol[a]
α-Methyldopa
Amlodipine
Azathioprine
Betanidine (bethanidine)[a]
Bismuth salts
Captopril[a]
Carbimazole
Cetirizine
Chlorpropamide[a]
Clofibrate
Clozapine
Cyclosporine
Deferasirox
Diltiazem
D-Penicillamine
Etanercept
Exenatide
Fenofibrate[a]
Fluindione
Gold salts
Griseofulvin
Interferon
Isotretinoin
Liraglutide
Nifedipine[a]
Phenindione[a]
Phenothiazine
Phenylpropanolamine
Probenecid
Propranolol
Propylthiouracil
Sirolimus
Streptokinase
Sulfinpyrazone
Warfarin
Zopiclone

Drugs most commonly involved are in **bold**.
[a]Drugs that can cause granulomatous AIN.
AIN, Acute interstitial nephritis; *NSAIDs,* nonsteroidal antiinflammatory drugs.

not related to AIN, including patients with drug-induced acute tubular necrosis.

Specific Drug Associations

The clinical and biologic manifestations of AIN may have some specificity, depending on the drug involved.

As outlined earlier, methicillin-induced AIN was characterized by a high frequency of abnormal urinalysis and extrarenal symptoms and by well-preserved kidney function. Kidney failure was reported in only about 50% of patients (see Fig. 64.2).[2]

More than 200 cases of rifampin-induced AKI have been reported.[12] Prior exposure is common; most cases occurred after readministration

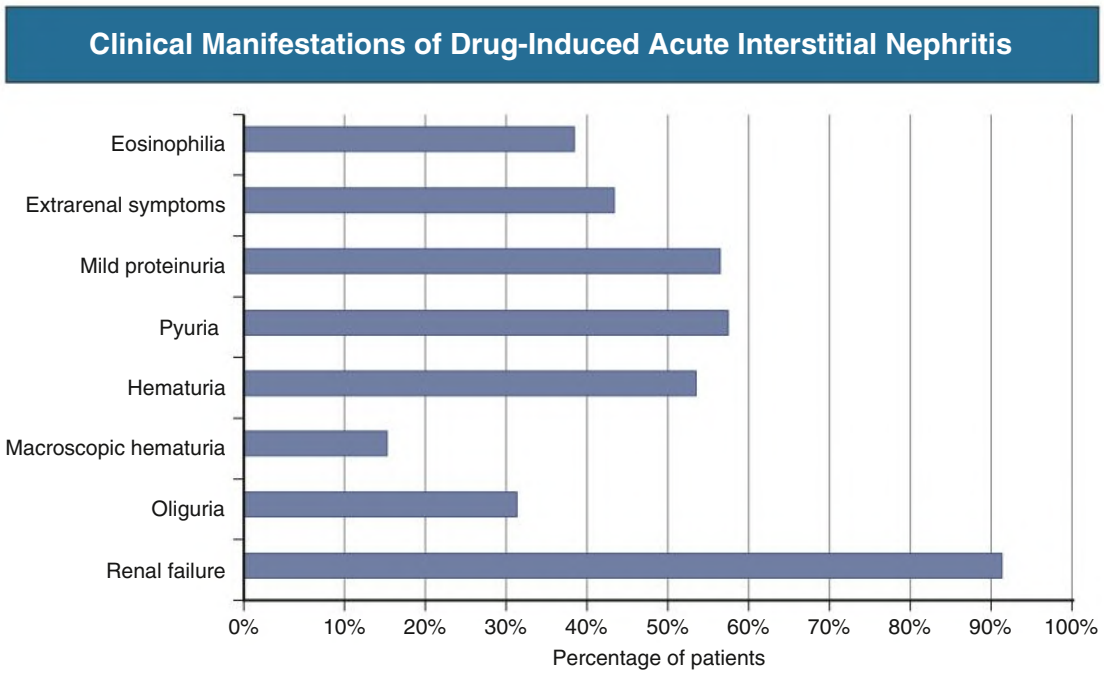

Fig. 64.2 Clinical Manifestations of Drug-Induced Acute Interstitial Nephritis (AIN). Data were pooled from different case reports, including more than 200 patients with drug-induced AIN. Patients with AIN associated with methicillin therapy or with a nephrotic syndrome are not included.

Fig. 64.3 Maculopapular Rash in a Patient With Drug-Induced Acute Interstitial Nephritis (AIN). Such cutaneous lesions occur in about 40% of patients with drug-induced AIN, but they can also be seen in patients with drug-induced acute tubular necrosis.

of rifampin or several months after intermittent administration of the drug had begun. Kidney failure is usually associated with the sudden onset of fever, gastrointestinal symptoms (nausea, vomiting, diarrhea, abdominal pain), and myalgias. It also may be associated with hemolysis, thrombocytopenia, and, less frequently, hepatitis. Kidney biopsy usually shows tubular injury and interstitial inflammatory infiltrates. Although circulating antirifampin antibodies are often found, immunofluorescence (IF) staining of kidney biopsy specimens for immunoglobulin and complement is negative in most cases, suggesting that cell-mediated immunity plays a key role in the induction of the nephritis. In a few cases, AIN developed after continuous treatment with rifampin for 1 to 10 weeks in which extrarenal symptoms or antirifampin antibodies were absent, and kidney biopsy specimens showed severe interstitial infiltrates but few tubular lesions.

Phenindione-induced AIN is generally associated with the development of hepatitis, which can be fatal.

Allopurinol-induced AIN appears to occur more often in patients with CKD and is usually seen in association with rash and liver dysfunction and sometimes with full manifestations of Stevens-Johnson syndrome.[13] This severe allergic reaction is primarily observed in patients with the human leukocyte antigen B58 genotype.

AIN caused by NSAIDs is associated with nephrotic syndrome in about 75% of cases. Patients are usually older than 50 years, and although it has been observed with all NSAIDs, including cyclooxygenase 2–selective inhibitors, half of the cases have been reported with fenoprofen. Most occurrences develop after the patient has taken NSAIDs for months (6 months on average), but AIN can occur within days or after more than a year. With the exception of the heavy proteinuria and associated edema, the presentation of these patients is similar to that of patients with other forms of drug-induced AIN (Fig. 64.4), although extrarenal symptoms are present in only about 10% of patients. Kidney disease caused by NSAIDs must be differentiated from other NSAID kidney manifestations, including hemodynamically mediated AKI, papillary necrosis, and NSAID-induced membranous nephropathy. Drugs other than NSAIDs can rarely induce AIN associated with the nephrotic syndrome; a few cases have been reported after administration of ampicillin, rifampin, lithium, interferon, phenytoin, pamidronate, and D-penicillamine.

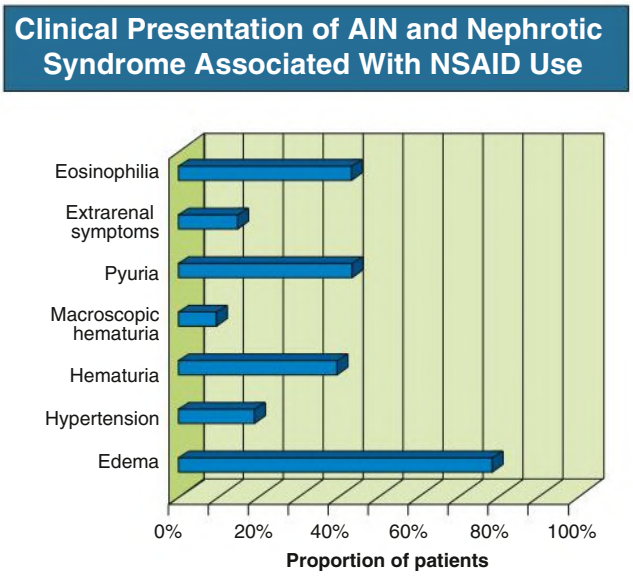

Fig. 64.4 Clinical Presentation of Acute Interstitial Nephritis (AIN) and Nephrotic Syndrome Associated With Nonsteroidal Antiinflammatory Drug (NSAID) Use. Data were pooled from different case reports including more than 60 patients.

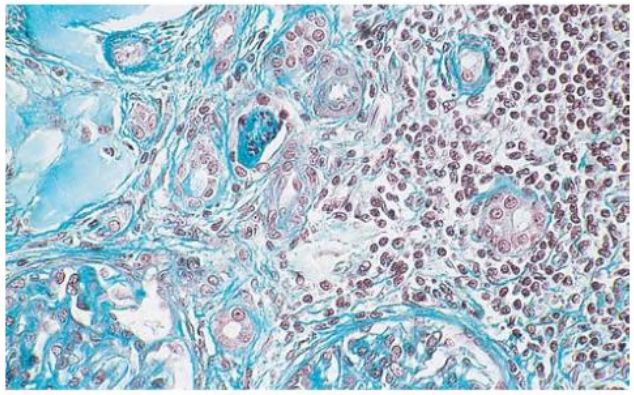

Fig. 64.5 Drug-Induced Acute Interstitial Nephritis. On light microscopy, the characteristic feature is interstitial infiltration with mononuclear cells, with normal glomeruli. It is usually associated with interstitial edema and tubular lesions. (Courtesy Dr. B. Mougenot, Paris VI University, Paris.)

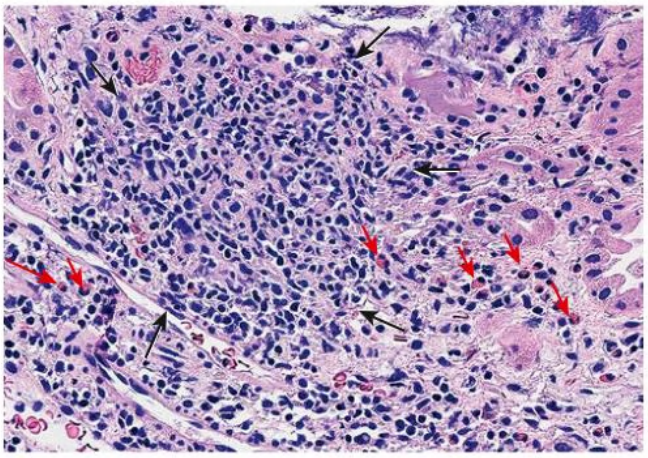

Fig. 64.6 Drug-induced granulomatous acute interstitial nephritis (AIN). The patient was taking omeprazole over the counter and presented with fever, chills, malaise, and cough. Workup showed a serum creatinine of 4.5 mg/dL (400 µmol/L) and 15.5-cm enlarged kidneys that were pushing up on the diaphragm, causing the cough. Biopsy shows AIN with eosinophils *(red arrows),* lymphocytes, and early granuloma formation (demarcated by *black arrows*). (Courtesy R.J. Johnson, University of Colorado, Denver.)

PPIs, such as omeprazole or pantoprazole, are commonly recognized as a cause of AIN. Symptoms are nonspecific, although approximately 10% of subjects present with fever, chills, and anorexia. Consistent with the fact that drug-induced AIN can lead to permanent kidney damage, large observational studies have shown that the use of PPIs is associated with an increased risk for development or progression of CKD, and development of AIN is viewed as being the likely underlying mechanism.[14]

Target immune therapies have transformed the treatment and outcomes of many cancers in the last few years but not without multiple immune-mediated adverse side effects, including AKI.[15] In one large study, immune checkpoint inhibitor–associated AKI usually occurred at an average of 14 weeks (range, 6–37 weeks), and the majority had other drugs known to cause AIN (69%) and often with multiple checkpoint inhibitors used on patients at the same time, with the majority recovering (85%). A small biopsy series demonstrated that 92% of patients had tubulointerstitial nephritis as the cause of the AKI, which was associated with persistent mild kidney impairment at 12 months.[11] The use of kidney biopsy versus just an empiric steroid pulse when any AKI occurs associated with checkpoint inhibitor use is controversial, but biopsy may aid decision making about whether to continue giving a checkpoint inhibitor and/or prescribe corticosteroids.[16]

Pathology

The hallmark of AIN is the presence of inflammatory infiltrates in the kidney interstitium (Fig. 64.5). These infiltrative lesions are often patchy, predominating in the deep cortex and outer medulla, but they can be diffuse in severe cases. They are composed mostly of T cells and monocytes-macrophages, but plasma cells, eosinophils, and a few neutrophilic granulocytes also may be present. The relative number of $CD4^+$ T cells and $CD8^+$ T cells is variable from one patient to another. In some cases, T lymphocytes infiltrate across the TBM and between tubular cells, mainly in distal tubules, and the resulting lesion is referred to as *tubulitis.*

In some cases of drug-induced AIN, kidney biopsy shows interstitial granulomas (Fig. 64.6). These granulomas are usually sparse and nonnecrotic, with few giant cells, and are associated with nongranulomatous interstitial infiltrates. Granulomas are also found in AIN related to infection (Box 64.2), sarcoidosis, Sjögren syndrome, and granulomatous polyangiitis.

Interstitial infiltrates are always associated with interstitial edema, which is responsible for separating the tubules (see Fig. 64.5). They can also be associated with focal tubular lesions, which range from mild cellular alterations to extensive necrosis of epithelial cells, and are sometimes associated with a disruption of the TBM. These tubular lesions usually predominate where the inflammatory infiltrates are most extensive.

Tubulointerstitial lesions are not associated with vascular or glomerular lesions. Even in AIN associated with a nephrotic syndrome, glomeruli appear normal on light microscopy; glomerular lesions are similar to those seen in minimal change disease (see Chapter 18).

In most patients with AIN, kidney biopsy specimens do not show immune deposits, and both IF and electron microscopy are negative. Nevertheless, staining of the tubular or capsular basement membrane

BOX 64.2 Infections That Can Be Associated With Acute Interstitial Nephritis

Bacteria
Brucella spp.
Campylobacter jejuni
Corynebacterium diphtheriae
Escherichia coli
Legionella spp.
Leptospira spp.
Mycobacterium tuberculosis[a]
Salmonella spp.[a]
Staphylococcus spp.
Streptococcus spp.
Yersinia pseudotuberculosis

Viruses
Adenovirus
Cytomegalovirus
Epstein-Barr virus[a]
Hantavirus
Hepatitis A virus
Hepatitis B virus
Herpes simplex virus
Human immunodeficiency virus
Measles virus
Polyomavirus
Rickettsia

Parasites
Toxoplasma spp.[a]
Leishmania donovani

Other
Chlamydia spp.
Mycoplasma spp.

[a] Infections that can induce granulomatous acute interstitial nephritis.

for IgG or complement may occasionally be seen by IF; the staining pattern is either granular or linear (Fig. 64.7). Linear fixation of IgG along the TBM indicates the presence of antibodies directed against membrane antigens or against drug metabolites bound to the TBM, and circulating anti-TBM antibodies have been detected in some cases. These linear deposits are seen mostly in patients taking NSAIDs, phenytoin, or allopurinol.

Diagnosis

The most accurate way to diagnose AIN is by kidney biopsy. However, both eosinophiluria and gallium scanning have been suggested as helpful in making the diagnosis.

Eosinophils can be detected in urine and, although eosinophiluria is frequently used to corroborate the diagnosis of drug-induced AIN, review of published series shows that this test has rather poor sensitivity and a low positive predictive value, even when only patients with AKI are considered. In the largest and most recent series, only 36% (26 of 73) of patients with drug-induced AIN had eosinophiluria, and 28% (20 of 69) of patients with acute tubular necrosis also had eosinophiluria (Fig. 64.8).[17] Eosinophiluria may also occur in patients with diseases such as proliferative or crescentic glomerulonephritis (GN), atheroembolic kidney disease, urinary tract infection, urinary schistosomiasis, and even prerenal AKI.[18] Thus, eosinophiluria should be abandoned as a test for AIN. Firm diagnosis requires kidney biopsy and/or a clinical response on withdrawal of the drug of concern.

An increased kidney uptake of gallium-67 (^{67}Ga) has been reported in AIN.[19] Analysis of available series shows that in 53 patients with AIN, 83% had an abnormal kidney scan (maximum after 48 hours), whereas it was normal in 17 of 18 patients with acute tubular necrosis. However, these studies were small and retrospective, and ^{67}Ga kidney scanning is not specific for AIN and may be abnormal in patients with pyelonephritis, cancer, or glomerular diseases. We do not recommend use of gallium scanning as a diagnostic tool.

Because the clinical presentation of AIN is variable and because noninvasive diagnostic procedures have limitations, kidney biopsy is often essential for the diagnosis of AIN. Several studies have shown that prebiopsy diagnosis may be incorrect in a substantial number of patients.

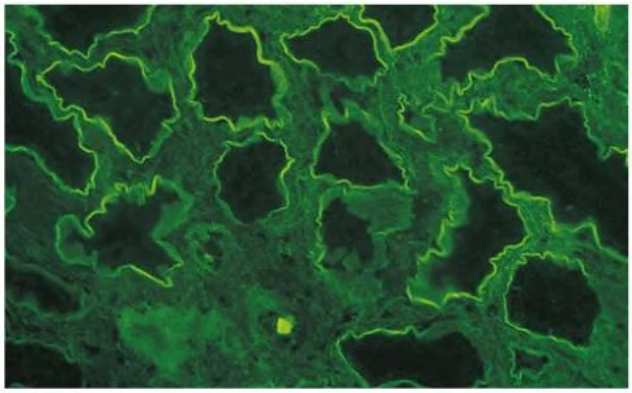

Fig. 64.7 Linear Deposits of Immunoglobulin G in Drug-Induced Acute Interstitial Nephritis. Deposits along the tubular basement membrane (TBM) are shown on immunofluorescence microscopy. These antibodies recognize either a component of the TBM or a drug metabolite bound to the TBM. (Courtesy Dr. B. Mougenot, Paris VI University, Paris.)

Identification of the Causative Drug

Identification of the causative drug is relatively easy when AIN occurs in a patient taking only one drug. However, patients are often taking more than one drug capable of inducing AIN and in a recent study,[6] 30% of cases had no offending drug clearly implicated. Two biologic tests have been used, primarily in research laboratories, to help identify the causative drug: the lymphocyte stimulation test and the identification of circulating antidrug antibodies. However, neither test appears to be clinically useful at this time because of issues with sensitivity and specificity.

Natural History

Drug-induced AIN was long considered benign, with complete recovery of kidney function if the inciting agent was removed. However, recent studies show that the course of AIN is not always benign, and serum creatinine does not return to baseline in about 40% to 50% of patients.[4,20] Even in those with kidney recovery, an increase in serum creatinine can persist for several weeks. Unfortunately, there are few known prognostic predictors. The severity of kidney failure does not appear to be linked with the prognosis.[4] It has been suggested that the presence on kidney biopsy of diffuse neutrophil- or macrophage-rich infiltrates, interstitial granulomas, or tubular atrophy is associated with a poor prognosis, but this has not been consistently found in all series. The best prognostic predictors may actually be the duration of AKI and the severity of interstitial fibrosis.

Treatment

In addition to removal of the inciting agent, which is essential and should be done as soon as possible, corticosteroids have been used to treat AIN. Most commonly, patients received high-dose oral corticosteroids sometimes associated with pulses of intravenous methylprednisolone. In the recent decade, properly controlled trials still suggest that corticosteroids improve outcomes, particularly in idiopathic AIN.[20] The largest recent study[6] confirmed short-course therapy (3 weeks) was as effective as a prolonged course (8 weeks).

In different series, corticosteroids rapidly induced a reduction in serum creatinine in patients whose kidney function did not improve within about 1 week after discontinuation of the inciting agent. It is interesting that in patients with NSAID-induced AIN, corticosteroids do not seem to modify the course of the nephrotic syndrome.

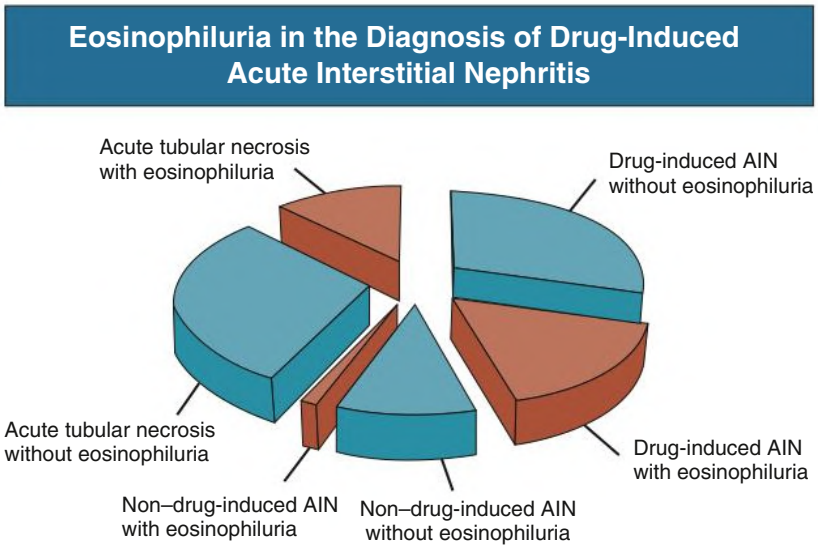

Fig. 64.8 Eosinophiluria in the Diagnosis of Drug-Induced Acute Interstitial Nephritis (AIN). Data from a recent and large retrospective series confirm that eosinophiluria (defined by the presence of 1% or more eosinophils in urine) lacks sensitivity and specificity for the diagnosis of drug-induced AIN in patients with acute kidney injury. (From Lazarus B, Chen Y, Wilson FP, et al. Proton pump inhibitor use and the risk of chronic kidney disease. *JAMA Intern Med.* 2016;176[2]:238–246.)

On the basis of anecdotal case reports, some authors have advocated use of mycophenolate mofetil in patients resistant to corticosteroids.[21]

We recommend administration of a 3-week course of prednisolone in patients whose kidney function fails to improve within 1 week after discontinuation of the inciting drug and rapidly return to baseline values, provided the diagnosis of AIN has been confirmed by kidney biopsy.[6] We initiate treatment with a dose of prednisone of 1 mg/kg/day and not higher than 60 mg/day, and after 1 to 2 weeks, we progressively taper the dose so that the total duration of treatment is 4 to 6 weeks.

ACUTE INTERSTITIAL NEPHRITIS SECONDARY TO INFECTIOUS DISEASES

Infections were once the most common cause of AIN, but the frequency of AIN induced by an infection has decreased with the widespread use of antibiotics. Nevertheless, the diagnosis of infectious AIN should not be overlooked, and AIN occurring in patients treated with antibiotics should not always be attributed to the drug.

Infectious agents can cause kidney parenchymal inflammation by direct infection, resulting in acute pyelonephritis (see Chapter 53). However, many infectious agents may induce an immunologically mediated AIN in the absence of direct invasion (see Box 64.2). In this case the clinical presentation depends mostly on the underlying infection. On histologic examination, lesions are identical to those described for drug-induced AIN, and they also can occasionally result in granulomas (see Box 64.2). Infection-associated AIN usually resolves with the treatment of the underlying infection, and corticosteroid therapy is not recommended.

An important cause of infection-associated AIN is hantavirus.[22] Hantavirus infections occur worldwide and are responsible for a disease that has been known as *hemorrhagic fever with renal syndrome*, epidemic hemorrhagic fever, and nephropathia epidemica. Rodents are the main reservoir of the virus, and humans are probably infected by the airborne route. Besides fever, fatigue, and muscle aches (sever lumbar pain that is sometime interpreted as nephrolithiasis), which are observed in all patients, extrarenal symptoms often include headache, lightheadedness, abdominal pain, nausea and vomiting, and thrombocytopenia; the last can be responsible for hemorrhagic complications. AKI is almost always associated with proteinuria, sometimes in the nephrotic range, and with hematuria. Kidney biopsy is usually not required for the diagnosis but if performed reveals not only interstitial inflammatory infiltrates, which predominate in the medulla, but also vascular congestion and interstitial bleeding (Fig. 64.9). In 50% of patients, IF studies show granular immune deposits along the TBM and within glomeruli. Kidney function usually improves after a few days, and complete recovery is the rule. Nevertheless, in severe cases, recovery can be complicated by the occurrence of hemorrhagic complications or severe shock. The diagnosis is based on serologic test results, which become positive early (within weeks) in the course of the disease.

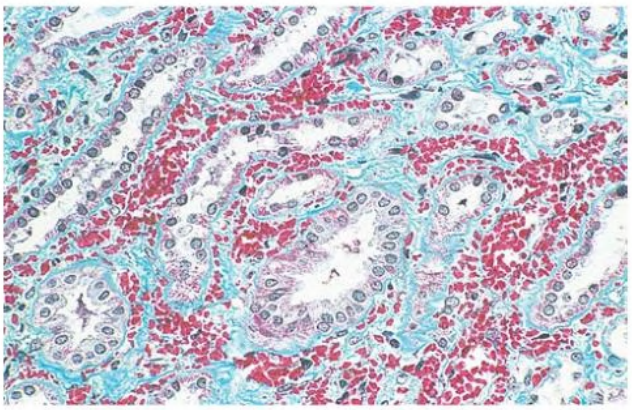

Fig. 64.9 Acute Interstitial Nephritis Secondary to Hantavirus Infection. Vascular congestion and foci of medullary hemorrhage are suggestive of the diagnosis. (Courtesy Dr. B. Mougenot, Paris VI University, Paris.)

Tubulointerstitial lesions are common in human immunodeficiency virus (HIV)-positive patients who undergo a kidney biopsy for

AKI. Interstitial infiltrates are often associated with glomerular lesions, but they can be isolated. These forms of AIN have been observed in both White and Black patients, and they might be related not only to drugs and opportunistic infections but also to the HIV infection itself.[23,24]

ACUTE INTERSTITIAL NEPHRITIS ASSOCIATED WITH SYSTEMIC DISEASES

Sarcoidosis

In sarcoidosis, reductions in the glomerular filtration rate (GFR) usually occur as a complication of hypercalciuria and hypercalcemia, but granulomatous AIN associated with sarcoidosis also may occur (Fig. 64.10).[25,26] The presentation is usually that of AKI, which can be isolated or associated with mild proteinuria and sterile leukocyturia. It is associated with extrarenal symptoms of sarcoidosis in about 90% of patients, most frequently with lymphadenopathy and lung, eye, or liver involvement. Nevertheless, only slightly more than half of the patients have hilar lymphadenopathy or pulmonary interstitial fibrosis at the time of diagnosis.[26] Treatment with high-dose corticosteroids quickly improves kidney function, but most patients do not recover completely. The starting dose should be prednisone 1 mg/kg/day and not higher than 60 mg/day, and corticosteroid therapy should be tapered slowly and not withdrawn before at least 1 year to prevent relapses. Whereas some authors advocate long-term maintenance therapy with low-dose corticosteroids, we usually stop corticosteroids after 2 to 3 years. Because of the risk for late relapse, these patients should be observed for a prolonged time.

Sjögren Syndrome

Clinically significant interstitial nephritis is rare in Sjögren syndrome and usually results in chronic tubular dysfunction.[27] Some patients may present with severe symptomatic hypokalemia with distal renal tubular acidosis. Rarely, Sjögren syndrome presents with AKI because of AIN, which is often responsive to treatment with high-dose corticosteroids.

Systemic Lupus Erythematosus

About two-thirds of kidney biopsy samples in patients with systemic lupus show tubulointerstitial involvement, but significant tubulointerstitial injury in the setting of minimal glomerular abnormalities is rare, with only about 10 cases reported in the literature.[28] In these cases, kidney biopsy shows typical features of AIN on light microscopy and IF staining always discloses immune deposits along the TBM, usually with a granular pattern. Kidney function improves after high-dose corticosteroids, and additional immunosuppressive drugs are not usually required. Azathioprine also has been used as a corticosteroid-sparing agent.

Immunoglobulin G4–Related Disease

IgG4-related disease is a newly recognized systemic autoimmune disease that predominantly affects men older than 50 years (see Chapter 65). In the kidney, it is most commonly responsible for AIN characterized by the presence of interstitial infiltrates rich in IgG4-positive plasma cells and immune deposits along the TBM.[29,30] This interstitial nephritis can be associated with membranous nephropathy, with kidney inflammatory masses visible on imaging, or with ureteral obstruction. It usually responds rapidly to treatment with corticosteroids.

Other Systemic Diseases

Among patients with cryoglobulinemia and AKI, a few exhibit significant interstitial inflammatory infiltrates associated with granular immune deposits in the interstitium and along the TBM. This AIN is usually associated with characteristic glomerular lesions and, rarely, lesions of the arterioles, and treatment is the same as for cryoglobulinemia-induced GN (see Chapter 26).

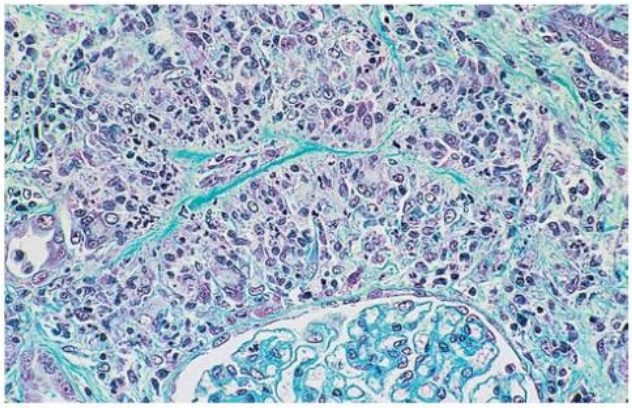

Fig. 64.10 Granulomatous acute interstitial nephritis in a patient with sarcoidosis. (Courtesy Dr. B. Mougenot, Paris VI University, Paris.)

Most kidney lesions associated with small-vessel vasculitis consist of both extracapillary GN and tubulointerstitial nephritis (see Chapter 26). Nevertheless, a few patients with AIN and minimal glomerular lesions have been described.

ACUTE INTERSTITIAL NEPHRITIS ASSOCIATED WITH MALIGNANCY

Infiltration of kidney parenchyma by malignant cells is common in patients with leukemia or lymphoma. Most of the time, this infiltration is clinically silent (or causes enlarged kidneys), but a few patients with AKI have been described.[31] Chemotherapy or radiotherapy may rapidly improve kidney function in these patients, but before these treatments are started, it is important to exclude more common causes of AKI associated with cancer (see Chapter 67).

IDIOPATHIC ACUTE INTERSTITIAL NEPHRITIS

More than 50 cases of idiopathic AIN with anterior uveitis have been reported (tubulointerstitial nephritis and uveitis [TINU] syndrome).[32] This syndrome is found most commonly in females of pubertal age but also can occur in pubertal males and in adults. Initial symptoms may be ocular, with ocular pain and visual impairment, or pseudoviral, with fever, myalgia, and asthenia. AIN is responsible for AKI, ranging from mild to severe, that may be associated with abnormal urinalysis. Kidney biopsy shows diffuse interstitial inflammatory infiltrates, almost always without granulomas and without immune deposits. In children, kidney prognosis is excellent, and serum creatinine usually returns to baseline values within a few weeks, with or without corticosteroid therapy. In adults the kidney prognosis seems to be less favorable, and corticosteroid therapy might be useful in preventing evolution to chronic kidney impairment. Uveitis, which can occur at any time in respect to AIN, is usually responsive to topical corticosteroids, but it may relapse without any recurrence of AIN.

Cases of idiopathic AIN without uveitis have been reported. IF studies of kidney biopsy specimens can show linear deposits of IgG along the TBM, granular deposits of IgG along the TBM, or no immune deposits, suggesting this entity is heterogeneous. The treatment of patients with idiopathic AIN is still controversial. Patients who receive corticosteroids usually show a dramatic improvement of kidney function, but others have recovered normal kidney function without any treatment.

ACUTE INTERSTITIAL NEPHRITIS IN KIDNEY TRANSPLANTS

Acute rejection is by far the most common cause of AIN in kidney allograft recipients (see Chapter 109). Nevertheless, AIN can be induced by drugs or infections. Cases of drug-induced AIN have been reported even in the first weeks after transplantation, when immunosuppression is maximal.[33] Among patients with infectious AIN, the frequency of polyomavirus-induced AIN appears to be increasing, and it should be suspected in patients with acute deterioration of kidney function and so-called decoy cells in urine (see Chapter 110).[34]

SELF-ASSESSMENT QUESTIONS

1. A 65-year-old man presents with unexplained AKI. A kidney biopsy shows the presence of diffuse inflammatory infiltrates within the interstitium, leading to the conclusion that the AKI is a result of AIN. He has a recent history of treatment with an NSAID and a PPI for osteoarthritis. Which one of the following statements is *correct?*
   - **A.** Both NSAIDs and PPIs are among the classes of drugs most commonly responsible for AIN.
   - **B.** Only very few cases of AIN have been attributed to treatment with a PPI, and the AIN was most likely induced by treatment with an NSAID.
   - **C.** Only very few cases of AIN have been attributed to treatment with an NSAID, and the AIN was most likely induced by treatment with a PPI.
   - **D.** Only very few cases of AIN have been attributed to treatment with a PPI or an NSAID, and the AIN is unlikely to have been induced by treatment with an NSAID or a PPI.
2. A 75-year-old woman presents with AKI associated with mild proteinuria (albumin-to-creatinine ratio 500 mg/g), microscopic hematuria, and pyuria. AKI developed while she was being treated with a fluoroquinolone, and her treating physician suspects that it was caused by AIN induced by the fluoroquinolone. Which one of the following statements is *correct?*
   - **A.** The patient should be tested for eosinophiluria. If less than 1% of urinary white blood cells are eosinophils, the diagnosis of AIN can almost certainly be ruled out.
   - **B.** The patient should undergo a kidney gallium scan. If there is no kidney uptake, the diagnosis of AIN can almost certainly be ruled out.
   - **C.** The presence of an elevated ratio of albumin to creatinine is sufficient to rule out the diagnosis of drug-induced AIN in a patient who previously did not have albuminuria and who has not been treated with an NSAID.
   - **D.** A kidney biopsy is the only test that can be performed to reliably rule out or confirm the diagnosis of AIN.
3. A 30-year-old woman develops AKI while being treated with penicillin. A kidney biopsy shows diffuse interstitial infiltrates, confirming the diagnosis of AIN. Her serum creatinine has been stable at 3.0 mg/dL for the last 5 days. Which one of the following statements is *correct?*
   - **A.** The prognosis for drug-induced AIN is excellent, and full recovery should be expected within 6 weeks after removal of the inciting agent.
   - **B.** The prognosis for drug-induced AIN is excellent in patients who do not have granulomas on renal biopsy, and full recovery should be expected.
   - **C.** The prognosis for drug-induced AIN is excellent in patients who do not require dialysis, and full recovery should be expected if serum creatinine does not continue to rise.
   - **D.** The course of drug-induced AIN is not always benign, and it leads to chronic kidney disease in at least 40% of cases.

Chronic Interstitial Nephritis

Tetsuhiro Tanaka, Masaomi Nangaku

DEFINITION

Chronic interstitial nephritis is a histologic entity characterized by progressive scarring of the tubulointerstitium, with tubular atrophy, macrophage and lymphocytic infiltration, and interstitial fibrosis. Because the degree of tubular damage accompanying interstitial nephritis is variable, the term *tubulointerstitial nephritis* is used interchangeably with *interstitial nephritis. Tubulitis* refers to infiltration of the tubular epithelium by leukocytes, usually lymphocytes.

There are many primary and secondary causes of chronic interstitial nephritis (Box 65.1). Tubulointerstitial injury is clinically important because it is a better predictor than the degree of glomerular injury of present and future renal function. Although any glomerular disease can cause secondary injury to the tubulointerstitium through the effects of proteinuria and ischemia, in this chapter we discuss only primary chronic interstitial nephritis.

PATHOGENESIS

The tubulointerstitium can be injured by toxins (e.g., heavy metals), drugs (e.g., analgesics), crystals (e.g., calcium phosphate, uric acid), infections, obstruction, immunologic mechanisms, and ischemia. Regardless of the initiating mechanism, the tubulointerstitial response shows little variation. Tubular injury results in the release of chemotactic substances and the expression of leukocyte adhesion molecules that attract inflammatory cells into the interstitium. Tubular cells express human leukocyte antigens, serve as antigen-presenting cells, and secrete complement components and vasoactive mediators, all of which may further stimulate or attract macrophages and T cells. Growth factors released by tubular cells and macrophages, such as platelet-derived growth factor and transforming growth factor β, may stimulate fibroblast proliferation and activation, leading to matrix accumulation.[1] The source of fibroblasts in renal interstitial fibrosis remains controversial but may include an intrinsic fibroblast (perivascular Gli1-positive progenitors) population, migration of circulating fibrocytes from perivascular areas, and phenotypic transition of pericytes into fibroblasts.[2] Over time, a loss of peritubular capillaries and decreased oxygen diffusion caused by expansion of the interstitium render the kidney hypoxic, and progressive apoptosis leads to local hypocellularity and fibrosis.[2] Kidney function can become severely decreased, and kidney replacement therapy may be required.

EPIDEMIOLOGY

Whereas chronic interstitial nephritis occurs with progressive kidney disease of all causes, primary chronic interstitial nephritis is not a common cause of end-stage kidney disease (ESKD); reports range from 42% in Scotland to 3% to 4% in China and the United States.[3–5] This variability in reported incidence may relate to differences in how diagnoses are made, exposure to causal factors, and treatment modalities, such as the choice of antibiotics and the indication for pain killers.

Marked increases in the incidence of chronic interstitial nephritis have been reported in certain areas. Chronic kidney disease of unknown etiology/uncertain cause (CKDu) is a type of CKD that mainly affects agricultural communities in specific areas of the world. These regional nephropathies include Sri Lanka and India, some coastal areas of Central America, and the Balkan region in Europe (see Chapters 66 and 79).

PATHOLOGY

The pathologic features of chronic interstitial nephritis are nonspecific. They include tubular cell atrophy or dilation; interstitial fibrosis that is composed of interstitial (types I and II) collagens; and mononuclear cell infiltration with macrophages, T cells, and occasionally other cell types (neutrophils, eosinophils, and plasma cells). Tubular lumina vary in diameter but may show marked dilation, with homogeneous casts producing a thyroid-like appearance, hence the term *thyroidization.*

Some forms of chronic interstitial nephritis are associated with granulomatous lesions. Whereas a noncaseating granulomatous pattern is typical of sarcoidosis, interstitial granulomatous reactions also occur in response to infection of the kidney by mycobacteria (Fig. 65.1), fungi, or bacteria; certain drugs (including rifampin, sulfonamides, proton pump inhibitors [PPIs], and narcotics); and oxalate or uric acid crystal deposition.[6] Interstitial granulomatous reactions have been noted in renal malacoplakia (Chapter 53), granulomatous polyangiitis, heroin abuse, and after jejunoileal bypass surgery. The etiology for granulomatous interstitial nephritis remains obscure in 10% of cases.

CLINICAL MANIFESTATIONS

The impaired kidney function is often insidious, and the early manifestations of the disease are those of tubular dysfunction, which may go undetected (Box 65.2).[7] Diagnosis is often made incidentally on routine laboratory screening or during evaluation of hypertension, in association with reduced glomerular filtration rate (GFR). Proteinuria is commonly less than 1 g/day. Urinalysis may show only occasional white blood cells (WBCs) and, rarely, WBC casts. Hematuria is uncommon. Anemia may occur relatively early because of dysfunction or loss of renal erythropoietin-producing cells in the interstitium.

The tubular dysfunction is often generalized, but some conditions may manifest with proximal tubular defects, including aminoaciduria, phosphaturia, proximal renal tubular acidosis (RTA), or, rarely, complete Fanconi syndrome (see Chapter 50). Distal tubular defects can be associated with distal RTA (type 1 or type 4; see Chapter 13).

BOX 65.1 Major Causes of Chronic Interstitial Nephritis[a]

Diseases in Which the Kidneys Are Macroscopically Normal

- Drugs and toxins (e.g., aristolochic acid, lithium, cyclosporine, tacrolimus, indinavir, cisplatin, proton pump inhibitors)
- Metabolic (hyperuricemia, hypokalemia, hypercalcemia, hyperoxaluria, cystinosis)
- Heavy metals (lead, cadmium, arsenic, mercury, gold, uranium)
- Radiation
- Balkan nephropathy
- Mesoamerican nephropathy
- Immune-mediated conditions (systemic lupus erythematosus, Sjögren syndrome, sarcoidosis, granulomatous polyangiitis, other vasculitides)
- Vascular diseases (atherosclerotic kidney disease) (see Chapter 43)
  - Transplantation (chronic transplant rejection)
  - Hematologic disturbances (multiple myeloma, light-chain deposition disease, lymphoma, sickle cell disease, paroxysmal nocturnal hemoglobinuria) (see Chapters 51 and 68)
- Progressive glomerular disease of any cause (glomerulonephritides, diabetes, hypertension)
- Idiopathic

Diseases in Which the Kidneys Are Macroscopically Abnormal

- Analgesic nephropathy
- Chronic obstruction (see Chapter 61)
- Hereditary (nephronophthisis, medullary cystic kidney disease, familial juvenile hyperuricemic nephropathy, autosomal dominant polycystic kidney disease, autosomal recessive polycystic kidney disease)
- Infection (chronic pyelonephritis, malacoplakia, xanthogranulomatous pyelonephritis; see Chapter 53)

[a] Kidneys of any clinical entity can be shrunken at end-stage. Some diseases categorized as macroscopically normal can, in later stages, result in macroscopically abnormal kidneys. For example, kidneys of sickle cell nephropathy are macroscopically normal unless papillary necrosis is present.

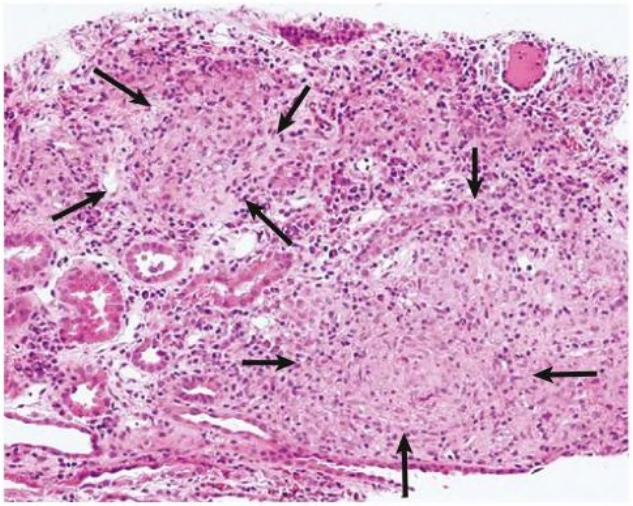

Fig. 65.1 Renal Tuberculosis. Noncaseating granulomas with epithelioid cells in miliary tuberculosis (*arrows* show the peripheries of the granulomas). Although the typical pathologic change is granuloma with caseous necrosis with Langerhans-type giant cells, these atypical granulomas can be observed in tuberculosis and should be differentiated from sarcoidosis. BOX 65.2 Functional Manifestations of Chronic Interstitial Nephritis

- Deterioration of glomerular filtration rate with insidious onset
- Tubular proteinuria mainly composed of low-molecular-weight protein (generally <1 g/day)
- Inactive urinary sediment
- Anemia of chronic kidney disease at a relatively early stage
- Proximal tubular dysfunction (aminoaciduria, phosphaturia, proximal renal tubular acidosis, Fanconi syndrome)
- Distal tubular dysfunction (type IV renal tubular acidosis)
- Medullary dysfunction (concentrating defects)
- Salt-wasting syndrome
- Salt-sensitive hypertension

Concentrating defects (increased urinary frequency and nocturia) can be a sign of medullary dysfunction and may be severe enough to result in nephrogenic diabetes insipidus. Some patients develop a salt-wasting syndrome. Others, particularly with microvascular disease, may have a relative inability to excrete salt with resultant salt-sensitive hypertension.[8]

Clues to the causes of tubulointerstitial nephritis by history and physical examination are shown in Table 65.1.[9]

TREATMENT

Treatment includes identification and elimination of any exogenous agents (drugs, heavy metals), metabolic causes (hypercalcemia), or conditions (obstruction, infection) potentially causing the chronic interstitial lesion. In addition to classic drugs and toxins, a growing list of medications (e.g., PPIs) is now being linked to the risk for developing CKD, which emphasizes the need to consider the risk and benefit of any drug carefully, particularly in patients with a progressive course. Specific treatments may be required for an underlying cause of chronic interstitial nephritis, such as corticosteroids for sarcoidosis. General measures include control of blood pressure. Most clinicians favor the use of angiotensin-converting enzyme (ACE) inhibitors or angiotensin receptor blockers (ARBs), which reduce glomerular and systemic pressures, decrease proteinuria, and increase renal blood flow. However, the role of ACE inhibitors and ARBs is less clear when blood pressure is normal or when there are excessive solute losses (such as salt-wasting). Specific therapies for each clinical entity are discussed later.

DRUG-INDUCED CHRONIC INTERSTITIAL NEPHRITIS

Several drugs and herbs can cause chronic interstitial nephritis. Cyclosporine- and tacrolimus-induced nephropathy are discussed in Chapter 106; aristolochic acid as a cause of aristolochic acid–associated nephropathy (formerly known as *Chinese herbs nephropathy* and *Balkan nephropathy*) is discussed in Chapter 79.

Lithium Nephropathy

Definition and Epidemiology

Lithium is commonly used in the treatment of bipolar disorder. Complications of lithium treatment include nephrogenic diabetes insipidus, acute lithium intoxication, and chronic lithium nephrotoxicity. A meta-analysis of the data of 14 studies involving 1172 patients receiving chronic lithium therapy showed that the prevalence of reduced GFR was 15%.[10]

TABLE 65.1 Clues to Causes of Tubulointerstitial Nephritis by History and Physical Examination

Feature	Symptom, Sign, or Historical Clue	Potential Diagnosis
Occupational history	Exposure to heavy metals (e.g., batteries, alloys)	Lead or cadmium nephropathy
Alcohol	History of moonshine ingestion	Lead nephropathy
Social history	Country of origin	Balkan nephropathy
Past history	Systemic lupus erythematosus	Disease-associated chronic interstitial nephritis
	Sjögren syndrome	
	Sarcoidosis	
	Inflammatory bowel disease	
	Autoimmune pancreatitis	
	Chronic pain syndrome	Analgesic nephropathy
	Gouty attack	Lead nephropathy
Medication	Prescribed	Drug-induced chronic interstitial nephritis
	OTC (NSAIDs, PPIs)	Analgesic
	Herbal	Aristolochic acid-associated nephropathy
	Indinavir	Crystal nephropathy
Physical examination	Dry eyes	Sjögren syndrome
	Uveitis	TINU syndrome
Laboratory examination	Hyperuricemia	Chronic uric acid nephropathy
	Hypokalemia	Hypokalemic nephropathy
	Hypercalcemia	Hypercalcemic nephropathy
	High serum IgG4 levels	IgG4-related sclerosing disease
Radiologic examination	Decreased volume, bumpy contours, and papillary calcification on CT	Analgesic nephropathy
	Microcysts on MRI or ultrasound	Lithium nephropathy
	Nephrocalcinosis on CT	Hypercalcemic nephropathy

CT, Computed tomography; *IgG,* immunoglobulin G; *MRI,* magnetic resonance imaging; *NSAIDs,* nonsteroidal antiinflammatory drugs; *OTC,* over the counter; *PPIs,* proton pump inhibitors; *TINU,* tubulointerstitial nephritis and uveitis.
Modified from Beck LH Jr, Salant DJ. Glomerular and tubulointerstitial diseases. *Prim Care*. 2008;35:265–296.

Pathogenesis

Diabetes insipidus results from accumulation of lithium in the collecting tubular cells after entry into these cells through sodium channels in the luminal membrane. Lithium blocks vasopressin-induced reabsorption by inhibiting adenylate cyclase activity, and hence cyclic adenosine monophosphate production, and also by decreasing the apical membrane expression of aquaporin 2, the collecting tubule water channel. Chronic lithium-induced interstitial nephritis may occur, possibly because of inositol depletion and inhibition of cell proliferation.

Pathology

Biopsies show focal chronic interstitial nephritis with interstitial fibrosis, tubular atrophy, and glomerulosclerosis. Although similar histologic changes have been reported in psychiatric patients without a history of lithium therapy, patients with lithium exposure often show microcystic changes in the distal tubule; interstitial inflammation and vascular changes are relatively minor. The degree of interstitial fibrosis is related to the duration of administration and cumulative dose.

Clinical Manifestations

Lithium-associated diabetes insipidus. The most common presentation of lithium-induced nephrotoxicity is nephrogenic diabetes insipidus, characterized by resistance to vasopressin, polyuria, and polydipsia. Impaired urinary concentrating ability is found in about 50% of patients, and polyuria resulting from nephrogenic diabetes insipidus occurs in about 20% of patients chronically treated with lithium.

Lithium is also rarely a cause of hypercalcemia, which could potentially exaggerate the tubular concentrating defect and contribute to the development of chronic interstitial nephritis in lithium-treated patients. Nephrogenic diabetes insipidus in lithium treatment may be associated with distal RTA, although this partial functional defect is virtually never of clinical importance.

Chronic lithium nephropathy. In a retrospective analysis of data from the United Kingdom, the presence of lithium in serum was associated with an increased risk for stage 3 CKD (hazard ratio 1.93), with females aged younger than 60 years and those with lithium concentrations higher than median at increased risk.[11] Nephrogenic diabetes insipidus induced by lithium may persist despite the cessation of treatment, indicating irreversible renal damage.

In one study, the mean serum creatinine concentration of patients with biopsy-proven chronic lithium nephrotoxicity was 2.8 mg/dL (247 μmol/L) at the time of biopsy, and 42% of patients had proteinuria greater than 1 g/day.[12] After kidney biopsy, all but one patient discontinued treatment with lithium, but seven patients nevertheless progressed to ESKD. A study of 74 lithium-treated patients in France showed that lithium-induced nephropathy developed slowly over several decades, with an average latency between the start of therapy and ESKD of 20 years.[11]

Magnetic resonance imaging, in particular the half-Fourier acquisition single-short turbo spin-echo T2-weighted sequence, without the use of gadolinium, or ultrasound may help in detection of the characteristic microcysts in the kidney.[13]

Treatment

After other potential causes of polyuria and polydipsia have been excluded, particularly psychogenic polydipsia, the first step to consider

is a reduction in lithium dosage. The potassium-sparing diuretic amiloride improves the polyuria and also blocks lithium uptake through sodium channels in the collecting duct. Thiazide diuretics should be avoided because they increase the risk for acute lithium intoxication because of the resultant volume contraction and an increase in sodium and lithium reabsorption in the proximal tubule. ACE inhibitors are generally not used because of the risk for hypotension and worsening GFR in the setting of volume depletion.

Patients undergoing long-term lithium treatment should have kidney function (serum creatinine and estimated GFR) and 24-hour urine volume measured yearly. Lithium has a narrow therapeutic index, so levels should be monitored and maintained between 0.6 and 1.25 mmol/L. The severity of chronic lithium intoxication correlates directly with the serum lithium concentration and may be categorized as mild (1.5–2.0 mmol/L), moderate (2.0–2.5 mmol/L), or severe (>2.5 mmol/L). Once-daily regimens are less toxic than multiple daily administration schedules, perhaps because of the possibility of renal tubular regeneration with a once-daily administration schedule.[14] Prevention of volume depletion is also important.

Because progressive kidney injury with reduced GFR in patients without prior acute lithium intoxication is relatively unusual, reductions in GFR initially should be treated by decreasing the dose of lithium. If GFR is persistently reduced, a kidney biopsy should be considered, although the findings rarely mandate the cessation of lithium treatment. At all times, the risk for discontinuation in a patient with a severe unipolar or bipolar affective disorder needs to be balanced against the relatively low risk for progressive kidney injury.

Analgesic Nephropathy

Definition and Epidemiology

Analgesic nephropathy resulted from the abuse of analgesics, commonly mixtures containing phenacetin, aspirin, and caffeine, that were available as over-the-counter preparations in Europe and Australia. It is now extremely rare; indeed, some doubt that new cases are still presenting, after restrictions in compound analgesic sales.[15] A large study in the United States showed no association between use of current analgesic preparations and increased risk for chronic kidney dysfunction,[16] although it does increase the risk for acute kidney injury (see Chapter 70).

Pathogenesis and Pathology

The primary injury in analgesic nephropathy is medullary ischemia caused by toxic concentrations of phenacetin metabolites combined with relative medullary hypoxia, aggravated by inhibition of vasodilatory prostaglandin synthesis and glutathione (an antioxidant) levels. The main pathologic consequence is papillary necrosis, with secondary tubular atrophy, interstitial fibrosis, and a mononuclear cellular infiltrate (Fig. 65.2).

Clinical Manifestations

Analgesic nephropathy is five to seven times more common in females than in males. Kidney manifestations are nonspecific and consist of slowly progressive CKD with impaired urine concentrating ability, urinary acidification defects, and impaired sodium conservation. Patients may present with hypertension, reflecting the use of nonsteroidal anti-inflammatory drugs (NSAIDs), and degree of kidney parenchymal injury. Urinalysis shows sterile pyuria and mild proteinuria. Patients with analgesic nephropathy are at increased risk for transitional cell carcinoma of the uroepithelium. A recent prospective analysis of the Nurses' Health Study and the Health Professionals Follow-up Study also showed an association of regular use of nonaspirin NSAIDs with an increased risk of renal cell carcinoma, but aspirin and acetaminophen use were not implicated.[17]

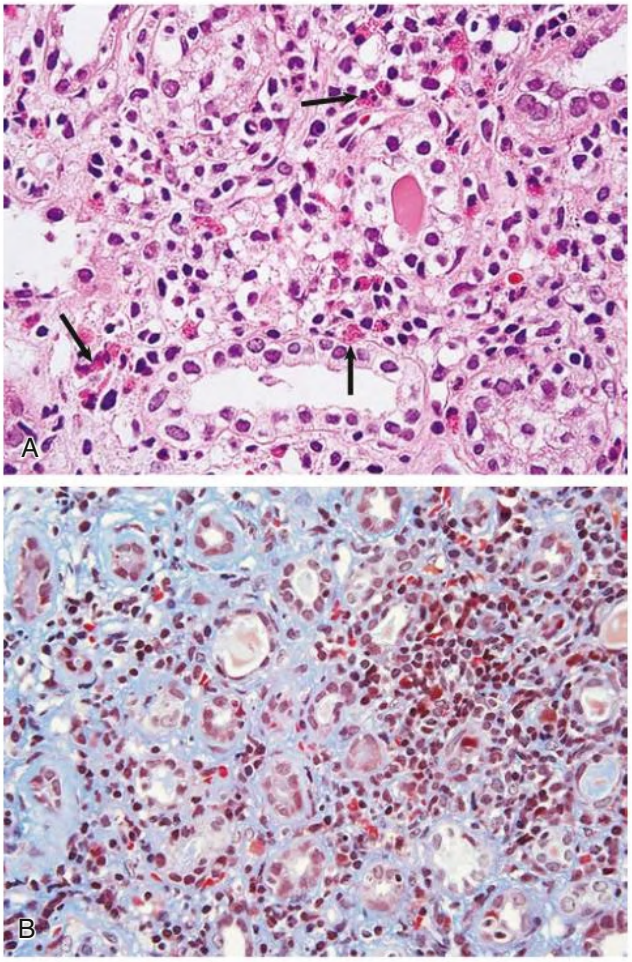

Fig. 65.2 Histologic Changes in Analgesic Nephropathy. (A) Interstitial nephritis in a patient with analgesic nephropathy associated with marked mononuclear cellular infiltrate including eosinophils *(arrows).* (H&E stain; original magnification ×600.) (B) Analgesic nephropathy with interstitial fibrosis and inflammatory cell infiltration. (Masson trichrome stain; original magnification ×400.) (Courtesy Drs. Akira Shimizu and Hideki Takano, Nippon Medical School, Tokyo.)

Diagnosis

Papillary necrosis is present histologically in almost all patients, but it can be detected radiologically only if part or all of the papilla has sloughed. Papillary necrosis is not pathognomonic of analgesic nephropathy; it is also seen in diabetic nephropathy (particularly during an episode of acute pyelonephritis), sickle cell nephropathy, urinary tract obstruction, and renal tuberculosis. Non–contrast-enhanced computed tomography (CT) demonstrates a decrease in renal mass with either bumpy contours or papillary calcifications (Fig. 65.3; see also Chapter 51).[18]

Treatment

Management consists of stopping or at least reducing the intake of analgesic medications. Because of the increased incidence of uroepithelial tumors, close follow-up, including regular urinalysis, is necessary. New hematuria requires early referral for urologic evaluation, which includes urinary cytology, cystoscopy, and CT scan. It would be prudent to perform yearly urinary cytologic examination at least several years after cessation of analgesics.

Analgesic nephropathy associated with over-the-counter medicines is also discussed in Chapter 79.

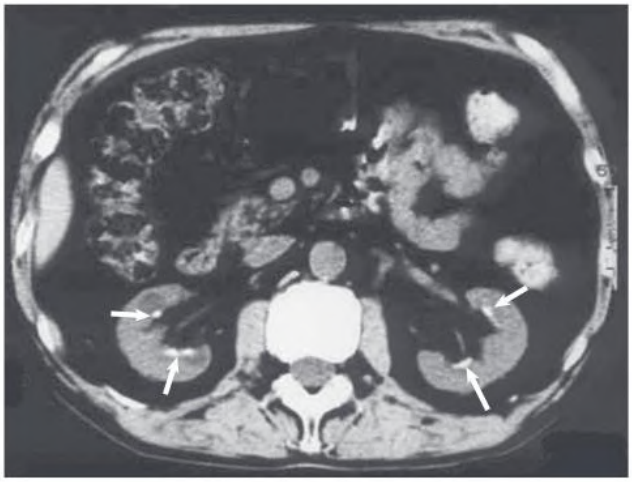

Fig. 65.3 Papillary Calcifications in Analgesic Nephropathy. Non–contrast-enhanced computed tomography scan of a patient with long-time analgesic abuse shows thinning of the renal parenchyma and typical papillary calcifications *(arrows)*. (Courtesy Dr. Yoshifumi Ubara, Toranomon Hospital, Tokyo.)

CHRONIC INTERSTITIAL NEPHRITIS CAUSED BY METABOLIC DISORDERS

Metabolic disorders that cause interstitial nephritis are discussed here. Hyperoxaluria is described in Chapter 60 and cystinosis in Chapter 50.

Chronic Uric Acid Nephropathy

Definition and Epidemiology

Nearly half of patients with gout have reduced GFR, and most have evidence for CKD at autopsy. An elevated serum uric acid has also been consistently shown to predict the development of CKD.[19] This has led many investigators to propose that hyperuricemia and/or gout may be a cause of CKD,[20] either from the deposition of urate crystals in the kidney or from effects of soluble uric acid to active inflammatory processes. Nevertheless, two recent clinical trials of urate-lowering therapy in subjects with CKD were negative, challenging whether chronic uric acid nephropathy exists.[21,22]

Pathogenesis

Chronic gout and severe hyperuricemia can be associated with the deposition of uric acid crystals in the renal medulla (Fig. 65.4). A recent study suggests this may be present in as many as a third of subjects with gout and that it can be diagnosed by ultrasound findings of a hyperechoic renal medulla.[23] The deposition of urate crystals can cause injury to the tubules and rupture into the interstitium where they cause inflammasome activation with inflammation and fibrosis. Experimental studies also suggest that high levels of soluble uric acid may also cause chronic kidney injury by activating the renin-angiotensin system and inducing oxidative stress, resulting in microvascular disease, glomerular hypertension, and impaired renal autoregulation.[24]

Pathology

Renal functional abnormalities are observed in 30% to 50% of patients who have had gout for many years, and histologic changes are observed in more than 90%.[25] The most consistent histologic findings are arteriolosclerosis, focal or global glomerulosclerosis, and chronic tubulointerstitial disease. Uric acid crystals also can be occasionally found within tubules and in the interstitium (see Fig. 65.4), especially in the outer medulla, and, on rare occasions, medullary kidney tophi can be found on gross anatomic dissection.

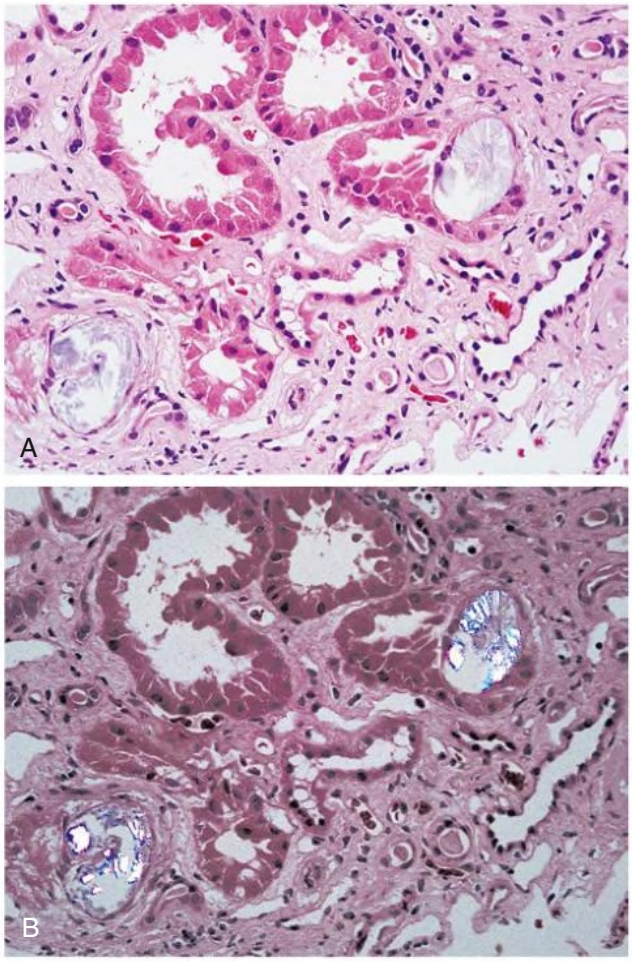

Fig. 65.4 Chronic Uric Acid Nephropathy. (A) Large collections of elongated or fragmented uric acid crystals are present in association with atrophic tubules. (H&E stain; original magnification ×400.) (B) The crystalline masses are refractile under polarized light. (Courtesy Drs. Akira Shimizu and Hideki Takano, Nippon Medical School, Tokyo.)

Clinical Manifestations

Patients with gout often present with hypertension with mildly impaired kidney function, mild proteinuria, unremarkable urinary sediment, and minor tubular dysfunction (usually impairment of urine-concentrating ability manifested as isosthenuria). Approximately one-third of subjects with CKD also have a history of gout, and nearly 50% have hyperuricemia. A role for uric acid in CKD should particularly be considered if there is a disproportionate elevation in serum uric acid in relation to the degree of GFR reduction (Table 65.2).[26]

Diagnosis

The most important differential diagnosis for chronic uric acid nephropathy is chronic lead nephropathy. Familial juvenile hyperuricemic nephropathy is a rare autosomal dominant disease that mimics chronic gouty nephropathy but manifests in adolescence or during early childhood (see Chapter 50).

Treatment

It remains controversial whether lowering uric acid can improve kidney disease in patients with gout or hyperuricemia. One randomized trial

TABLE 65.2 Serum Creatinine and Uric Acid Levels in Chronic Kidney Disease

SERUM CREATININE		SERUM URIC ACID	
mg/dL	µmol/L	mg/dL	µmol/L
<1.5	<132	9	536
1.5–2.0	132–176	10	595
>2.0	>176	12	714

Serum uric acid levels are increased with decreased glomerular filtration rate, but if uric acid levels are especially high for the level of creatinine, then chronic urate nephropathy should be considered. Shown are threshold levels of uric acid for which higher levels should increase the suspicion for chronic urate nephropathy.
Modified from Badve SV, Pascoe EM, Tiku A, et al.; CKD-FIX Study Investigators. Effects of allopurinol on the progression of chronic kidney disease. *N Engl J Med.* 2020;382:2504–2513.

demonstrated that allopurinol therapy is associated with preservation of eGFR in CKD, although the treatment did not show any effects on the defined study endpoint, which was ESKD.[27] Withdrawal of allopurinol from patients with stable CKD has resulted in worsening of hypertension and acceleration of kidney dysfunction, especially in patients who were not on ACE inhibitors.[28] Lowering uric acid in patients with asymptomatic hyperuricemia is also associated with an increase in eGFR.[29] There also have been reports that lowering uric acid may reduce the risk for cardiovascular disease in patients with CKD.[27,30] Recently, two placebo-controlled randomized trials did not find lowering uric acid to be of benefit in subjects with type 1 diabetes and CKD (the PERL study)[21] and in subjects with CKD (CKD-Fix Trial).[22] However, both studies recruited subjects with normal uric acid levels in which benefit was not expected, and both excluded subjects with a history of gout, which was the group most expected to benefit.

We still recommend lowering uric acid in subjects with CKD who have markedly elevated serum uric acid levels (>8–9 mg/dL) or a history of gout with evidence of active progression of CKD. To reduce the risk for a hypersensitivity reaction (Stevens-Johnson–like syndrome), allopurinol should be initiated at a dose of 50 to 100 mg/day, increasing to 200 or 300 mg/day after several weeks as tolerated. The allopurinol hypersensitivity syndrome is more common in subjects who carry HLA-*B58:01, and typing subjects before initiation of treatment may be of benefit in subjects who are Han Chinese or Korean that are more likely to carry this HLA antigen.

The newer xanthine oxidase inhibitor febuxostat does not require modification of dose at lower eGFR and appears to be less frequently associated with hypersensitivity or nephrotoxicity, but there are some studies that suggest that its use may be associated with greater cardiovascular mortality than that observed with allopurinol.[31]

Hypokalemic Nephropathy

Definition and Epidemiology

Hypokalemia, if persistent for prolonged periods, can induce kidney cysts, chronic interstitial nephritis, and progressive loss of kidney function, known as *hypokalemic nephropathy,* which can be inherited or acquired. Hypokalemic nephropathy occurs in 15% to 20% of individuals with anorexia nervosa.[32]

Pathology

The characteristic finding is vacuolation of the kidney tubules as a result of dilation of cisternae of the endoplasmic reticulum and basal folding, which is usually limited to the proximal tubular segments

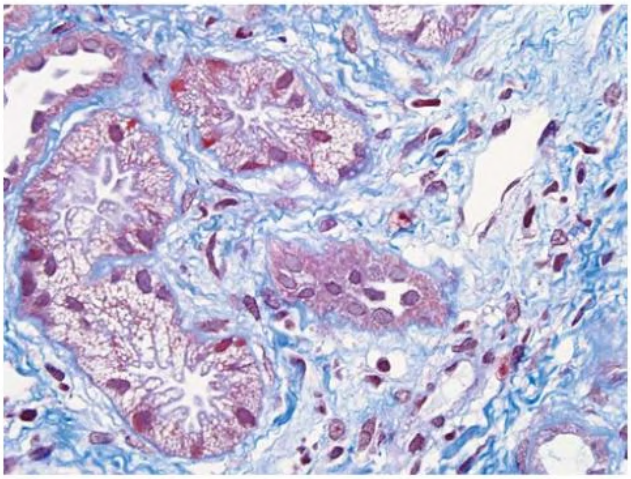

Fig. 65.5 Hypokalemic Nephropathy. Vacuolization of the renal tubules is observed in association with interstitial fibrosis in a patient with hypokalemic nephropathy. (Masson trichrome stain; original magnification ×400.) (Courtesy Drs. Akira Shimizu and Hideki Takano, Nippon Medical School, Tokyo.)

(Fig. 65.5). This abnormality generally requires at least 1 month to develop and is reversible with potassium supplementation. More prolonged hypokalemia can lead to more severe changes, predominantly in the kidney medulla, including interstitial fibrosis, tubular atrophy, and cyst formation. There is experimental evidence that hypokalemic injury may be caused by hypokalemia-induced renal vasoconstriction with ischemia. Local ammonia production stimulated by hypokalemia also may lead to intrarenal complement activation that may contribute to the kidney injury. Furthermore, the associated intracellular acidosis can stimulate cell proliferation, which may account for the occasional development of cysts in hypokalemic patients.

Clinical Manifestations

Impaired urinary concentration, manifesting with nocturia, polyuria, and polydipsia, may occur, particularly when serum potassium concentration is consistently below 3.0 mmol/L for months or years. The average duration of hypokalemia reported in patients with chronic hypokalemic nephropathy is 3.5 to 9 years. The renal defect is associated with decreased collecting tubule responsiveness to vasopressin, possibly because of decreased expression of aquaporin 2.

Diagnosis

Although degenerative changes in proximal tubular cells are a consistent but nonspecific finding in hypokalemic nephropathy, a particularly characteristic finding is vacuolar changes in the proximal tubules (see Fig. 65.5). Similar vacuolization of the convoluted tubules is observed in ethylene glycol poisoning.

Treatment

Hypokalemia usually can be treated with oral potassium supplements. The treatment of hypokalemia is discussed in Chapter 10. Coarse cytoplasmic vacuoles may persist for some time after normalization of serum potassium values.

Hypercalcemic Nephropathy

Definition and Epidemiology

Hypercalcemia can cause transient and reversible kidney vasoconstriction with a decrement in kidney function and chronic interstitial nephritis secondary to tubular cell necrosis and intratubular

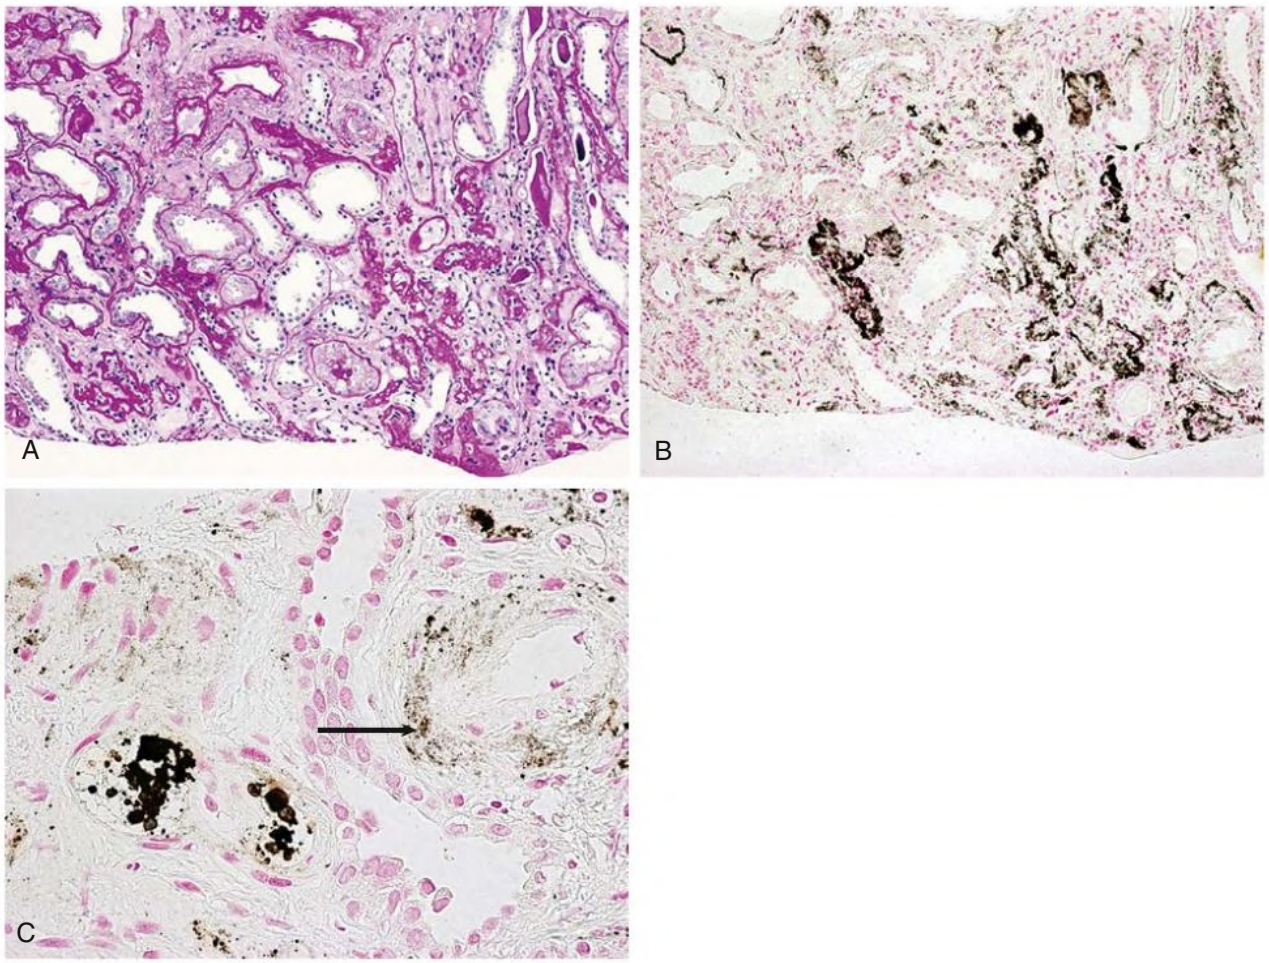

Fig. 65.6 Hypercalcemic Nephropathy Caused by Sarcoidosis. (A) Marked tubular atrophy and interstitial fibrosis with mild lymphocytic infiltrate. (B) Dense calcium deposits are seen in the thickened basement membrane of the atrophic tubules and in the fibrotic area of interstitium (serial section of A). (C) Intraluminal calcium plaque in the atrophic tubules. Granular calcium deposits are observed in the arterial wall *(arrow)*. (A, PAS stain. B–C, von Kossa stain.) (Courtesy Dr. Noriko Uesugi, Ibaraki, Japan.)

obstruction. In addition, hypoparathyroidism (especially after surgical treatment of hyperparathyroidism) can result in marked hypercalciuria and a similar syndrome in the absence of hypercalcemia.

Pathology

Focal degeneration and necrosis of the tubular epithelium, primarily in the medulla, where calcium is concentrated, develop soon with persistent hypercalcemia. Although focal degenerative and necrotic lesions of the tubular epithelium can be observed with acute hypercalcemia, the most distinctive histologic feature of long-standing hypercalcemia is calcific deposits in the interstitium (nephrocalcinosis; Fig. 65.6). Deposition begins in the medullary tubules, followed by deposition in the cortical proximal and distal tubules and within the interstitial space and secondarily leads to mononuclear cell infiltration and tubular necrosis.

Clinical Manifestations

Macroscopic nephrocalcinosis is often detected on radiography or ultrasound. A defect in urinary concentration is the most notable tubular dysfunction and manifests as polyuria and polydipsia. The mechanism is incompletely understood, but the impairment relates both to a reduction in medullary solute content and to interference with the cellular response to vasopressin. Reversible impairment of eGFR can result from either acute or chronic hypercalcemia by decreased renal blood flow. Irreversible, advanced CKD is a rare consequence of long-standing hypercalcemia and is almost invariably associated with calcium crystal deposition in the interstitium of the kidney.

CHRONIC INTERSTITIAL NEPHRITIS CAUSED BY HEREDITARY DISEASES OF THE KIDNEY

Nephronophthisis (NPHP) and medullary cystic kidney disease (MCKD), or autosomal dominant tubulointerstitial kidney disease (ADTKD) (or the NPHP-MCKD complex) are hereditary diseases associated with renal cysts at the corticomedullary junction. Karyomegalic interstitial nephritis is a hereditary form of chronic tubulointerstitial nephritis histologically characterized by nuclear enlargement with irregular outlines, hyperchromatic aspect, and prominent nucleoli. These disorders are described in detail in Chapters 47 and 50.

CHRONIC INTERSTITIAL NEPHRITIS ASSOCIATED WITH HEAVY METAL EXPOSURE

Lead Nephropathy

Definition and Epidemiology

Acute lead intoxication is rare but may manifest with abdominal pain, encephalopathy, hemolytic anemia, peripheral neuropathy,

and proximal tubular dysfunction (Fanconi syndrome). In contrast, chronic low-level exposure to lead is associated with CKD, often with hyperuricemia. Because lead has a biologic half-life of several decades, both intermittent acute poisoning and low-level environmental exposure result in chronic cumulative lead poisoning.

Although some epidemiologic studies have suggested that low-level exposure may be associated with CKD or hypertension,[33–35] data indicating that lead causes CKD and ESKD are relatively sparse,[36] although there may be regional differences in the observed risk because of geographic variation in exposure. The pathogenesis of the kidney disease may be related to the accumulation of reabsorbed lead in the proximal tubule cells, effects of chronic lead exposure on the vasculature, or lead-induced hyperuricemia. Additional well-controlled longitudinal studies with adequate exposure and effect variables are awaited to confirm that lead exposure causes deterioration of renal function and eventual ESKD.

Pathology

The kidneys are granular and contracted. The characteristic morphology is chronic interstitial nephritis demonstrating nonspecific tubular atrophy, interstitial fibrosis, and a paucity of inflammatory cells. The earliest histologic finding is proximal tubular injury, with intranuclear inclusion bodies composed of a lead-protein complex. Glomerular scarring can be observed as a secondary event, and arteries and arterioles demonstrate medial thickening and luminal narrowing, probably related to hypertension. Immunofluorescence (IF) studies are noncontributory.

Clinical Manifestations

Chronic lead nephropathy is usually identified when a source of high exposure is known (occupational hazard or consumption of illicitly distilled spirits [moonshine]). Hyperuricemia is common because of impaired uric acid excretion. Urine sediment is benign, and urinary protein excretion is less than 2 g/day. Hypertension is almost always present, and in the absence of appropriate testing or a careful exposure history, lead nephropathy is often misdiagnosed as hypertensive kidney disease. Gouty arthritis ("saturnine gout") affects about half of patients. Patients with chronic lead intoxication may occasionally manifest other signs, including peripheral motor neuropathy, anemia with basophilic stippling, and perivascular cerebellar calcification.

Diagnosis

Lead nephropathy may be underdiagnosed because no simple diagnostic blood test is available. Lead nephropathy is easily confused with chronic uric acid nephropathy, in which uric acid deposits (tophi) may form in the renal interstitium. All patients with hyperuricemia and reduced eGFR should have a history of occupational lead exposure excluded. The blood lead concentration is an insensitive measure of cumulative body stores. A clinical diagnosis of lead nephropathy is based on a history of exposure, evidence of kidney dysfunction, and an abnormal calcium disodium edetate ($CaNa_2$ EDTA) lead chelation test. The association with gout and CKD is strong enough to merit lead chelation testing in patients with CKD who have gout and risk for lead exposure. $CaNa_2$ EDTA is administered (2 doses of 0.5 g in 250 mL 5% dextrose given 12 hours apart), and urine is collected for 3 days because urinary excretion is slower when eGFR is reduced. Normal urinary lead levels are less than 650 μg/3 days. x-Ray fluorescence, which provokes the emission of fluorescent photons from the target area, is an alternative method that detects increased bone lead levels, which are also a reflection of cumulative lead exposure. Although x-ray fluorescence measurements allow a rapid, noninvasive estimation of lead in bone, detection equipment is available at only a small number of centers.

Treatment

Treatment involves infusions of $CaNa_2$ EDTA together with removal of the source of lead. The likelihood of a satisfactory response to $CaNa_2$ EDTA is influenced by the degree of interstitial fibrosis that has already occurred.

In industrial and occupational settings, such as in foundry workers and individuals working with lead-based paints and glazes, preventive measures to minimize exposure and low-level absorption are essential. Some studies in children show success with the oral chelating agent succimer (Chemet). Chelation therapy may slow progressive CKD, even in patients with mild lead intoxication.[37] However, chelation therapy has not been widely used because of adverse drug effects and concerns about the effects of remobilized lead. It is generally not indicated for adults with blood lead concentrations of less than 45 μg/dL. Because of a lack of clinical trials demonstrating the efficacy and safety of chelation, recommendations for treatment with chelating agents are empiric and may be controversial.

Other Heavy Metal–Induced Nephropathies

Cadmium is a metal with a wide variety of industrial uses, including the manufacture of glass, metal alloys, and electrical equipment. Cadmium is preferentially concentrated in the kidney, principally in the proximal tubule, in the form of a cadmium-metallothionein complex that has a biologic half-life of about 10 years. Cadmium contamination may be an important contributor to the high risk for chronic interstitial nephritis in some agricultural communities in the developing world. A major outbreak of cadmium toxicity occurred in Japan as a result of industrial contamination. The disease was called *itai-itai,* or "ouch-ouch," because bone pain was the major clinical manifestation. Other manifestations included proximal tubular dysfunction (Fanconi syndrome), hyperphosphaturia, and vitamin D–resistant rickets with osteomalacia. The mechanism by which cadmium elicits chronic inflammation and fibrosis in the kidney is relatively unstudied. The diagnosis is suggested by a history of occupational exposure, increased urinary β_2-microglobulin, and increased urinary cadmium levels (>7 μg of cadmium per 1 gram of creatinine). Once manifested, kidney injury tends to be progressive, even if exposure is discontinued. Chelation is not effective in humans, and prevention is the only effective treatment.

Arsenic, used as a poison gas in World War I, is present in insecticides, weed killers, wallpaper, and paints. Chronic arsenic toxicity from inorganic arsenic most commonly manifests as sensory and motor neuropathies, distal extremity hyperkeratosis, palmar desquamation, diarrhea and nausea, Aldrich-Mees lines (white bands on the nails), and anemia. In rare cases, it may cause kidney disease, manifested by proximal RTA and chronic interstitial fibrosis. Diagnosis is made by demonstration of an elevated urinary inorganic arsenic level.[38]

Mercury is found in alloy plants, mirror plants, and some batteries, and mercury intoxication usually occurs as a result of accidental exposure to mercury vapor. Mercury has been shown to induce membranous nephropathy (MN) in experimental animals and has been reported with the use of mercury-containing skin-lightening creams.[39] Neither elemental mercury nor the mercurous salt (Hg_2Cl_2) produces sustained renal tubular injury, but mercury dichloride ($HgCl_2$) may produce acute tubular necrosis and subsequent chronic interstitial nephritis in laboratory animals. However, a report of endemic methyl mercury poisoning in Japan (Minamata disease) revealed a clinical picture dominated by neurologic sequelae; kidney disease in these patients was surprisingly benign, consisting only of tubular proteinuria without changes in serum creatinine.

RADIATION NEPHRITIS

Definition and Epidemiology

Although radiation nephritis was relatively common decades ago, the incidence has decreased considerably because recognition of radiation-induced renal damage has altered protocols for the administration of therapeutic radiation. In general, direct exposure of the kidney to 20 to 30 Gy (1 Gy = 100 rad) over 5 weeks or less will produce radiation nephritis.

Pathology

In general, vascular and glomerular lesions of thrombotic microangiopathy may predominate. The initial target of ionizing radiation within the kidney appears to be endothelial cells, leading to endothelial cell swelling. Electron microscopy (EM) reveals a split appearance of the capillary wall caused by the mesangial interposition and widening of the subendothelial space by a nondescript fluffy material. These features are shared by hemolytic uremic syndrome and thrombotic thrombocytopenic purpura, suggesting a common pathogenic mechanism originating from endothelial injury. However, tubulointerstitial changes are also usually present. Vascular occlusion leads to tubular atrophy, and severe disease is characterized by progressive interstitial fibrosis and the presence of interstitial inflammatory cells.

Clinical Manifestations

Hypertension is commonly observed. Progression to a chronic form of radiation nephritis may occur if resolution of acute radiation nephritis is incomplete. These patients present with proteinuria, progressive CKD, and eventual development of ESKD several years after irradiation in the absence of an acute phase.

Treatment

Prevention is the best approach; risk can be minimized by shielding the kidneys or fractioning the total-body irradiation into several small doses over several days. No specific treatment is available for established radiation nephritis. The general approach is control of hypertension and supportive treatment of CKD.

INTERSTITIAL NEPHRITIS MEDIATED BY IMMUNOLOGIC MECHANISMS

Sjögren Syndrome

Definition and Epidemiology

Sjögren syndrome may be associated with chronic interstitial nephritis. The reported prevalence of kidney involvement in Sjögren syndrome varies from 2% to 67%, principally because of different definitions between studies. Recent analysis of 130 patients with primary Sjögren syndrome in China showed an 80% incidence of biopsy-proven chronic interstitial nephritis.[40]

Pathology

The lesion is characterized histologically by infiltration of lymphocytes and plasma cells in the interstitium with tubular cell injury and, rarely, granuloma formation. This progresses to tubular atrophy and interstitial fibrosis over time. IF reveals granular deposits of immunoglobulin G (IgG) and C3 along the tubular basement membrane (TBM).

Clinical Manifestations

The clinical and biochemical manifestations of interstitial nephritis may be the presenting or only features of Sjögren syndrome. Serum creatinine concentration is generally only mildly elevated in association with a bland urine sediment and abnormalities in tubular function, including Fanconi syndrome, distal RTA, hypokalemia, and nephrogenic diabetes insipidus. Sjögren syndrome is one of the most common causes of acquired distal (type 1) RTA in adults, and the hypokalemia may be marked, resulting in a clinical presentation of severe weakness. Hypokalemia may occur in the absence of RTA, resulting from salt wasting and secondary hyperaldosteronism.

Treatment

Treatment with corticosteroids at the stage of cellular infiltration is frequently beneficial for protecting kidney function. Although CKD tends to slowly progress over time, ESKD is relatively rare.

Sarcoidosis

Definition and Epidemiology

Histologic evidence of interstitial nephritis with noncaseating granulomas is common in patients with sarcoidosis, but the frequency of clinically significant disease is low.[41] It may manifest as either acute interstitial nephritis or chronic interstitial nephritis.

Pathogenesis and Pathology

Kidney biopsy reveals normal glomeruli; interstitial infiltration, mostly with mononuclear cells; tubular injury; and, with more chronic disease, interstitial fibrosis. Whereas the classic finding is noncaseating granulomas in the interstitium, they are uncommon and nonspecific. An analysis of 18 patients with granulomatous interstitial nephritis showed that in 5 the disorder was associated with sarcoidosis; in 2, tubulointerstitial nephritis and uveitis; in 2, medication; and in 9, the condition was idiopathic.[42] IF and EM studies typically show no immune deposits.

Clinical Manifestations

Most affected patients have clear evidence of diffuse active sarcoidosis, although some present with an isolated elevation in serum creatinine and only minimal extrarenal manifestations. The urinalysis may be normal or show only sterile pyuria or mild proteinuria.

In addition, hypercalcemia induced by increased production of calcitriol (1,25-dihydroxyvitamin D_3) by activated mononuclear cells (particularly macrophages) in the lung and lymph nodes occasionally results in renal problems (see the previous discussion of hypercalcemic nephropathy).

The serum ACE level is used best not as a primary diagnostic tool but as a marker of disease activity and response to therapy. A normal serum ACE level does not exclude sarcoidosis of the kidney.

Treatment

Corticosteroid therapy tends to improve kidney function, although recovery is often incomplete. Limited data are available concerning the optimal protocol for corticosteroid therapy, but initial dose is usually prednis(ol)one 0.5 to 1 mg/kg/day, which is followed by a slow taper. Rapid tapering of corticosteroids can result in relapse.

Systemic Lupus Erythematosus

Definition and Epidemiology

Interstitial nephritis with immune complexes is defined by granular deposits of immunoglobulins and complement in the TBM, interstitium, or both. Systemic lupus erythematosus is the most common reason for this type of interstitial nephritis (Fig. 65.7), and interstitial involvement is present in half of kidney biopsy specimens in lupus. Tubulitis serves as an independent predictive factor for eGFR decline in lupus nephritis.[43] Rarely, tubulointerstitial immune complex disease may be the only manifestation of lupus nephritis.

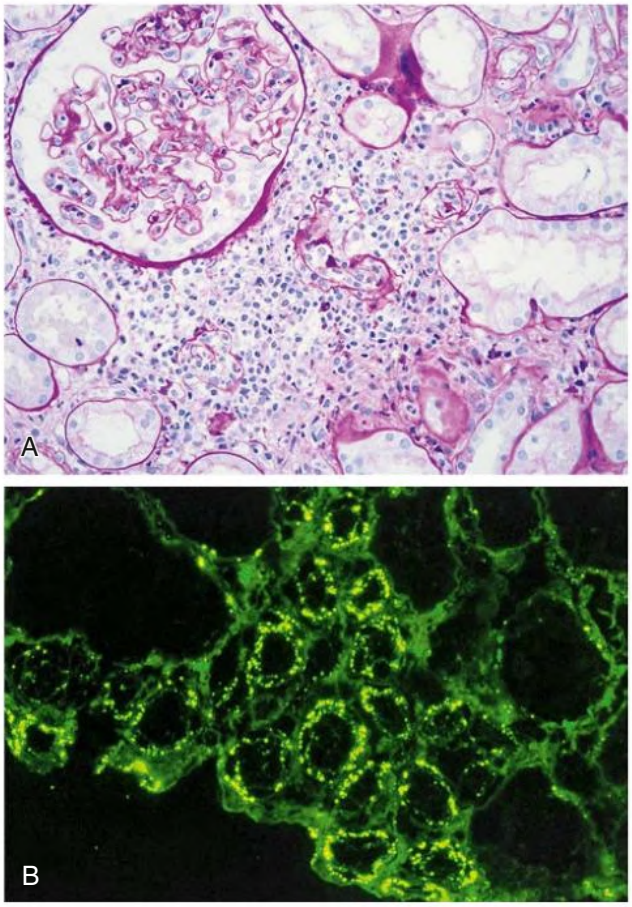

Fig. 65.7 Chronic Interstitial Nephritis in Systemic Lupus Erythematosus. (A) Interstitial nephritis observed in patients with systemic lupus erythematosus. (PAS stain; original magnification ×400.) B, Immunofluorescence study of the same patient revealed deposition of immunoglobulin G in the interstitium, in tubular cells, and along the tubular basement membrane. (Courtesy Drs. Akira Shimizu and Hideki Takano, Nippon Medical School, Tokyo.)

Clinical Manifestations

The presentation may be as acute or chronic interstitial nephritis. The possibility of interstitial involvement (without glomerular disease) is suggested by a rising serum creatinine concentration and a bland urine sediment. Interstitial involvement may be accompanied by signs of tubular dysfunction, such as distal RTA (type 1 or type 4); by isolated hyperkalemia resulting from impaired distal potassium secretion; or by hypokalemia resulting from salt wasting. The potentiating effects of sodium wasting on potassium secretion include an increase in sodium delivery to the potassium secretory site in the collecting tubules and associated volume depletion with subsequent stimulation of aldosterone secretion.

Treatment

Corticosteroid therapy is usually effective in suppressing tubular dysfunction and preserving renal function.

Inflammatory Bowel Disease

Although the most frequent kidney-related complications of Crohn disease are calcium oxalate stones and renal amyloidosis, interstitial nephritis has been reported in patients treated for chronic inflammatory bowel disease. Aminosalicylates (5-aminosalicylic acid, mesalazine, and sulfasalazine) are responsible for most of these cases, but nephrotoxicity of these agents is very uncommon (mean rate only 0.3% per patient-year).[44] The median time for development of kidney injury after commencing aminosalicylates is 3 years.[45] There is no clear relationship between aminosalicylate dose and the risk for nephrotoxicity, suggesting that this is an idiosyncratic response. Some patients have been reported to have biopsy-proven interstitial nephritis before the diagnosis of Crohn disease.

Aminosalicylates should be withdrawn when reduced eGFR develops in a patient with inflammatory bowel disease; if this does not result in a fall in serum creatinine, renal biopsy should be considered. Only one-third of cases recover completely after drug withdrawal.[45] Corticosteroids are recommended when kidney function does not respond to drug withdrawal.

Immunoglobulin G4-Related Kidney Disease

Definition and Epidemiology

On the basis of histologic and immunohistochemical examination of various organs of patients with autoimmune pancreatitis, a novel clinicopathologic entity of immunoglobulin (Ig) G4-related sclerosing disease has been proposed.[46] This systemic disease is characterized by extensive IgG4-positive plasma cells and T-lymphocyte infiltration of various organs (Fig. 65.8). Initial reports of IgG4-related sclerosing disease came from Japan, but it has now been described in Europe and the United States and is considered to be a worldwide entity.

Pathogenesis

Whether IgG4 is pathogenic or is a "bystander" remains unknown. IgG4 does not activate the classical complement pathway effectively. However, immune complex formation may play a pathogenic role, raising the possibility of complement fixation via the lectin pathway or activation of the classical pathway of complement by some unknown mechanism.

Pathology

The most common pattern of involvement by IgG4-related kidney disease is tubulointerstitial nephritis with dense infiltration of IgG4-positive mononuclear cells. Distinctive features of the tubulointerstitial nephritis include: (1) well-demarcated borders between involved and uninvolved areas; (2) involvement of the cortex and deep medulla, often extending beyond the renal capsule; (3) interstitial inflammatory cells made up predominantly of plasma cells and lymphocytes, with a high prevalence of IgG4-positive cells often admixed with fibrosis; (4) peculiar features of interstitial fibrosis called *storiform fibrosis* or *bird's-eye* pattern; and (5) deposits visible by light microscopy and IF in the TBM, Bowman's capsule, and interstitium.[47] Recent pathologic analysis revealed perivascular inflammation or fibrosis of medium- and small-sized vessels as a newly identified pathologic feature of IgG4-related kidney disease and proposed the term *interstitial fibrosclerosis* because storiform fibrosis contains mainly nonfibrillar collagens.[48] IF shows granular TBM staining for IgG accompanied by C3 of lesser staining intensity. MN also has been described as a manifestation of IgG4-related kidney disease.[49]

Clinical Manifestations

Clinical manifestations are observed in various organs, with presentations including sclerosing cholangitis, cholecystitis, sialadenitis, and retroperitoneal fibrosis. IgG4-related tubulointerstitial nephritis can be mass forming, similar to IgG4-related inflammatory lesions in other organs. Of patients with IgG4-related disease, 80% are reported to have had radiographic abnormalities of the kidneys: bilateral and multiple small low-attenuation lesions, a mass, or bilateral kidney enlargement.[50]

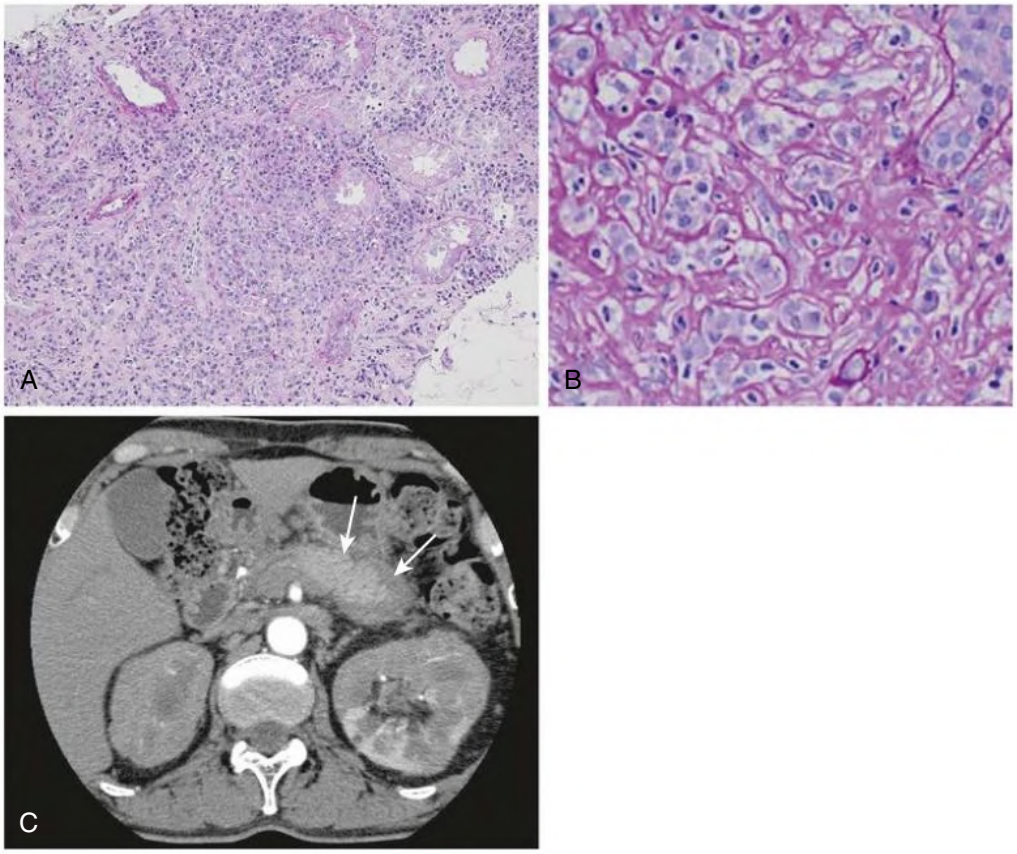

Fig. 65.8 Chronic Interstitial Nephritis in Immunoglobulin (Ig) G4-Related Sclerosing Disease. (A) Interstitial nephritis with numerous mononuclear cell infiltrates observed in a patient with autoimmune pancreatitis. Many of these cells are positive for IgG4 in typical cases. (PAS stain; original magnification ×200.) (B) Small nests of swollen plasma cells or individual plasma cells are encircled by collagenous tissue. The features resemble a maple wood grain pattern called "bird's eye." Plasma cells look like birds' eyes in the wood, whereas fibrotic tissues correspond to branches of the wood. (C) Computed tomography scan of the patient revealed pancreatic swelling *(arrows)*. (A and C, Courtesy Dr. Hiroshi Nishi, University of Tokyo, Tokyo. B, From Joss N, Morris S, Young B, Geddes C. Granulomatous interstitial nephritis. *Clin J Am Soc Nephrol.* 2007;2:222–230.)

Although most IgG4-related sclerosing disease is associated with autoimmune pancreatitis, cases without pancreatic involvement have been described. The disease occurs predominantly in older males. Serum IgG4 levels are raised, and IgG4-positive cells are found in the interstitium. According to a recent meta-analysis, a cut-off value of serum IgG4 ranging from 135 to 144 mg/dL confers a sensitivity of 87% and a specificity of 83%.[51] However, the finding of an elevated serum IgG4 is not specific because this may occur in 5% of the normal population. The patients often show hypocomplementemia and eosinophilia. Recently proposed diagnostic criteria are shown in Table 65.3.

Treatment

The response to corticosteroids is generally favorable, but reappearance of clinical manifestations is common. The protocol has not been established, but a starting dose of approximately 40 mg/day may be prudent. There is no correlation between histologic pattern and response to therapy, and even patients with extensive fibrosis on biopsy have shown a response to corticosteroid therapy. Rituximab may be an alternative treatment for IgG4-related kidney disease. In a recent open-label pilot trial of 30 patients, two doses of rituximab (1000 mg each) achieved the primary outcome composed of improvement of disease activity and damage, no disease flares before month 6, and no steroid use between months 2 and 6, in 77% of participants.[52]

Other Forms of Immune-Mediated Interstitial Nephritis

Primary anti-TBM nephritis is an extremely rare form of interstitial nephritis that usually is acute and characterized by linear deposits of immunoglobulins, commonly IgG, and complement in the TBM, together with tubular interstitial inflammation and anti-TBM antibodies in the serum. Anti-TBM antibodies, usually IgG, may be found in 50% to 70% of patients with anti–glomerular basement membrane nephritis and occasionally in patients with MN, systemic lupus, IgA nephropathy, minimal change disease, and malignant hypertension. The antibodies are directed against a protein that is found in the proximal TBM and regulates tubulogenesis.

OBSTRUCTIVE UROPATHY

Complete or partial urinary tract obstruction is accompanied by pathologic changes in both the tubulointerstitium and glomeruli consisting of interstitial fibrosis, tubular atrophy, and occasionally focal glomerular sclerosis. Details are discussed in Chapter 61.

TABLE 65.3 Diagnostic Criteria for IgG4-Related Tubulointerstitial Nephritis

Histology	Plasma cell–rich tubulointerstitial nephritis with >10 IgG4-positive plasma cells per high-power field in the most concentrated field[a] Tubular basement membrane immune complex deposits by immunofluorescence, immunohistochemistry, and/or electron microscopy[b]
Imaging	Small peripheral low-attenuation cortical nodules, round or wedge-shaped lesions, or diffuse patchy involvement Diffuse marked enlargement of kidneys
Serology	Elevated serum IgG4 or total IgG level
Other organ involvement	Includes autoimmune pancreatitis, sclerosing cholangitis, inflammatory masses in any organ, sialadenitis, inflammatory aortic aneurysm, lung involvement, retroperitoneal fibrosis

Diagnostic criteria for IgG4-related TIN. Diagnosis of IgG4 TIN requires the histologic feature of plasma cell–rich TIN with increased IgG4-positive plasma cells and at least one other feature from the categories of imaging, serology, or other organ involvement.
[a]Mandatory criterion.
[b]Supportive criterion, present in >80% of cases.
IgG, Immunoglobulin G; *TIN,* tubulointerstitial nephritis.

VASCULAR DISEASES

Ischemia resulting from intrarenal vascular involvement causes tubular atrophy, interstitial fibrosis, and cellular infiltration. This is further discussed in Chapter 43. Chronic ischemia in the tubulointerstitial compartment also plays a crucial role in the progression of a variety of glomerular and tubulointerstitial diseases.[2]

INFECTION-ASSOCIATED CHRONIC INTERSTITIAL NEPHRITIS

Although a variety of bacterial and viral infections can be associated with acute interstitial nephritis (see Chapter 64), chronic interstitial nephritis secondary to infectious agents appears to be rare. Insidious *Mycobacterium tuberculosis* infection can cause chronic granulomatous tubulointerstitial nephritis.[53] Chronic bacterial infections can result in xanthogranulomatous pyelonephritis or renal malacoplakia (see Chapter 53). In mice, an atypical virus termed mouse kidney parvovirus is capable of driving a stepwise progression of pathology ranging from sporadic tubular inclusions to tubular degeneration and interstitial fibrosis.[54]

SELF-ASSESSMENT QUESTIONS

1. A 29-year-old woman was admitted to the hospital because of anorexia, binge eating, and self-induced vomiting. On admission, her body mass index was 12.2 and she presented with nocturia and polyuria. The serum potassium level was 2.8 mEq/L. Which one of the following do you expect as the pathologic change of the kidney biopsy specimen of this patient?
   A. Calcific deposits in the interstitium
   B. Vacuolation of the kidney tubules
   C. Noncaseating granulomas
   D. Infiltration of IgG4-positive mononuclear cells
   E. Acellular interstitial nephritis with intranuclear inclusion bodies in the proximal tubules
2. IgG4-related tubulointerstitial nephritis is an emerging clinicopathologic entity that is a part of the systemic disease characterized by infiltration of IgG4-positive plasma cells in various organs. Which one of the following is *most* likely to be associated with this disease?
   A. Uroepithelial carcinoma
   B. Inflammatory bowel disease
   C. Cerebral aneurysm
   D. Autoimmune pancreatitis
   E. Angiokeratoma
3. A 58-year-old woman with a 30-year history of bipolar affective illness was admitted to hospital because of thirst, polyuria, and weight loss. Lithium had been prescribed for the preceding 18 years. On admission, she presented with hypernatremic dehydration. Which one of the following represents the *best* next step to diagnose the characteristic morphologic changes in the kidney?
   A. Non–contrast-enhanced MRI
   B. Blood oxygen level–dependent MRI
   C. Non–contrast-enhanced computed tomography
   D. Scintigraphy
   E. Intravenous urography

Endemic Nephropathies

Ramón Garcia-Trabanino, Shuchi Anand, Richard J. Johnson, Magdalena Madero

Localized epidemics of chronic kidney disease (CKD) have been reported in various parts of the world and are known as *endemic nephropathies.* The word *endemic* is used in a lay rather than epidemiologic sense, to emphasize their regionally confined nature. By definition, these nephropathies are distinct from CKD of standard causes and tend to manifest insidiously. Although aging and the metabolic syndrome are also associated with reductions in estimated glomerular filtration rate (eGFR), endemic nephropathies are distinguished by earlier onset, absence of classic risk factors, and more rapid progression to kidney failure.

There have been remarkable examples in which the cause of endemic nephropathies have been identified. In the 1920s, an increased frequency of CKD in children and young adults in Queensland, Australia, was shown to be due to lead poisoning, such as from exposure to paints. Patients presented with either Fanconi syndrome from acute lead intoxication or CKD and hypertension associated with chronic intoxication. Likewise, an epidemic of CKD resulting from chronic interstitial nephritis and associated with Fanconi syndrome with hypophosphatemia and osteomalacia was observed in the 1950s and 1960s in the Toyama prefecture, Japan, and was shown to be caused by cadmium poisoning; a factory was dumping cadmium into the Jinzu River leading to contamination of the rice and soybeans. The disease was called *itai-itai* ("ouch-ouch") by the locals due to the severe joint pains, and manifested over decades, especially among older women. For more information on nephropathies associated with heavy metals, see Chapter 65. Finally, Balkan endemic nephropathy is another example in which the cause, the herb *Aristolochia clematis* contaminating wheat, has been identified. It is now considered to be an aristolochic acid–induced nephropathy, along with the Chinese herb nephropathy, a chronic tubulointerstitial disease observed in individuals taking these herbs for weight loss in the early 1980s. Diseases caused by *Aristolochia* (*Aristolochia*-associated nephropathy) are discussed in Chapter 79.

MESOAMERICAN NEPHROPATHY

In 2002, physicians from the Hospital Rosales in San Salvador, El Salvador, reported a large number of patients presenting to the emergency room with kidney failure of undetermined etiology and a distinct epidemiologic pattern: most were Hispanic men between ages 20 and 60 performing manual work in the Pacific coast fields.[1] Subsequently, similar epidemic clusters were described along the Pacific coast of Guatemala, Nicaragua, and Costa Rica (Fig. 66.1). Sugarcane cutters have been the most studied, although the disease may be found among all types of farmers, miners, and construction and transportation workers, among others. Review of historical records suggest the phenomenon has been present since the 1970s, but diagnosis and registry has only been performed during recent decades (Fig. 66.2).[2] In some areas, such as in Chichigalpa, Nicaragua, the prevalence of CKD (defined as eGFR <60 mL/min/1.73 m^2) approaches 40% of men between ages 20 and 40 years.[3] This contrasts with an overall prevalence of 8.3% for all adults and with less than 0.4% for men ages 20 to 40 years in the United States.

Pathogenesis

Although rare reports link Mesoamerican nephropathy with exposure to carbamate pesticides or methyl parathion, no confirmatory data exist.[4,5] However, lag between exposure and disease, the variability in environmental fate and stability of agrochemicals, and changes in compounds over time, added to their seasonal use, make the contribution from agrochemicals difficult to evaluate. Heavy metals have been investigated as well, along with silica and nickel,[6-8] but definitive evidence has not yet emerged.

One common risk factor is heat stress and recurrent dehydration, leading some to suggest this might be a type of heat stress nephropathy. Heat stress is known to cause acute kidney injury (AKI) from a variety of mechanisms, including heat stroke and rhabdomyolysis, but the concept of CKD occurring from heat exposure is new. Consistent with this possibility is the observation that Mesoamerican nephropathy is much more common in people who work at low altitudes, where it is warmer than at higher altitudes, despite similar working conditions and pesticide exposure.[9] Experimentally, recurrent heat stress and dehydration have been shown to induce CKD in animals through hyperosmolarity-induced activation of the polyol-fructose and vasopressin pathways, and the kidney injury is amplified if animals are rehydrated with fructose-containing beverages as opposed to water. Kidney injury is also worse if body temperatures are higher in response to heat. Heat stress also may result in subclinical rhabdomyolysis, uric acid overproduction, and supersaturation of urine leading to intermittent uric acid crystalluria.[10] Some infectious diseases, such as leptospirosis, have also been proposed as a causal or potentiating factor, although supporting evidence is limited.[7]

Pathology

The primary finding in patients with advanced CKD is chronic tubulointerstitial fibrosis with variable degrees of glomerulosclerosis (Fig. 66.3).[11] Whether the glomerular changes are secondary to chronic disease or represent a primary glomerular injury is unclear. Immune deposits are absent. A subset of patients may present with AKI and acute tubulointerstitial disease on biopsy.[12] Hyperuricemia, a common feature, has been found experimentally to cause glomerular hypertension, and vasopressin induces hyperfiltration in addition to the effects on tubular injury; however, uric acid crystals are not present in biopsies.

Clinical Manifestations

In early stages, some patients present with AKI or with muscle weakness related to hypokalemia or with aseptic dysuria, possibly related to uric acid crystalluria. Other asymptomatic patients are identified during

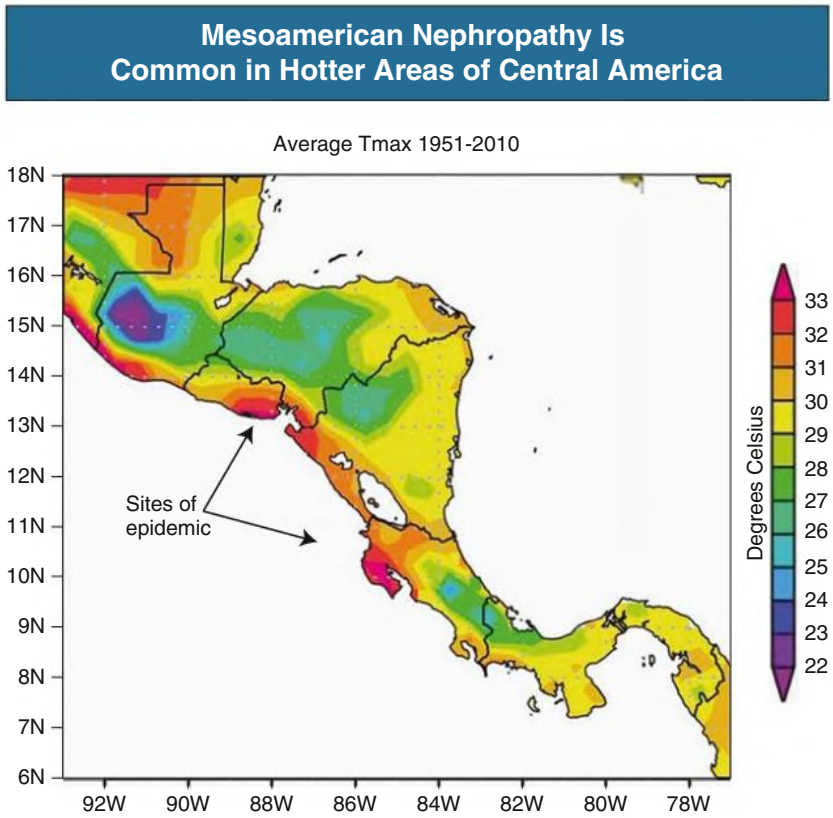

Fig. 66.1 Mesoamerican Nephropathy. Major areas where Mesoamerican nephropathy has been observed are along the Pacific Coast, especially involving the Guanacaste region of Costa Rica, the Bajo Lempa region of El Salvador, and the Chinandega region of Nicaragua. These are also the hottest areas in Central America. (From Glaser J, Lemery J, Rajagopalan B, et al. Climate change and the emergent epidemic of chronic kidney disease from heat stress in rural communities: the case for heat stress nephropathy. *Clin J Am Soc Nephrol.* 2016;11[8]:1472–1483.)

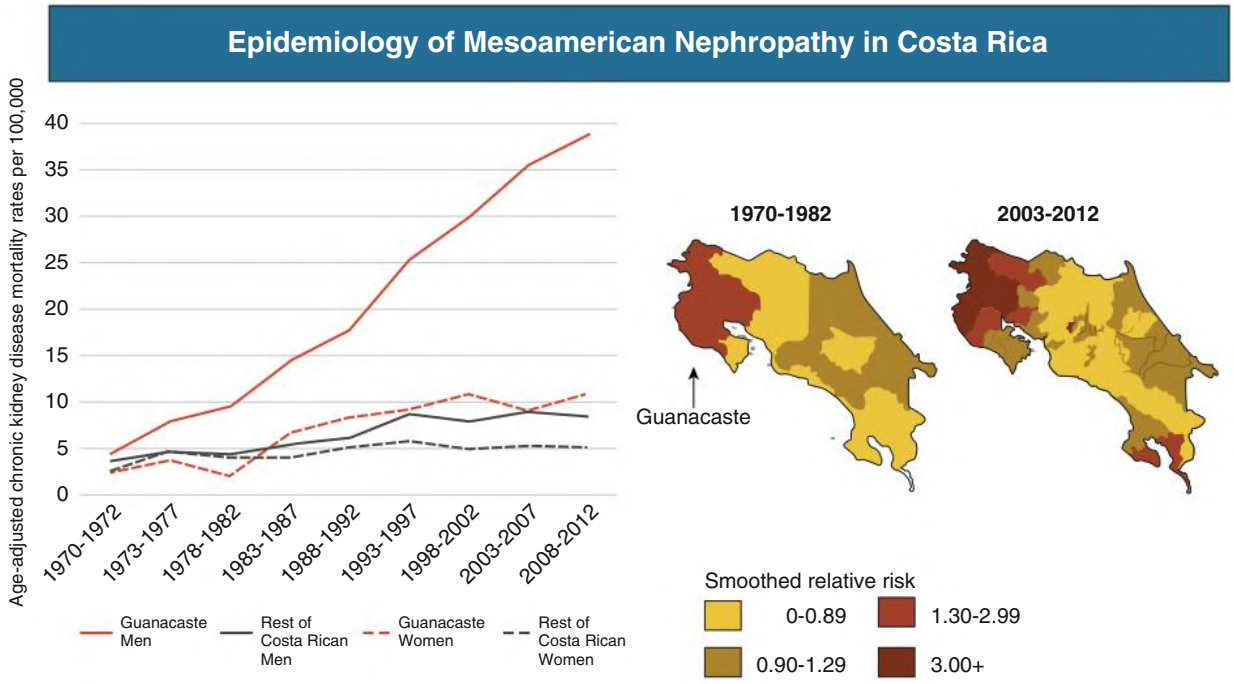

Fig. 66.2 Mortality of Chronic Kidney Disease in Guanacaste, Costa Rica. Mesoamerican nephropathy has been suspected since the 1970s in the Guanacaste region of Costa Rica. Shown is the increasing mortality of chronic kidney disease in the Guanacaste region of Costa Rica in men compared with the rest of Costa Rica. (From Wesseling C, van Wendel de Joode B, Crowe J, et al. Mesoamerican nephropathy: geographic distribution and time trends of chronic kidney disease mortality between 1970 and 2012 in Costa Rica. *Occup Environ Med.* 2015;72[10]:714–721.)

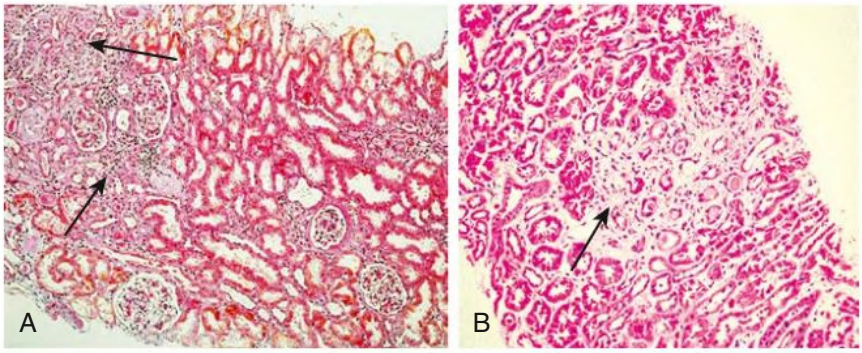

Fig. 66.3 Renal Pathology in Endemic Nephropathy. (A) Mesoamerican nephropathy is characterized by chronic tubulointerstitial fibrosis with localized inflammation *(arrows)*. Other findings include glomerular ischemia and variable glomerulosclerosis. Renal vascular disease is usually mild. (B) Sri Lankan nephropathy also has a similar histologic appearance with the tubulointerstitial fibrosis with some pockets of inflammatory cells. (×40 magnification. B, H&E stain.) (A, Courtesy Dr. Annika Wernerson, Karolinska Institute Sweden. B, From Wijetunge S, Ratnatunga NV, Abeysekera TD, et al. Endemic chronic kidney disease of unknown etiology in Sri Lanka: correlation of pathology with clinical stages. *Indian J Nephrol.* 2015;25[5]:274–280.)

TABLE 66.1 Characteristics of Patients With Mesoamerican Nephropathy

No evidence for common causes of CKD	Absence of diabetes (blood glucose <125 mg/dL or 7 mmol/L) BP normal or only slightly high Minimal evidence for GN (no RBC casts, urine protein <2 g/d) No evidence for obstruction (ultrasound) No evidence for polycystic kidney disease (ultrasound)
Clinical presentation	Asymptomatic rise in serum creatinine Minimal albuminuria Frequent hyperuricemia Serum potassium level often lower than expected Biopsy usually shows chronic tubulointerstitial disease and variable glomerulosclerosis (often performed late in disease)

BP, Blood pressure; *CKD,* chronic kidney disease; *GN,* glomerulonephritis, *RBC,* red blood cell.

health screening through elevated serum creatinine (Table 66.1). Blood pressure is normal or only slightly elevated, and urine sediment shows low-grade (<1 g/d) or no proteinuria with occasional red cells and leukocytes. Serum sodium and potassium are often low and appear to be associated with increased urinary losses[7]; similarly, elevated magnesium and phosphate losses in the urine are also common, supporting a tubular defect.[13] Serum uric acid is generally elevated, typically 2 mg/dL higher than expected for the eGFR.[14]

Diagnosis, Treatment, and Prognosis

Diagnosis is made on clinical grounds, based on living in an endemic area and presenting with CKD without clear cause (Fig. 66.4). The presence of hypokalemia and hyperuricemia and the absence of relevant proteinuria aids diagnosis. Kidney biopsies are rarely performed. Empiric treatment includes counseling on hydration and prevention of heat stress and avoidance of nonsteroidal antiinflammatory drugs. Given experimental data that rehydration with sugary beverages could worsen kidney injury, avoidance of soft drinks or sugary beverages as hydration drinks is recommended. Local nephrologists treat subjects empirically with low-dose angiotensin-converting enzyme inhibitors (especially if they are no longer at risk for dehydration and hypokalemia is present) and with allopurinol and bicarbonate when hyperuricemia is present to reduce the formation of urine urate crystals and improve the aseptic dysuria. Dialysis is infrequently available because of social determinants; prognosis is guarded, and mortality is high.[7,15]

SRI LANKAN NEPHROPATHY

Reports of an epidemic of CKD in the North Central Province of Sri Lanka began in the late 1980s. Regionally, this disease is simply labeled CKDu (chronic kidney disease of uncertain etiology). There are over 100,000 individuals affected, with an ongoing mortality of 5000 per year.[16] Typically, affected individuals are men between the ages of 30 and 60 years who are working in the rice paddies under hot conditions. Women also may develop the disease. The clinical presentation is similar to that of Mesoamerican nephropathy, with low-grade to no proteinuria and an asymptomatic elevation in serum creatinine, although biopsy data indicate concomitant CKDu among people with prior diagnoses of diabetes and hypertension as well[17] (see Table 66.1). Hyperuricemia is also common.[10] Kidney biopsies early in the disease show acute inflammation and/or chronic tubulointerstitial fibrosis, whereas later biopsies also show increasing glomerulosclerosis (see Fig. 66.3).[17,18] Many patients are poor and have little access to medical care, although the government has organized screening camps to detect disease earlier and is increasing dialysis capacity.[16,19]

The primary hypothesis has been that Sri Lankan nephropathy is caused by an agrochemical toxin or heavy metal exposure such as cadmium or arsenic. Nevertheless, levels of heavy metals in the drinking water are within acceptable ranges,[20] and it has been difficult to incriminate any specific agrochemical such as glyphosate.[16] For example, in an analysis of hair and nail samples of persons with biopsy-proven CKDu, concentrations of trace elements matched those measured in controls.[5] A genome-wide analysis identified potential loci for susceptibility that map to tubular function.[21]

Preliminary data also suggest those who drink local well water are at higher risk for CKD, suggesting the presence of an unidentified toxin.[21] Importantly, the risk for CKD was also increased in those highly exposed to the sun, those who worked more than 6 hours per day, and those who drank less than 3 L of liquids per day.[22] Noteworthy,

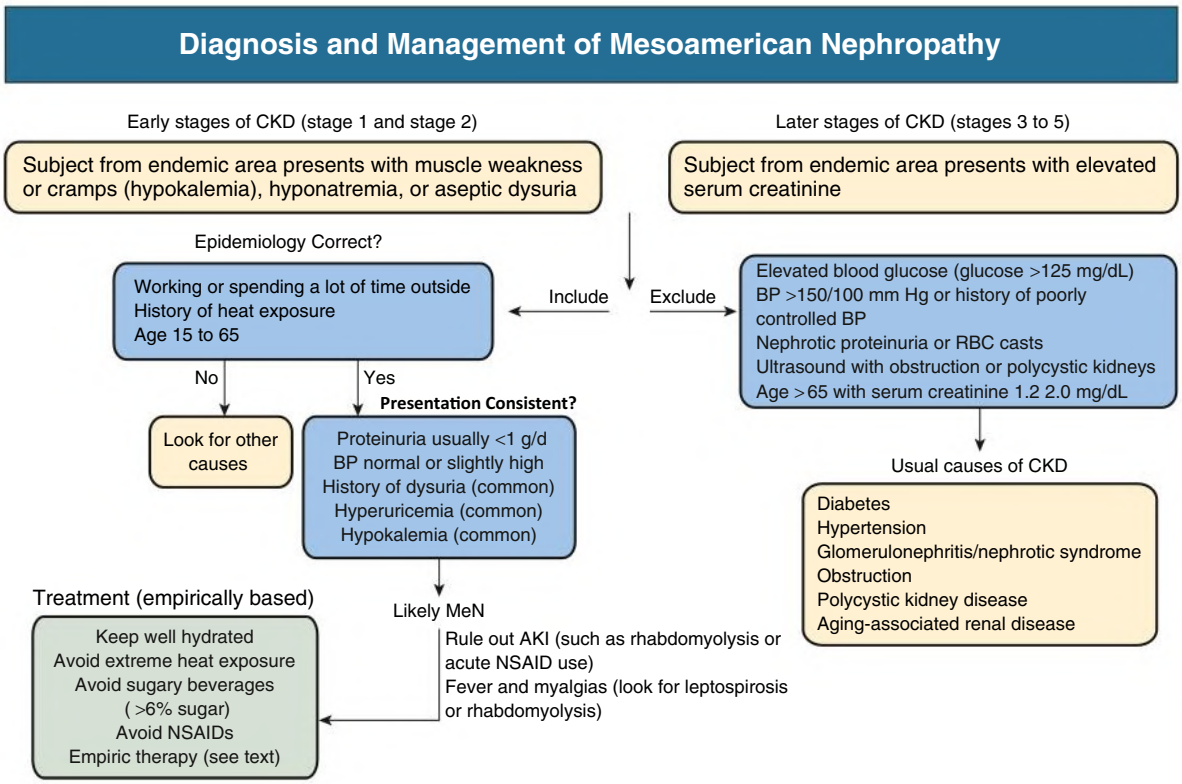

Fig. 66.4 Diagnosis and management of Mesoamerican nephropathy (MeN). *AKI,* Acute kidney injury; *BP,* blood pressure; *CKD,* chronic kidney disease; *NSAID,* nonsteroidal antiinflammatory drug; *RBC,* red blood cell.

because many workers believe the well water contains toxins, it seems likely that those who drink well water might be the same subjects who were limiting their water intake. Thus, these studies also raise the question whether heat stress and recurrent dehydration may be involved in this disease as well.[10]

Although a specific cause has not been identified, a publication from the Ministry of Health in Sri Lanka suggests that the incidence of CKD may be declining.[23]

OTHER ENDEMIC NEPHROPATHIES

An epidemic of CKD has been reported in the Uddanam region of Andhra Pradesh, southern India, and may have been present since the early 1990s.[24] Uddanam nephropathy is observed primarily in men working in the agricultural fields where the primary crops are cashews, coconuts, and rice. Similar to the other epidemics, patients present with minimal proteinuria and elevated serum creatinine and have chronic tubulointerstitial disease on kidney biopsy.[25] Hyperuricemia is also common. Large-scale prospective efforts to investigate disease incidence and risk factors are underway.

Other similar epidemics are also emerging elsewhere. This includes an epidemic among agricultural workers within Tierra Blanca in the Veracruz region of Mexico, where heat stress also has been mentioned as a risk factor, and agricultural work was associated with low eGFR.[26,27] Similarly, the Central Valley of California and Rio Grande Valley in Texas have among the highest incidence of end-stage kidney disease (ESKD) in the United States,[28] and these "hot spots" have also been linked to agricultural activity.[29] There are also early reports that similar epidemics may be manifesting in northeastern Thailand, Egypt, and Sudan. Indeed, to date there are no distinguishing features among the various epidemics, and many believe the disease may have similar etiologies worldwide.

POTENTIAL ROLE OF CLIMATE CHANGE AND GLOBAL WARMING

The similarity between the various epidemics has placed special emphasis on the role of heat stress and dehydration in CKD. The sites where these endemic nephropathies are reported are usually extremely hot and located between the equator and the Tropic of Cancer. Although mean temperatures have increased only 0.8°C in the last 50 years, the frequency of extreme heat events (exceeding the 99th percentile) has increased by nearly 75%.[10] Remarkably, the sites where reports are emerging of epidemic CKD in India correlate with areas of increased extreme heat events such as heat waves (Fig. 66.5). This has led to the hypothesis that these epidemics may represent a type of heat stress nephropathy or that global warming may have a role in accelerating the epidemics. If true, the increase in frequency being observed is likely related to increasing world temperatures. It also remains possible that toxins may contribute to the various epidemics or may be acting in synergy with heat stress to cause CKD, as suggested by the presence of some Fanconi-like features in Mesoamerica and other locales.

To date, none of the proposed hypotheses has been able to explain the origin of these endemic nephropathies alone. Thus, two or more factors could be required.[7] Many facts support a possible genetic or epigenetic role in the development of the disease: its localized endemic nature, frequent familiar recurrence, Hispanic ethnicity selection in Mesoamerica, and its absence from other places where similarly severe environmental and occupational conditions are present.[7,9] A successful research approach to these disorders will require a multidisciplinary approach, the establishment of systematic registries and reinforcing the local capacity for kidney biopsies, genetic and environmental studies, and controlled trials of current diagnosis and management protocols. Given the linkage with heat stress and climate, there is also a need to determine whether similar epidemics are occurring in other hot regions where similar conditions are present.

Sites of Endemic Nephropathy in India Correlate With Sites of Prolonged Heat Waves

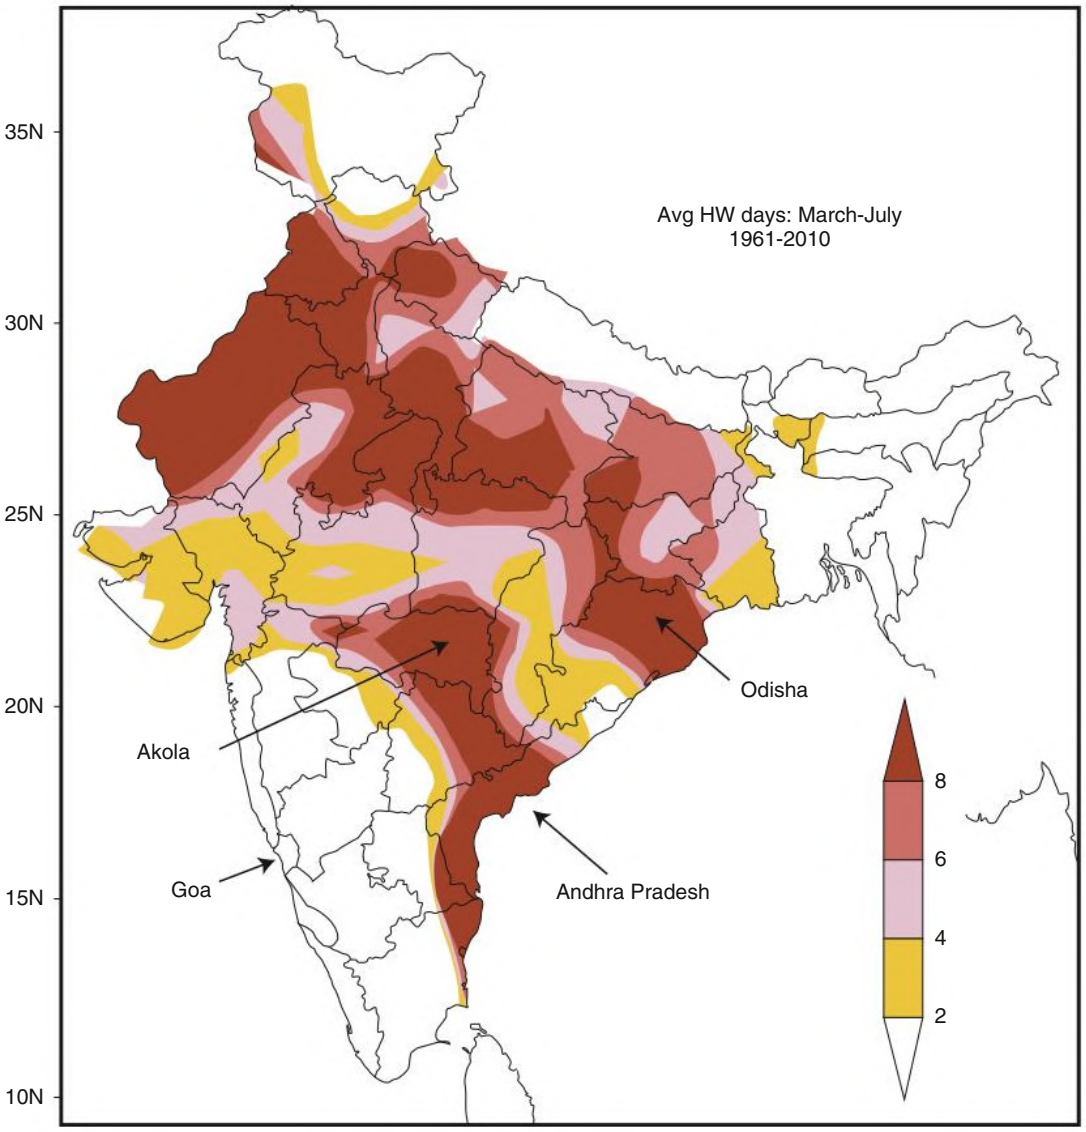

Fig. 66.5 Reported Sites in India With Increased Frequency of Chronic Kidney Disease (CKD) Correlate With Sites of Prolonged Heat Waves. Shown is the average number of heat wave days between March and July (hottest time of the year) in India, based on the number of heat wave days over the 50-year period. A heat wave is usually defined as sustained temperatures of greater than 40°C or an increase of 5 to 6°C over the normal maximal temperature of that region. Andhra Pradesh (including the Uddanam region) has had some of the longest heat waves, with one recorded at 35 days. Other suspected sites of CKD of unknown etiology include the Akola district of Maharashtra and the central Odisha region. *HW,* Heat wave. (Data from Pai DS, Nair S, Ramanathan AN. SELF-ASSESSMENT QUESTIONS

1. Endemic nephropathies refer to:
   - **A.** regions where CKD of any cause is highly prevalent.
   - **B.** regions with a high prevalence of CKD that is unrelated to common causes such as hypertension and diabetes.
   - **C.** ethnic groups with high susceptibility to CKD.
   - **D.** ethnic groups with high prevalence of CKD.
   - **E.** regions with high prevalence of patients undergoing renal replacement therapy.
2. Which statement *best* describes Mesoamerican nephropathy?
   - **A.** A type of CKD of undetermined cause highly prevalent in the Pacific coast of Central America
   - **B.** A type of CKD caused by exposure to aristolochic acid
   - **C.** A type of CKD related to exposure to cadmium
   - **D.** A type of CKD often seen in Mesoamerican Maya ethnicity patients
   - **E.** A type of CKD that locals call *itai-itai*
3. Which of the following are similarities between Sri Lankan endemic nephropathy and Mesoamerican endemic nephropathy?
   - **A.** Highly symptomatic, predominantly glomerular damage with proteinuria, young patients from hot regions
   - **B.** Mostly asymptomatic, predominantly tubulointerstitial damage with low proteinuria, young workers from hot regions
   - **C.** Fanconi-like syndrome with high mortality rates and exposure to lead
   - **D.** Fanconi-like syndrome with high mortality rates and exposure to heat stress
   - **E.** Highly symptomatic, predominantly tubulointerstitial damage with proteinuria, elderly patients
4. The idea of a potential role of climate change and global warming is suspected in emerging endemic nephropathies because of which of the following?
   - **A.** Most emerging endemic regions correlate with areas of increased extreme heat.
   - **B.** Chronic kidney disease is much more common in workers in warmer areas despite similar working conditions.
   - **C.** Patients are exposed to extreme heat stress and dehydration; dehydration may be fueled by the fear of water contamination.
   - **D.** Most emerging endemic regions are located between the equator and the Tropic of Cancer.
   - **E.** All the above.

Oncology: Kidney Disease in Cancer Patients

Ala Abudayyeh, Mark A. Perazella

CANCER AND KIDNEY DISEASE

Malignancy is commonly associated with acute and chronic kidney disease (Box 67.1), which in turn increases morbidity and mortality in cancers patients.[1-3] Rapid advancements in oncology over the past 2 decades have turned many previously fatal cancers into chronic diseases. This relates mainly to recognition of gene mutations in various malignancies that are prime targets of anticancer therapies and using drugs to leverage the immune system for killing tumor cells. Cancer therapy with conventional chemotherapeutic agents, as well as targeted agents, immunotherapies, cytotoxic T-cell therapies, and stem cell transplantation, underpins this transition. However, these positives come with a price, including acute and chronic kidney disease. Nephrologists have been inundated with information on the nephrotoxicity of new drugs and appropriate dosing of anticancer drugs in chronic kidney disease (CKD) and end-stage kidney disease (ESKD) patients, as well as the need to manage CKD in cancer survivors. An increased knowledge gap for many clinicians providing kidney care for these patients and the need for targeted education in this area has fueled the birth of onconephrology, an area of subspecialization within nephrology.

ACUTE KIDNEY INJURY

Acute kidney injury (AKI) is common in cancer patients, particularly in those who are hospitalized or admitted to the intensive care unit (ICU). In these settings, AKI is associated with increased lengths of stay and higher costs. The 1-year risk for AKI as defined by the *r*isk, *i*njury, *f*ailure, *l*oss of kidney function, and *e*nd-stage kidney disease (RIFLE) in a large Danish study of incident cancer patients was 17.5%.[1] The 1-year risk for more severe AKI, defined as the *injury* and *failure* categories, was 8.8% and 4.5%, respectively. Moreover, the 5-year risks for the *risk, injury,* and *failure* AKI categories were even higher, at 27%, 14.6%, and 7.6%, respectively. The incidence of AKI was highest in patients with renal cell cancer, liver cancer, multiple myeloma, and leukemia. Among 9613 cancer patients with any AKI stage, 5.1% required renal replacement therapy (RRT) within 1 year of AKI onset. Unsurprisingly, older patients were most heavily represented in this analysis. In patients admitted to a comprehensive cancer center, AKI was 12%, nearly threefold higher than most noncancer settings, and was associated with worse clinical outcomes.[4] Among those with acute kidney injury, 45% of AKI developed in the first 48 hours and the remainder developed thereafter.[4]

Critically ill cancer patients are at even higher risk of AKI than critically ill patients without cancer. Of 288 patients admitted to a cancer-focused ICU from 2006 to 2008, 54.1% developed AKI.[5] The *risk* category occurred in 33.3% of patients, and the *injury* and *failure* categories each developed in 10.4% of patients. In addition to an increased risk for AKI, critically ill cancer patients have a higher incidence of AKI requiring RRT compared with patients without cancer. Depending on the AKI definition employed and the underlying case mix, 13% to 42% of critically ill patients with cancer may develop AKI, and 8% to 60% require RRT.[6] Those with hematologic malignancies, myeloma, and septic shock are at highest risk to develop AKI. A study of 429 cancer patients admitted to the ICU demonstrated that AKI was an independent risk factor for both ICU and 28-day mortality. In addition, developing AKI after 24 hours in ICU was associated with higher mortality than admission AKI.[7]

Hospital-acquired AKI in cancer patients can be due to prerenal, intrarenal, and postrenal causes (see Chapter 70). Risk factors for AKI in cancer patients include typical comorbidities such as underlying diabetes mellitus and CKD, as well as exposure to radiocontrast, chemotherapy, nonsteroidal antiinflammatory drugs (NSAIDs), and antibiotics.[4] It is therefore critical to identify at-risk cancer patients to allow prophylactic measures. This will allow clinicians to avert AKI and improve clinical outcomes for this fragile group.[4]

Prerenal Acute Kidney Injury

Nearly one-third of AKI in cancer patients is prerenal and results from volume depletion from chemotherapy-induced nausea, vomiting, and diarrhea; chemotherapy-associated hypoalbuminemia contributes to the reduction in effective plasma volume and to compromised renal perfusion. Extracellular volume depletion as a result of third spacing, as in malignant ascites or pleural effusion or insensible losses from neutropenic fever, also can lead to prerenal AKI. Abdominal compartment syndrome from tense ascites can lead to AKI from renal underperfusion.

Intrarenal Acute Kidney Injury

Intrarenal AKI is one of the most common forms of renal injury in cancer patients. The cause is often multifactorial (see Chapter 70). Several chemotherapeutic agents and other nephrotoxic medications commonly used in cancer patients may cause toxic acute tubular necrosis (ATN). Cancer patients with sepsis are also at risk to develop severe ischemic ATN.[7] High and repetitive doses of chemotherapy,

BOX 67.1 Kidney Disease Associated With Common Cancers and Cancer Treatments

Leukemia
Common: AKI from sepsis, volume depletion, drug toxicity
Rare: infiltrative disease, GN, AKI from TLS, and leukostasis

Multiple Myeloma
Common: cast nephropathy, AKI from volume depletion and drug toxicity
Rare: amyloidosis, LCDD, Fanconi syndrome, AKI from hypercalcemia, C3 glomerulopathy, PGNMIgD

Lymphoma
Common: AKI from TLS and volume depletion
Rare: obstructive uropathy, infiltrative disease, MCD (Hodgkin lymphoma), MPGN (non-Hodgkin lymphoma)

Renal Cell Carcinoma
Common: anti–vascular endothelial growth factor toxicity, postnephrectomy CKD
Rare: obstructive uropathy, membranous GN

Lung and Head and Neck Cancer
Common: platinum toxicity
Rare: SIADH, membranous GN

Genitourinary and Gynecologic Cancers
Common: obstructive uropathy
Rare: platinum toxicity

Kidney Disease in Commonly Used Cancer Treatments
Common: AKI, tubulopathy and CKD from chemotherapeutic agents (e.g., cisplatin, ifosfamide, methotrexate), complications of conditioning regimen and HSCT, and from toxicities of targeted anticancer therapies (includes proteinuria, TMA, and hypertension), acute interstitial nephritis from immune checkpoint inhibitors
Rare: radiation nephritis, TMA, GN

Obstructive Uropathy
Common: genitourinary and gynecologic cancers
Rare: lymphoma

AKI, Acute kidney injury; *CKD,* chronic kidney disease; *GN,* glomerulonephritis; *HSCT,* hemopoietic stem cell transplantation; *LCDD,* light chain deposition disease; *MCD,* minimal change disease; *MPGN,* membranoproliferative GN; *PGNMIgD,* proliferative GN with monoclonal immunoglobulin deposits; *SIADH,* syndrome of inappropriate antidiuretic hormone; *TLS,* tumor lysis syndrome; *TMA,* thrombotic microangiopathy.

concurrent with other nephrotoxic agents, may increase AKI risk. Drug-induced acute interstitial nephritis (AIN) is a common cause of AKI in cancer patients, and exposure to the new immunotherapies and targeted therapies is increasing the prevalence of AIN.[8]

Postrenal Acute Kidney Injury

Genitourinary cancers may cause urinary tract obstruction and postrenal AKI. Cancers commonly associated with urinary tract obstruction involve the bladder, prostate, cervix, and ovary. Among these, pelvic irradiation and urogenital surgery for cancer are more likely to cause urinary obstruction. Cervical and ovarian cancers with metastatic spread involving the ureters or bladder are associated with postrenal AKI. In hematopoietic stem cell transplantation (HSCT) recipients with BK infection, ureteral obstruction is a common cause of renal impairment, and bulky retroperitoneal adenopathy associated with lymphoma may cause obstruction.

CHRONIC KIDNEY DISEASE

Chronic kidney disease is also a complication of many cancers and their therapy, and, like AKI, it is associated with increased morbidity and mortality. Preexisting CKD from underlying comorbidities is highly prevalent in patients with various types of malignancy. Additionally, CKD may develop after multiple episodes of AKI, after nephrectomy for kidney cancer, and from nephrotoxic medications that cause glomerulosclerosis and tubulointerstitial fibrosis. The Renal Insufficiency and Anticancer Medications (IRMA) studies observed that 53% (IRMA-1) and 50% (IRMA-2) of patients with active malignancy had an estimated glomerular filtration rate (eGFR) less than 90 mL/min/1.73 m^2, respectively.[9] In this group, the prevalence of stage 3 CKD was 12% in both studies, whereas stage 4 CKD was rare (0.9% and 0.7%, respectively). In an Australian cohort with various cancers ($n = 4077$), eGFR less than 60 mL/min/1.73 m^2 was observed in 30% of patients, and 8% had eGFR less than 45 mL/min/1.73 m^2.[10] In a cohort of Chinese patients with cancer, eGFR 30 to 59.9 mL/min/1.73 m^2 was noted in 13% of 8223 patients.[11] The relatively common occurrence of CKD in many cancer patients has been confirmed in other studies.

The relationship between kidney disease and cancer appears to be bidirectional. Although there is an increase in CKD prevalence in cancer patients, both CKD and ESKD are risk factors for development of a number of malignancies[1] (see Chapter 92). In a retrospective cohort study of more than 1 million adults, lower eGFR was associated with an increased risk for kidney cancer after adjustment for time-updated confounders. In addition, the adjusted hazard ratio was 2.28 (95% confidence interval, 1.78–2.92) for eGFR less than 30 mL/min/1.73 m^2.[12] In patients with ESKD on dialysis, there is an increased risk for renal parenchymal cancer in patients with acquired renal cystic disease.

MORTALITY IN CANCER PATIENTS WITH KIDNEY DISEASE

The increased mortality associated with cancer-related AKI and CKD is related to a number of factors. The occurrence of AKI may require cessation of effective chemotherapeutic regimens, allowing unhindered tumor growth. Preexisting CKD may limit use of chemotherapeutic agents or promote underdosing of curative anticancer regimens. CKD and AKI may alter the bioavailability and/or safety profile of some anticancer drugs leading to use of suboptimal therapies. In addition, CKD and ESKD may impair immune surveillance, allowing cancers to grow and metastasize, especially when combined with insufficient drug dosing. It is also possible that anticancer agent nephrotoxicity is associated with worsening of preexisting CKD, which leads to increased all-cause mortality unrelated to cancer. A recent retrospective study of 128,489 patients from Ontario, Canada, with newly diagnosed solid cancer concluded that survival among patients with advanced kidney disease (stages 3a–5), ESKD, and transplants was inversely correlated with kidney function. In addition, receipt of all treatment modalities (systemic therapy, radiation, and palliative care) was significantly reduced in this group of patients.[13]

IMPORTANT MALIGNANCIES ASSOCIATED WITH KIDNEY DISEASE

Multiple Myeloma and Amyloidosis

Kidney involvement occurs in about 50% of patients with myeloma but varies depending on the myeloma type[14] (see Chapters 28 and 68

). Monoclonal light chain (LC) overproduction is commonly associated with kidney injury, with as many as 50% of patients requiring dialysis.[15] The LC type is also important; cast nephropathy and renal amyloidosis are common with λ LCs, whereas severe proximal tubular injury causing Fanconi syndrome and LC deposition disease are common with κ LCs. Cast nephropathy has been diagnosed in 41% of patients with myeloma and kidney disease, and the use of therapeutic plasma exchange or high cut-off hemodialysis has not been demonstrated to improve kidney or overall survival outcomes.[16] Prior to the use of proteasome inhibitors, kidney failure in patients with myeloma was associated with reduced overall survival. Myeloma and amyloid patients' outcomes have further improved with autologous stem cell transplantation (ASCT), which is now standard care in patients who have adequate organ function. Multiple studies have demonstrated improved kidney function following ASCT.[17] Importantly, myeloma-related kidney failure did not affect progression-free survival or overall survival.[18] Primary systemic amyloidosis in patients with LC disease is another infrequent manifestation of myeloma (see Chapter 28). When amyloidosis complicates myeloma, it carries a grave prognosis. Kidney enlargement, gross proteinuria, and amyloid deposition are hallmarks of renal amyloidosis, which occurs in about 5% to 10% of patients with myeloma based on autopsy studies.[19]

Leukemia and Lymphoma

Various forms of kidney disease occur in patients with lymphoma and leukemia. Those admitted to an ICU had an AKI hazard ratio of 2.23 for AKI, compared with otherwise comparable patients without ICU admission.[20] In 200 patients with newly diagnosed high-grade lymphoma and leukemia, the incidence of RIFLE AKI was 68.5%, with 50% requiring RRT.[21] Possible causes of AKI in patients with leukemia and lymphoma include prerenal processes,[22] intrarenal causes such as ATN (especially from sepsis and nephrotoxic medications),[23] or postrenal causes such as mechanical obstruction from lymphadenopathy or retroperitoneal fibrosis.[24] Patients with leukemia or lymphoma commonly develop infiltrative disease of the kidney.[25] Most often, renal infiltration is asymptomatic or subclinical, as noted in autopsy studies in which 34% of patients were found to have lymphomatous infiltration of the kidneys.[25] Leukemic or lymphoma cell infiltration is suggested by large kidneys on imaging (Fig. 67.1A), and urinalysis shows bland urine sediment and tubular proteinuria.[26] When AKI does occur, it is thought to be due to tubular compression and increased interstitial pressure from the massive malignant cell infiltration (see Fig. 67.1B).[27] Overproduction of lysozyme, which is a freely filtered cationic protein reabsorbed in the proximal tubule, may cause ATN and/or proximal tubular injury with full-blown Fanconi syndrome.[28] Intrarenal leukostasis may cause AKI in patients with acute myeloid leukemia (>100,000 white blood cells). Renal leukostasis is associated with reduced kidney perfusion, blast aggregation within the renal microvasculature, and endothelial damage triggered by soluble cytokines. Emergent treatment with cytoreductive chemotherapy and leukapheresis is generally required.[29]

ANTICANCER DRUGS AND KIDNEY DISEASE

Chemotherapeutic Agents

Oncologists generally assess kidney function before initiation of chemotherapeutic agents. Nevertheless, chemotherapy-related nephrotoxicity has become an important area for the nephrologist. Understanding renal metabolism and excretion of these drugs is critical in ensuring efficacy while also avoiding toxicity. Nephrotoxicity associated with the more common chemotherapeutic drugs includes AKI primarily from ATN and AIN, as well as other metabolic perturbations (Box 67.2). However, emergence of immunotherapies and targeted therapies has been associated with an increased incidence of various nephrotoxicities (Table 67.1).[30]

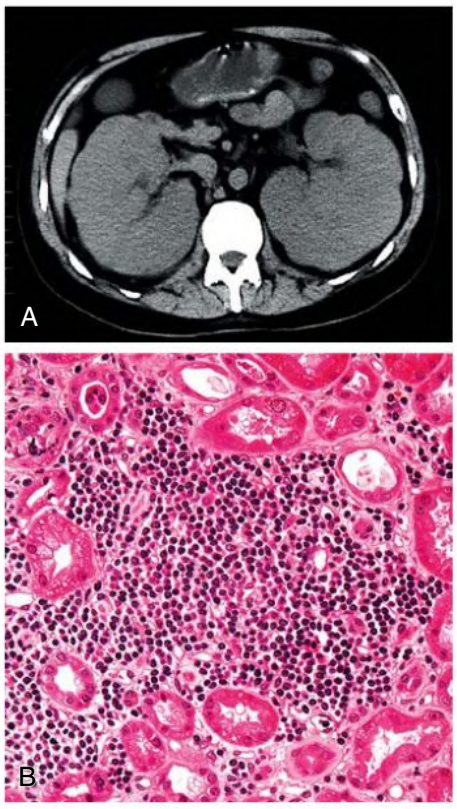

Fig. 67.1 (A) Computed tomographic scan demonstrating large kidneys from lymphomatous infiltration of the kidneys. (B) Kidney biopsy demonstrating low-grade B-cell lymphoma cells within the renal parenchyma (H&E stain; ×400).

Immunotherapies

Immune Checkpoint Inhibitors

Leveraging the immune system to destroy cancer cells has become an attractive strategy for several different malignancies. Immune checkpoint inhibitors (ICIs) impair the checkpoints that function to suppress adaptive immune response and prevent autoimmunity. T cells possess surface receptors, such as programmed death-1 protein (PD-1) and cytotoxic T-lymphocyte–associated antigen-4 (CTLA-4), which bind to their ligands on antigen-presenting cells, leading to T-cell exhaustion. This normally prevents the development of autoimmunity. Tumor survival may be enhanced in malignancies that overexpress ligands that bind these inhibitory T-cell receptors, thereby decreasing activated T-cell infiltration into the tumor microenvironment and inhibiting antitumor T-cell responses. To combat this, monoclonal antibody drugs that block ligand binding to PD-1 and CTLA-4 receptors and antibodies directed at PD-L1 were designed to facilitate T-cell rescue and restore antitumor immunity (Fig. 67.2). Ipilimumab, a fully human immunoglobulin G1 (IgG1) monoclonal antibody blocking CTLA-4; nivolumab, a fully human IgG4 antibody blocking the PD-1 receptor; and pembrolizumab, a humanized monoclonal IgG4-κ isotype antibody against PD-1, are the more common ICIs available in clinical practice. Many more have entered the clinical arena, including PD-L1 antibodies (atezolizumab, avelumab, and durvalumab). However, blocking immune checkpoints risks development of pathologic autoimmunity and end organ injury, such as AIN. Several single and multicenter studies evaluating AKI after ICIs note the incidence to

BOX 67.2 Commonly Used Cancer Therapies Associated With Kidney Toxicity

Tubular Injury

Acute Tubular Injury

- Platinum-based agents, zoledronate, ifosfamide, mithramycin, pentostatin, imatinib, diaziquone, pemetrexed, zoledronate

Tubular Syndromes

Renal Tubular Acidosis

- Ifosfamide, amphotericin, calcineurin inhibitors

Fanconi Syndrome

- Cisplatin, ifosfamide, azacitidine, diaziquone, imatinib, pemetrexed

Salt Wasting

- Cisplatin, azacitidine

Magnesium Wasting

- Cetuximab, cisplatin, panitumumab

Nephrogenic Diabetes Insipidus

- Cisplatin, ifosfamide, pemetrexed

Acute Interstitial Nephritis

- Sorafenib, sunitinib, checkpoint inhibitors

Crystalline Nephropathy

- Methotrexate, acyclovir, sulfa-based drugs

Syndrome of Inappropriate Antidiuretic Hormone

- Cyclophosphamide, vincristine

Glomerular Injury

Focal Segmental Glomerulosclerosis

- IFN, pamidronate, tyrosine kinase inhibitors

Minimal Change Disease

- IFN, pamidronate

Proteinuria

- Sorafenib, sunitinib, vatalanib, axitinib

Renal Vascular Injury

Thrombotic Microangiopathy

- Bevacizumab (anti-VEGF monoclonal antibody)

Tyrosine Kinase Inhibitors

- Sorafenib, sunitinib, imatinib

Other Agents

- Gemcitabine, mitomycin C, IFN-α, calcineurin inhibitors

IFN, Interferon; *VEGF,* vascular endothelial growth factor.

range from 1.4% to 4.9%.[31-33] Among a number of lesions that have been described, AIN is the most common cause of AKI.[34-36] Although some patients develop rash and eosinophilia, AKI is the only consistent clinical manifestation. A small number of cases have required RRT, but most respond to drug discontinuation and steroid therapy. The mechanisms associated with ICI-induced nephrotoxicity are poorly understood, but drugs such as NSAIDs and proton pump inhibitors (PPIs) are associated with increased risk of AIN in several studies.[31-33] Immune checkpoint inhibitor (ICI)-induced loss of tolerance to these drug antigens may lead to development of AIN. Induction of autoimmune disease or reactivation of preexisting autoimmune disease in the kidney has also been demonstrated with ICI exposure and poses a further challenge in cancer therapy, as treatment of ICI-associated inflammation often requires aggressive immunosuppression, which may promote cancer progression and offset the antitumor effects.[37-39]

In addition, ICI therapy for cancer may increase the risk of graft loss in kidney transplant recipients, a group with high risk for certain cancers due to immunosuppression. Single center retrospective studies and multicenter cohorts note rejection rates as high as 40% with ICI therapy in organ transplant patients and more specifically in those with kidney transplants.[40] The median time from therapy to rejection ranged from 14 days to 24 days. There are no accepted guidelines for immunosuppression management during ICI use in kidney transplants. However, prioritizing cancer treatment over salvaging a kidney transplant has been the general approach.

Chimeric Antigen Receptor T Cells

Infusion of autologous ex vivo modified T lymphocytes that express chimeric antigen receptors (CARs) targeting specific tumor antigens is a more focused approach to immune destruction of tumor cells (Fig. 67.3).[41] A more expansive approach is the use of CAR-expressing natural killer (NK) cells or macrophages. These therapies are effective in treating patients with refractory/relapsing leukemias and lymphomas with potential future use for multiple myeloma and solid tumors. CAR T-cell therapy is often associated with cytokine release syndrome (CRS), that can be severe and lethal. In addition to capillary leak syndrome and other end-organ injury such as AKI, patients may progress to hemophagocytic lymphohistiocytosis, characterized by high ferritin, low fibrinogen, and cytopenias. Prerenal physiology and ATN are toxicities associated with CRS in clinical trials. A recent single-center study of 78 patients receiving CAR T-cell therapy noted CRS in 85% of the patients, of which 19% developed AKI, split between prerenal and ATN.[42] In addition to AKI and a high mortality, electrolyte abnormalities were also reported, including hypophosphatemia (75%), hypokalemia (56%), and hyponatremia (51%). Because CRS is primarily driven by interleukin 6 (IL-6), the anti–IL-6 antibody tocilizumab has proven effective in reversing this life-threatening complication.

Interferon Therapy

Treatment with interferon (IFN) is associated with proteinuria secondary to glomerular injury that is primarily a podocytopathy.[43] Minimal change disease (MCD) was first described, but more recent reports describe collapsing and noncollapsing focal segmental glomerulosclerosis (FSGS). Nephrotic-range proteinuria and AKI are observed within weeks of commencing IFN therapy. Although proteinuria declines with IFN discontinuation, complete resolution is more common with MCD than with FSGS. Corticosteroids are associated with complete remission in fewer than one-third of patients with IFN-associated FSGS; however, an attempt at corticosteroid therapy is still warranted with rapid taper if no response.

Targeted Therapies

Antiangiogenesis Therapy

The discovery that vascular endothelial growth factor (VEGF) is an important mediator of tumor growth and angiogenesis led to the development of drugs targeting this pathway for cancer therapy.

TABLE 67.1 Kidney Toxicities Associated With Targeted Therapies

Drug Class	Renal Excretion	Most Frequent Adverse Kidney Events	EVIDENCE FOR DOSE REDUCTION in CKD		
			Mild/Moderate[a]	Severe[b]	Dialysis
VEGF/VEGFR–Targeting Agents					
Bevacizumab	No	Hypertension, proteinuria	No	No	No
Aflibercept	No	Hypertension, proteinuria	No	No	No
Sunitinib	16%	Hypertension, proteinuria	No	No	No
Pazopanib	<4%	Hypertension, proteinuria	No	No	No
Axitinib	23%	Hypertension, proteinuria	No	No	No
Other Multikinase Inhibitors					
Sorafenib	19%	Hypertension, proteinuria, hypophosphatemia	No	No	No
Regorafenib	19%	Hypertension, proteinuria, electrolyte disorders	No	No	No
Vandetanib	25%	Hypertension, proteinuria, AKI	No	Yes	No
Imatinib	13%	More renoprotective effects, AKI described	No	No	No
mTOR Inhibitors					
Everolimus	2%	Proteinuria, AKI, electrolyte disorders	No	No; suspend if AKI	No
Temsirolimus	4.6%	Proteinuria, AKI, electrolyte disorders	No	No; suspend if AKI	No
EGFR Inhibitors					
Gefitinib	<4%	Electrolyte disorders	No	No	No
Erlotinib	<9%	Electrolyte disorders	No	No	No
Afatinib	<5%	Electrolyte disorders	No	No	No
Cetuximab	No	Hypomagnesemia, other electrolyte disorders	No	No	No
Panitumumab	No	Hypomagnesemia, other electrolyte disorders	No	No	No
B-RAF Inhibitors ± MEK Inhibitors					
Vemurafenib	1%	AKI (tubular necrosis?)	No	No	Possible (risk for arrhythmia)
Dabrafenib	23%	Hypophosphatemia (granulomatous nephritis?)	No	No	No
Trametinib	<20%	Hypertension, hyponatremia (with dabrafenib)	No	No	No
ERBB2-Targeting Agents					
Trastuzumab	No	Hypertension, AKI (with cisplatin)	No	No	No
Pertuzumab	No	No issues	No	No	No
Lapatinib	2%	No issues	No	No	No
Trastuzumab emtansine	<5%	Hypokalemia	No	No	No
Antibodies Against CTLA-4					
Ipilimumab	No	Autoimmune nephritis, (potential drug reaction with eosinophilia and systemic symptom syndrome)	No	No	No
Other Agents					
Crizotinib	No	Reduction of eGFR (tubular necrosis?), renal cysts	Possible, with caution	Possible, with caution	No
Catumaxomab	No	No issues	No	No	No

[a]30–90 mL/min/1.73 m^2.

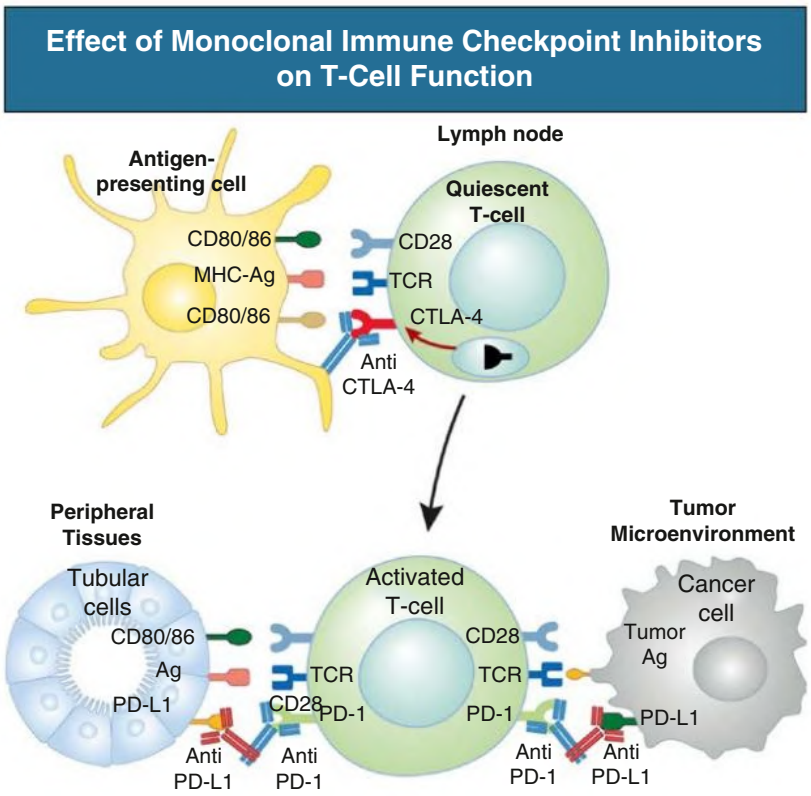

Fig. 67.2 Effect of Monoclonal Immune Checkpoint Inhibitors on T-Cell Function. In the lymph tissue, T cells are quiescent but can be activated by antigen presentation by an antigen-presenting cell. Antigen binding to the T-cell receptor (TCR) is modulated by costimulatory signals such as CD80/86 binding CD28 and coinhibitory signals such as CD80/86 binding cytotoxic T-lymphocyte–associated protein-4 (CTLA-4), which is shuttled to the cell surface upon antigen binding the TCR. Blocking the CTLA-1 receptor with monoclonal antibody allows T-cell activation, which can participate in cancer destruction. In peripheral tissues, activated T cells can be deactivated by the binding of programmed cell death ligand-1 (PD-L1; or PD-L2) to the PD-L1 receptor. Host tissues prevent autoimmune injury by deactivating T cells, whereas cancer cells prevent tumor killing through the same process. Blocking the PD-1 receptor (or blocking PD-L1) with immune checkpoint inhibitors allows T cells to remain activated and allows eradication of cancer cells. However, this can also be associated with host organ injury such as acute kidney injury. *Ag,* Antigen; *MHC-Ag,* major histocompatibility complex antigen.

However, VEGF is also an essential growth factor to maintain glomerular endothelial health. It is secreted by podocytes and traverses the basement membrane, where it binds to VEGF receptors on endothelial cells and maintains glomerular endothelial cell integrity and filtration barrier function. In addition, VEGF enhances production of local regulatory complement factors, thereby preventing pathologic endothelial injury and thrombosis.[44] Anti-VEGF drugs (e.g., the monoclonal antibody bevacizumab) and drugs that inhibit tyrosine kinase (e.g., sunitinib) both block VEGF function. This leads to glomerular endothelial cell dysfunction and filtration barrier disruption, resulting in proteinuria, thrombotic microangiopathy (TMA), hypertension, and AKI.[45] TMA may also develop from loss of VEGF-associated regulatory complement factor production. Mild and asymptomatic albuminuria is common, and heavy proteinuria occurs in less than 10% of subjects.[46] Hypertension or aggravation of preexisting hypertension is common. The reported incidence varies between 17% and 80%.[47] Development of hypertension reflects efficacy of VEGF blockade therapy, perhaps explaining why bevacizumab-induced hypertension correlates with clinical outcomes.[48] Hypertension is managed with standard antihypertensive medications, although the use of angiotensin-converting enzyme inhibitors/angiotensin receptor blockers is preferable in patients with proteinuria. Kidney side effects that develop with anti-VEGF therapy (especially TMA) may require dose reduction or drug discontinuation.[46]

B-RAF Inhibitors

Malignant melanoma frequently has a B-RAF V600 mutation that can be effectively targeted by the selective B-RAF inhibitors vemurafenib and dabrafenib. Although they are effective anticancer agents, these drugs are nephrotoxic. A GFR decline at 1 and 3 months of therapy occurred in 15 of 16 patients, which was complicated by persistent kidney injury after 8 months of follow-up. Eight patients developed AKI after vemurafenib, with ATN seen in 1 patient. AKI that was clinically suggestive of AIN was observed in 4 patients treated with vemurafenib, with 3 of 4 patients recovering kidney function after drug discontinuation, although no biopsy data were available.[49] Nearly 60% of 74 patients treated with vemurafenib developed AKI, primarily Kidney Disease: Improving Global Outcomes (KDIGO) stage 1, within 3 months of drug exposure.[50] Kidney biopsy revealed tubulointerstitial injury in 2 patients. Kidney function recovered within 3 months of B-RAF discontinuation. The combination of dabrafenib and trametinib was shown to cause AKI in 21% of 199 patients in a retrospective cohort study.[51] Although the mechanism of kidney injury is unknown,

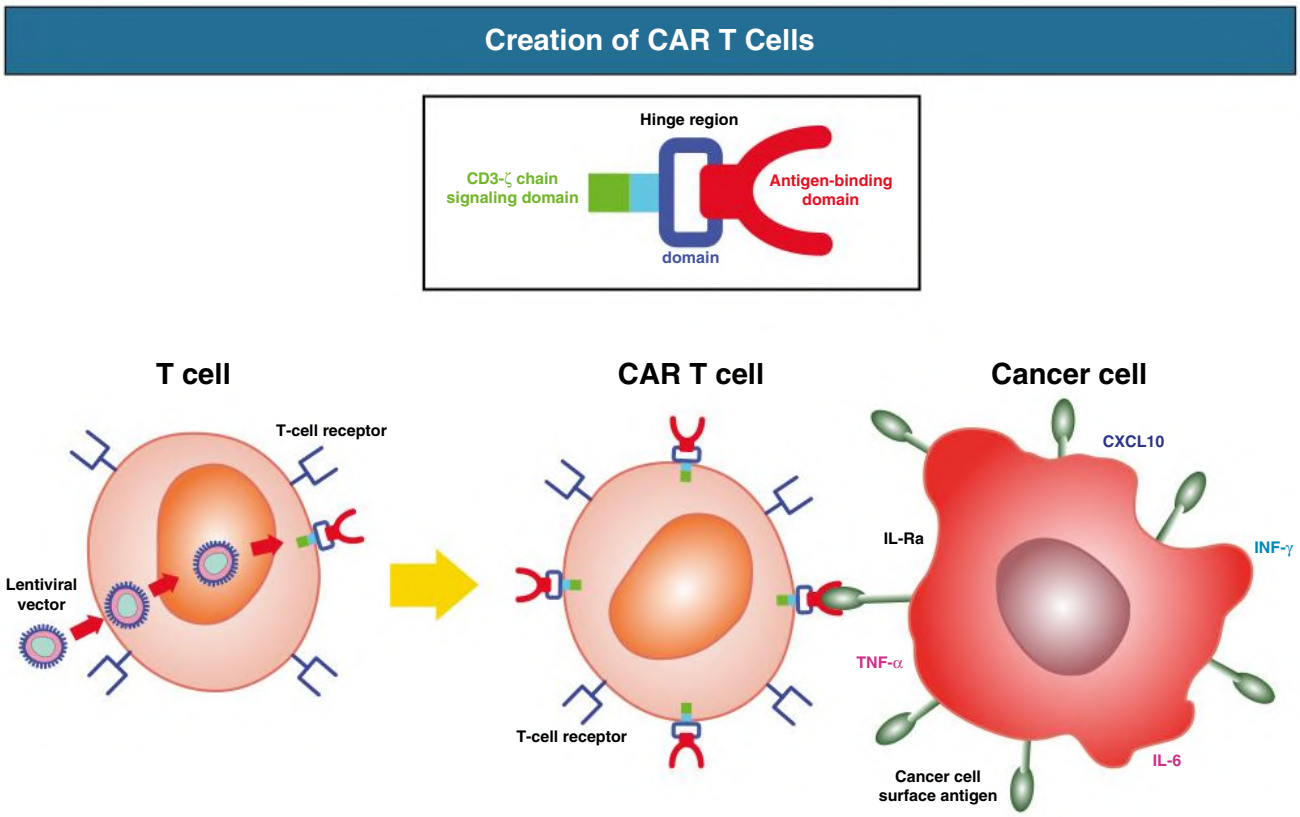

Fig. 67.3 The creation of chimeric antigen receptor (CAR) T cells involves harvesting T cells from patients and subsequently genetically modifying them using a lentiviral vector to place an antigen-binding domain, which recognizes tumor antigen. The antigen-binding receptor is linked to an intracellular costimulatory domain (CD28 or 4–1BB) and CD3-ζ signaling domain to amplify the immune response against tumor cells. Chimeric antigen receptor T cells engage tumor antigen by using extracellular antigen receptors, which are linked to intracellular costimulatory and signaling domains to amplify the immune response against tumor cells. Proinflammatory cytokines and chemokines are produced, which participate in eradication of cancer cells. *CXCL10,* C-X-C motif chemokine ligand 10; *IL-Ra,* interleukin-1 receptor antagonist; *IL-6,* interleukin-6; *INF-γ,* interferon-γ; *TNF-α;* tumor necrosis factor-α.

these drugs may interfere with the downstream mitogen-activated protein kinase pathway, increasing susceptibility to ischemic tubular injury. Therapy is supportive along with drug discontinuation.

Anaplastic Lymphoma Kinase Inhibitors

Anaplastic lymphoma kinase 1 (ALK-1) is a member of the insulin receptor tyrosine kinase family, for which small molecule inhibitors include crizotinib and ceritinib. Crizotinib is an effective agent for treatment of advanced ALK-positive non–small cell lung cancer and appears to be associated with two major issues: AKI and an increased risk for the development and progression of renal cysts.[52] In addition, this agent is also associated with development of peripheral edema and, rarely, electrolyte disorders. Crizotinib is associated with true and pseudo-AKI, the latter due to drug-induced reduced tubular creatinine secretion. If true AKI, temporary discontinuation of drug is recommended. Rechallenge with drug is possible if full recovery of kidney function has occurred.

METABOLIC COMPLICATIONS

Tumor Lysis Syndrome

High-grade lymphomas, acute leukemias, and other rapidly proliferating tumors are prone to tumor lysis syndrome (TLS). Among these, patients with Burkitt lymphoma are particularly at risk. Volume depletion, hypotension, large primary or metastatic tumor load, preexisting CKD, and concurrent exposure to potential nephrotoxic agents are common risk factors for TLS-induced AKI. Cell lysis leads to hyperuricemia, hyperkalemia, hyperphosphatemia, and acidosis causing AKI, primarily from urate crystal deposition in the tubules. Hyperuricemia may also play a role in TLS-associated AKI independent of crystals, possibly as a result of inflammation and endothelial dysfunction.[53] Myocardial deposition of calcium-phosphate crystals may contribute to the development of life-threatening arrhythmias. TLS prevention in high-risk patients involves hydration to maintain a high urine output (>100 mL/h) and allopurinol or rasburicase to reduce hyperuricemia. Rasburicase, which degrades uric acid to water-soluble allantoin, effectively lowers uric acid levels but has not been shown to be superior to allopurinol for prevention of TLS-associated AKI.[54] Early dialysis should be considered when progressive AKI develops in patients with TLS who will be unable to handle the excessive cellular contents (e.g., potassium, phosphate) to prevent life-threatening electrolyte abnormalities. Furthermore, accumulation of tumor lysis products can aggravate renal injury. In patients with severe TLS and oliguric AKI, continuous RRT may be required to control hyperkalemia and persistent hyperphosphatemia.

Common Electrolyte Disorders

Although electrolyte abnormalities are common in cancer patients, factitious laboratory findings may occur. Paraproteins, especially IgM, may cause assay interferences with several tests that are mostly due to their physical interferences with reagents, reactions, or both.[55] Pseudohyperkalemia secondary to in vitro release of potassium from cells may occur in patients with acute leukemia, chronic lymphocytic leukemia, and chronic myeloproliferative disorders. When factitious

values are suspected, careful collection and prompt analysis of repeat samples are required.

Hyponatremia is the most common electrolyte abnormality and affects nearly 50% of hospitalized cancer patients.[56,57] Hyponatremia is frequently due to the syndrome of inappropriate antidiuretic hormone (SIADH), which occurs with many malignancies, including lung cancers, head and neck cancers, and some hematologic cancers.[58] Nausea, pain, and analgesics such as morphine and its derivatives, antidepressants, and several chemotherapeutic agents may cause hyponatremia either by increasing arginine vasopressin secretion or enhancing its effect. Although SIADH is common, one-third of cancer cases develop hyponatremia from volume depletion, which is responsive to normal saline repletion. Treatment with fluid restriction is difficult in cancer patients with SIADH, especially in subjects receiving chemotherapy or HSCT, because these procedures require high intravenous fluid intake. Oral sodium chloride (titrated to target sodium correction) and loop diuretics are sometimes effective in those not receiving large intravenous fluid volumes, whereas vasopressin V2 receptor antagonists may be an option to correct hyponatremia in such patients.[58] Hypernatremia is much less frequent compared with hyponatremia (3% vs. 47%) but is associated with higher mortality and longer hospital stays.[59] Most hypernatremia occurs in the hospital and is observed primarily in critically ill leukemia and HSCT patients who are receiving loop diuretics.

Other common electrolyte abnormalities in cancer patients (especially those who are receiving chemotherapy) include hypokalemia, hypomagnesemia, and hypophosphatemia. Nausea/vomiting, diarrhea, and poor nutrition from chemotherapy account for many of these abnormalities. However, severe abnormalities are usually due to drug-induced Fanconi syndrome. Ifosfamide and cisplatin are the most common agents, but κ LC myeloma also can cause this syndrome. Cetuximab causes hypomagnesemia, which occasionally can be severe. In health, epidermal growth factor (EGF) binds its receptor (EGFR) and stimulates distal tubular magnesium reabsorption. Cetuximab (EGFR antibody) competes with EGF for its receptor, thereby inhibiting normal reabsorption of luminal magnesium and causing hypermagnesiuria.

Hypercalcemia is common in patients with advanced cancer with bone metastasis and heralds a poor prognosis (see Chapter 11). Hypercalcemia is frequently associated with multiple myeloma and can be the presenting feature. Several mechanisms may underlie tumoral hypercalcemia such as elevated parathyroid hormone–related peptide levels associated with lung cancer, ectopic vitamin D in certain lymphomas, or tumor resorption of bones as in advanced cancer (see Chapter 11). Treatment of hypercalcemia mandates vigorous intravenous fluid administration in those who are volume depleted (Box 67.3). Although corticosteroids (for myeloma and vitamin D–related hypercalcemia) and calcitonin are useful, persistent hypercalcemia often requires bisphosphonate therapy for long-term control. Rarely, hemodialysis with low calcium dialysate alone is sufficient to control severe hypercalcemia in symptomatic patients. Use of bisphosphonates, especially zoledronate and pamidronate, can be complicated by AKI and collapsing FSGS, respectively. Ibandronate and denosumab are less nephrotoxic options.[60]

CANCER-RELATED GLOMERULONEPHRITIS

Cancer-related glomerulonephritis is a relatively rare but important entity in patients with certain malignancies. Proteinuria or (rarely) nephrotic syndrome can be the manifesting feature of cancer. Membranous nephropathy (MN) (see Chapter 21) is the most common glomerular pathology associated with solid tumors. In the largest series of 240 patients with biopsy-proven MN, a cancer diagnosis was noted in 10%.[61] Common cancers associated with MN are lung, gastric, colon, and renal carcinomas, but several other solid tumors, such as prostate and breast cancer, are also linked (Table 67.2). In Hodgkin disease, the most common lesion is MCD (see Chapter 18), possibly related to tumor-related T-cell dysfunction. Chronic lymphocytic leukemia is commonly associated with a histologic pattern of membranoproliferative glomerulonephritis (see Chapter 22), especially in the presence of cryoglobulinemia. HSCT is associated with membranous nephropathy, and, rarely, MCD can be a manifestation of chronic graft-versus-host disease.[62] The use of IFN-α, anti-VEGF therapies, and bisphosphonates in cancer therapy is associated with various glomerular diseases and thrombotic microangiopathy.[63]

BOX 67.3 Management of Cancer-Related Hypercalcemia

1. General measures: IV fluids followed by loop diuretics if hypervolemia.
2. Administer calcitonin (4 U/kg SQ every 6–12 h based on calcium response), corticosteroids (prednisone 20–40 mg/d PO depending on cause), or both for acute and short-term calcium control.
3. If patient severely symptomatic and with reduced urine output and impaired kidney function, consider dialysis with low bath calcium.
4. Start bisphosphonates (pamidronate 30–90 mg IV over 2–4 h depending on GFR; zoledronate 4 mg IV over 15 min, dose adjusted for GFR, contraindicated for GFR <30 mL/min) for longer-term hypercalcemia control (adjust for kidney dysfunction or switch to denosumab; see step 6).
5. Treat the underlying malignancy.
6. For bone resorption–associated hypercalcemia: humanized anti-RANKL antibody (denosumab 60–120 mg SQ) appears to be safer and more effective than bisphosphonates (particularly in patients with AKI or CKD).
7. For PTHrP-related hypercalcemia: humanized monoclonal antibody against human PTHrP may be more effective than bisphosphonates (under evaluation).

GFR, Glomerular filtration rate; *IV,* intravenous; *PO,* orally; *PTHrP,* parathyroid hormone–related peptide; *RANKL,* receptor activator of nuclear factor κ-B ligand; *SQ,* subcutaneously.

HEMATOPOIETIC STEM CELL TRANSPLANTATION

Among the types of HSCT, the myeloablative allogeneic form requires higher doses of irradiation, chemotherapy, or a combination and carries the highest risk for developing AKI (up to 70%). Acute kidney injury can have multiple causes in HSCT recipients and is associated with poor clinical outcomes in patients receiving any form of HSCT.[64] In addition to the usual causes of AKI (volume depletion, intravenous contrast, sepsis, and drug toxicity), there are several specific renal syndromes that should be suspected based on the length of time between HSCT and the development of AKI (Table 67.3).

CANCER THERAPY IN CHRONIC KIDNEY DISEASE AND END-STAGE KIDNEY DISEASE

Reduced GFR complicates the selection and administration of chemotherapy and may lead to unduly high doses and drug accumulation.[65] Careful dosing and dialysis timing are critical because overdosing can aggravate systemic toxicities, whereas underdosing can lead to ineffective cancer treatment. Common risk factors for chemotherapy-induced nephrotoxicity include volume depletion,

TABLE 67.2 Cancer-Associated Glomerular Diseases

Malignancy	Glomerular Diseases
Lung cancer	MN,[a] MCD, MPGN, IgAN, FSGS, CGN, TMA
Colon cancer	MN,[a] MCD, CGN

hypoalbuminemia, metabolic derangements, older age, presence of diabetes and other comorbid conditions, underlying AKI or CKD, presence of sepsis, and concomitant use of other potential nephrotoxins. Therefore, optimizing kidney function in those with CKD before chemotherapy can reduce risk for AKI and chemotoxicity. Moreover, administration of platinum compounds requires dose adjustments and timing with dialysis. Other commonly used agents for cancer treatment that need dose adjustment for GFR and dialysis or that should be avoided completely are melphalan, methotrexate, pemetrexed, capecitabine, hydroxyurea, fludarabine, etoposide, irinotecan, and lenalidomide.[66] In contrast, the ICIs do not need dose adjustments for liver or kidney disease. Tumor lysis developing in CKD/ESKD patients can be particularly challenging because the reduced ability to eliminate the tumor products can be life-threatening. In this situation, institution of daily dialysis or continuous RRT may become necessary. Moreover, in CKD/ESKD patients on active cancer treatment, erythropoietin should be used judiciously because higher doses may be associated with poorer cancer outcomes.[67] A suggested approach is noted in Fig. 67.4.[68]

SELF-ASSESSMENT QUESTIONS

1. Which one of the following kidney lesions is most likely to be observed on kidney biopsy in a patient with multiple myeloma that develops acute kidney injury with urinalysis showing trace protein and a spot urine protein/creatinine ratio of 4.8 mg/mg?
   - **A.** Light chain–associated proximal tubulopathy
   - **B.** Light chain deposition disease
   - **C.** Primary systemic amyloidosis
   - **D.** Light chain cast nephropathy
   - **E.** Plasma cell interstitial infiltration
2. A 67-year-old woman with a history of metastatic melanoma is undergoing therapy with nivolumab. After 6 weeks, the patient develops AKI (serum creatinine 3.8 mg/dL). Urinalysis reveals 1+ protein, blood, and leukocyte esterase; 3 to 5 white blood cells per high-power field (HPF), 5 to 10 red blood cells/HPF, and 3 to 5 granular casts per low-power field are noted on urine microscopy. Which one of the following lesions is *most* likely to be observed on kidney biopsy?
   - **A.** Acute tubular injury/necrosis
   - **B.** Isolated proximal tubular injury
   - **C.** Acute interstitial nephritis
   - **D.** Acute glomerulonephritis
   - **E.** Acute fibrinoid necrosis of glomerulus
3. A 69-year-old woman presented with weight loss and nausea/vomiting. A computed tomography scan of the chest and abdomen demonstrated 18-cm bilateral kidneys without hydronephrosis. There was also associated retroperitoneal lymphadenopathy. Labs revealed the following: sodium 135 mEq/L; potassium 5.1 mEq/L; chloride 101 mEq/L; bicarbonate 18 mEq/L; blood urea nitrogen 59 mg/dL; creatinine 4.5 mg/dL (baseline 1.0 mg/dL); serum albumin 3.7 g/dL; calcium 11.1 mg/dL; phosphorus 7.6 mg/dL; and uric acid 11.7 mg/dL. Urinalysis showed specific gravity of 1.018, pH 5.0, and a negative dipstick examination. Urine output was 800 mL/24 h. What is the *most* likely cause of acute kidney injury in this patient?
   - **A.** Retroperitoneal lymphadenopathy with nonhydronephrotic urinary obstruction
   - **B.** Tumor lysis syndrome with acute crystalline nephropathy
   - **C.** Hypercalcemic AKI
   - **D.** Lymphomatous infiltration of the kidneys
   - **E.** Prerenal AKI from nausea and vomiting

Myeloma and the Kidney

Ashley B. Irish

Myeloma is an uncommon malignancy; it accounts for 1% of total malignancies and 10% of hematologic malignancies in the United States, with a stable age-adjusted incidence of 40 per 1 million. The incidence of myeloma is twice as high in African Americans as in Whites, and is higher for males than females. Myeloma is a disease of older people, with the median age at diagnosis exceeding 65 years.[1] Myeloma is characterized by a neoplastic proliferation of plasma cell clones producing monoclonal immunoglobulin, which in 95% of cases includes an excess of the light chain (LC) component, which can be nephrotoxic. Various causes and manifestations of acute kidney injury (AKI) are possible in myeloma (Table 68.1), but the major risk is myeloma cast nephropathy (MCN), which is a medical emergency that requires prompt diagnosis and intervention to avoid irreversible kidney failure. Other monoclonal B-cell–derived kidney disorders have been collectively described as monoclonal gammopathy of renal significance (MGRS); they differ from myeloma because they do not depend on expansion of the clonal mass for their nephrotoxicity and usually lack the additional features characteristic of myeloma, such as bone disease.[2]

ETIOLOGY AND PATHOGENESIS OF MYELOMA

Plasma cells derive from mature uncommitted B cells and after antigen stimulus undergo heavy-chain class switching from μ (immunoglobulin M [IgM]) expression to α, δ, ε, and γ. Whole immunoglobulin production requires the intracellular assembly of two heavy chains and two LCs, either kappa (κ) or lambda (λ), to derive whole IgG, IgA, IgD, and IgE. Normally, LCs are excreted in slight excess, with a κ/λ ratio of approximately 2:1. In myeloma a clone of cells secretes excessive quantities of a specific immunoglobulin and/or LCs (the paraprotein or M-protein). All myelomas (whole immunoglobulin or LC only) arise from a preclinical phase of monoclonal gammopathy (monoclonal gammopathy of undetermined significance [MGUS]) into a clinical or symptomatic phase as a consequence of somatic mutations. Mutations have important implications for prognosis and treatment and are incorporated into diagnostic and prognostic stratification tools.[3] Myeloma remains an incurable disease because of multiple subclones, which engender resistance to chemotherapy and account for the natural history of remission and relapse over time. Both deregulation of cell cycling and impaired apoptosis account for their progressive and dysfunctional accumulation within the bone marrow and occasionally other organs. Plasma cells express little surface immunoglobulin and are recognized by surface expression of CD38 and CD138; they normally reside only in the bone marrow. In myeloma, unrestrained plasma cell growth is supported by a complex milieu of autocrine and paracrine cytokines, especially interleukin-6 (IL-6). These cytokines are secreted from stromal cells, endothelial cells, and/or osteoclasts and maintain myeloma cell growth, survival, and migration; they also contribute to local organ dysfunction, such as bone resorption, fracture, and anemia.[4]

ETIOLOGY AND PATHOGENESIS OF KIDNEY DISEASE IN MYELOMA

Free light chains (FLCs) circulate as monomers (predominantly κ ≅ 25 kDa) and dimers (predominantly λ ≅ 50 kDa) with a very short half-life (2–6 hours) because of free glomerular filtration, whereas the much larger whole immunoglobulin circulates intact for several weeks. The filtered FLC is reabsorbed in the proximal tubule cell (PTC) by receptor-mediated endocytosis after binding with the glycoprotein receptor cubilin[5] (Fig. 68.1). LCs in excess can induce an inhibitory effect on endocytosis in vitro and are associated with lysosomal overload and rupture, releasing enzymatic contents into the cytosol, manifested histologically by crystallization, vacuolation, and desquamation of the PTC. Endocytosis of LCs induces the release of the proinflammatory cytokines IL-6, IL-8, and monocyte chemoattractant protein-1 (MCP-1) by activation of nuclear factor-κB (NF-κB) in the PTC.[6] Inhibition of proximal tubule uptake of LCs by silencing the megalin/cubilin genes with small interfering RNAs prevents proximal tubular toxicity.[7] This suggests that LC overload induces factors promoting interstitial injury and fibrosis, as described in other proteinuric states. Less common manifestations of PTC injury include the Fanconi syndrome, which is invariably associated with specific variant κ LCs and often with pathologic evidence of crystalline inclusions.[8]

Injury to the PTC allows escape or overflow of LCs to the distal nephron, where they can interact with uromodulin (Tamm-Horsfall protein) secreted by the cells of the thick ascending loop of Henle. Variations in the specificity of the binding region of different LCs modify the affinity of the LC for binding with uromodulin, which could in part explain the variable nephrotoxicity of LCs.[9] This specificity of the individual LC for uromodulin was illustrated by the finding that the intraperitoneal instillation of LCs isolated from humans with specific kidney LC-associated disease induces the same kidney injury in animals.[10] Inhibiting the binding of LCs to uromodulin prevents cast formation.[11] Not all LCs are associated with tubular injury, and neither the amount nor type of urinary LCs correlates with the severity of cast formation. Nevertheless, in general, the higher the urinary excretion of LCs, the greater is the risk for kidney failure and reduced response to chemotherapy.[12-14] In addition to LC-specific factors, tubular solute composition and tubular flow rates modulate the risk for cast formation. In animals, urinary acidification, furosemide, and urinary sodium and calcium concentrations may affect the tendency to increased binding or aggregation of LCs with uromodulin, whereas colchicine may reduce this tendency in animals but not in humans.[15,16] The formation and passage of casts distally can occlude the tubule and

TABLE 68.1 Etiology of Kidney Injury and Clinical Manifestations in Myeloma

	Cause	Manifestation
Prerenal		
Volume depletion	Hypercalcemia Gastrointestinal losses (nausea and vomiting) Sepsis	Polyuria and polydipsia Hypotension Fever
Hemodynamic	Hemodynamic effects of NSAIDs	Oliguria, hyperkalemia
Other	Hyperviscosity (IgA, IgG3) Hyperuricemia	Mental state alterations Tumor lysis
Intrarenal	Proximal tubular injury from light chains, uric acid, distal tubular injury from casts	Fanconi syndrome Tubular proteinuria Crystalluria
	Glomerular disease (LCDD, amyloid)	Nephrotic proteinuria Hematuria, active sediment
Postrenal	Calculi	Colic

Ig, Immunoglobulin; *LCDD,* light chain deposition disease; *NSAIDs,* nonsteroidal antiinflammatory drugs.

allow intratubular obstruction, with rupture and even backflow of contents (Fig. 68.2).

EPIDEMIOLOGY

Most myeloma manifests de novo, although around 1% evolves from patients with a known MGUS each year. In patients with newly diagnosed myeloma, the prevalence of IgG, IgA, IgD, and FLC-only myeloma was 52%, 21%, 2%, and 16%, respectively.[13] IgM and IgE myeloma are extremely uncommon. Approximately 70% of patients with myeloma also have a urinary M-protein. At the time of diagnosis, up to 50% of patients have evidence of impaired kidney function judged by increased serum creatinine, around 25% presenting with serum creatinine greater than 2 mg/dL (177 μmol/L).[13,14] In unselected series, 2% to 10% of patients present with severe kidney failure requiring dialysis; this figure is higher in series reported from nephrology units. In contrast to the general distribution of M-protein types in myeloma, LC and IgD myeloma are particularly associated with higher risk for kidney disease and are present in nearly 50% of patients with kidney failure requiring dialysis.[17]

CLINICAL PRESENTATION

Most patients present with constitutional symptoms (fatigue, weight loss) and skeletal pain, especially back pain. Kidney impairment is common and has a variety of causes (see Fig. 68.1). In a smaller proportion of patients, kidney failure is the presenting manifestation of myeloma and these patients often have more advanced disease with high morbidity/mortality.[17] Kidney findings are nonspecific, typically normal-size kidneys and bland urine. Urinary protein excretion may be increased because of the presence of LCs (Bence Jones protein). Urinary dipstick (or measurement of albuminuria) may indicate only small amounts of protein because they measure albumin only. Significantly increased levels of urinary albumin are suggestive of amyloidosis or other monoclonal kidney disorders, which affect the glomerulus (see Chapter 28). Normal or elevated ionized calcium, a decreased serum anion gap, lytic bone lesions on radiographs, hypogammaglobulinemia, reduced levels of other immunoglobulin classes (immunoparesis), significant cytopenias, or blood film changes (plasma cells and/or leukoerythroblastic film) are suggestive of myeloma. Clinical and laboratory findings that may distinguish MCN from other monoclonal B-cell disorders affecting the kidney are listed in Table 68.2.

PATHOLOGY

Histologic examination of the kidney in myeloma and AKI has diagnostic and prognostic utility, although it is not always required.[18-21] The introduction of the serum (FLC) ratio as a rapid diagnostic tool has reduced the requirement for biopsy for diagnosis. Cast nephropathy is the most common histologic finding, occurring in 30% to 50% of patients; however, a diverse range of diseases have been reported depending on the indication for biopsy (Table 68.3). Cast nephropathy is characterized by many distal tubular casts, which are strongly eosinophilic and consist of the monoclonal LC and laminated uromodulin, which often appear fractured after fixation. Casts promote local inflammation with giant cell formation.[22,23] In 30% of cases, cast formation may not be prominent despite extensive tubulointerstitial injury[24] (Box 68.1 and Fig. 68.3). Glomeruli are usually spared unless there is associated LC deposition disease or amyloidosis (see Chapter 28).

DIAGNOSIS AND DIFFERENTIAL DIAGNOSIS

The International Myeloma Working Group (2014) diagnostic criteria for symptomatic myeloma require one or more myeloma-defining events in addition to bone marrow clonally restricted plasma cells of 10% or greater or biopsy-proven plasmacytoma. A myeloma-defining event is a CRAB event (hyper*c*alcemia, *r*enal failure, *a*nemia or lytic *b*one lesions) or one of three biomarkers: clonal bone marrow plasma cells greater than 60%, serum FLC ratio of 100 or greater (involved to uninvolved LC *and* the involved LC absolute value >100 mg/L), or more than one focal bone lesion on magnetic resonance imaging. To meet the criteria for kidney failure as a myeloma-defining event, a reduction in estimated glomerular filtration rate (eGFR) to less than 40 mL/min/1.73 m^2 and a histologic diagnosis of cast nephropathy (or presumptive diagnosis based on a serum involved FLC of typically >1500 mg/L) is necessary to distinguish this from other paraprotein-defined kidney diseases.[25] About 97% of patients with a diagnosis of myeloma have a detectable intact whole immunoglobulin and/or a free LC by serum protein electrophoresis (SEP) and immunofixation

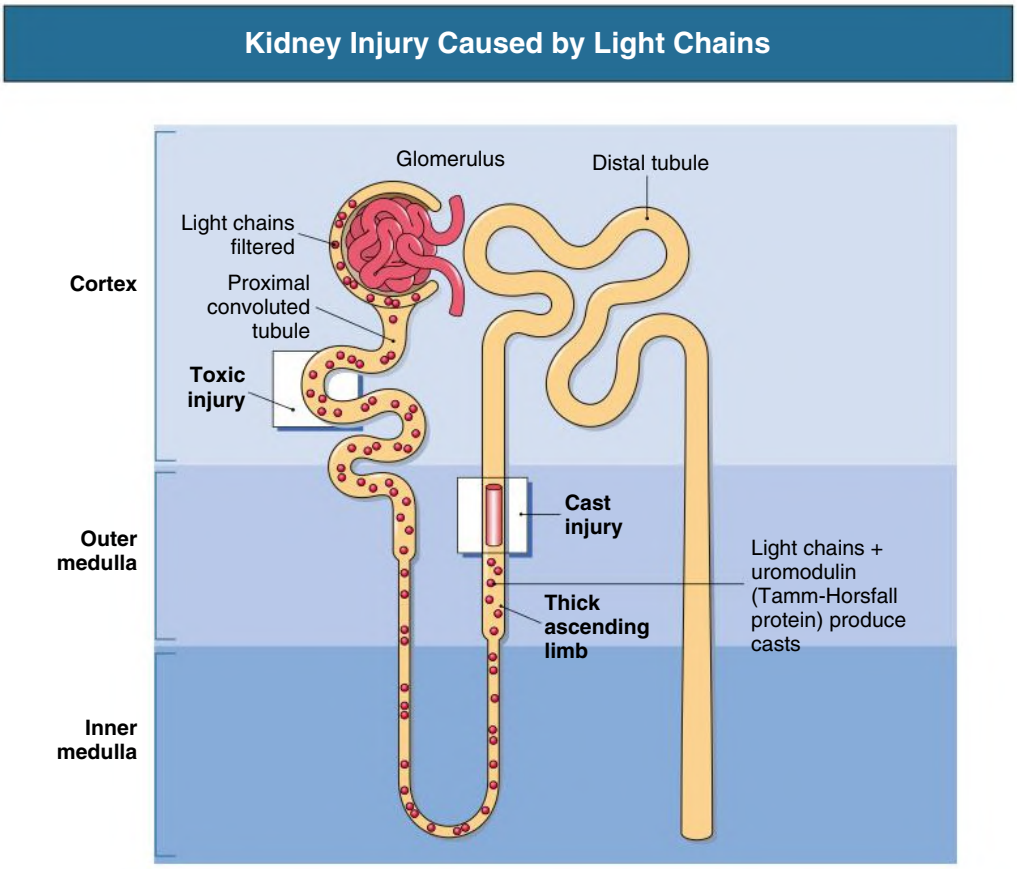

Fig. 68.2 Kidney Injury Caused by Light Chains. Sites *(white boxes)* where light chains injure the tubule. In the proximal tubule, there is direct tubular cytotoxicity. In the distal tubule, there is cast injury.

TABLE 68.2 Differentiating Features of Myeloma Kidney and Other Monoclonal Immune Deposition Diseases

	Myeloma Kidney	Other MIDDs
Proteinuria	<3 g/L	>3 g/L
Hematuria	Rare	LCDD, occasional Amyloidosis, rare
Hypercalcemia	Common	Absent
Hypertension	Uncommon	LCDD, common Amyloidosis, uncommon
Cytopenias	Anemia very common Leukopenia and thrombocytopenia, occasional	Uncommon
Immunoparesis[a]	Very common	Uncommon
Lytic bone lesions	Very common	Absent
Reduced GFR	Common	Common
Associated whole immunoglobulin	IgA, IgD, IgG	None
Type of light chain	Either	Amyloid λ > κ LCDD κ > λ
Serum light chain elevation	>500 mg/L	<500 mg/L

[a]Immunoparesis, reduction in noninvolved immunoglobulin classes.
Ig, Immunoglobulin; *LCDD,* light chain deposition disease; *MIDD,* monoclonal immunoglobulin deposition disease; *GFR*, glomerular filtration rate.

(IFE). The quantity of the M-protein is estimated from the SEP and may be used both for diagnosis and to monitor response to therapy. Urinary LC (Bence Jones protein) is determined from a concentrated sample, but despite this LC may be below the level of detection by IFE. The specific quantitative FLC assay (which measure only LC not bound to whole immunoglobulin in serum) is significantly more sensitive than SEP and IFE alone and is an automated assay that allows rapid diagnosis.[26,27] An abnormal monoclonal FLC increases the specific LC fraction and may suppress the other LC, which alters the normal ratio of FLC (0.26–1.65 κ/λ) to reflect the oversecretion of the abnormal LC clone (<0.26 for λ FLC clone, >1.65 for κ clone). The normal serum levels of FLC are very low (7–13 mg/L), but in patients with reduced GFR, accumulation of both (κ and λ) FLCs occurs as a result of reduced excretion, and because λ free light chains tend to circulate as dimers, their clearance is reduced more than the monomeric κ FLC. The use of an extended reference range of 0.37 to 3.1 improves diagnostic sensitivity for myeloma to 99% with 100% specificity in the presence of acute kidney failure requiring dialysis.[28] In patients with kidney failure and biopsy-proven cast nephropathy, the ratios are highly abnormal, and the absolute increase in the affected LC is of the order of 100 to 200 times normal with values greater than 500 mg/L at presentation and a median of 7000 mg/L[28,29] (Fig. 68.4). Measurement of serum FLC has significant advantages over SEP and IFE and is now incorporated into international clinical guidelines for the diagnosis and management of myeloma.[30]

Diagnostic difficulties can arise when elderly patients who are evaluated for newly diagnosed kidney impairment have an M-protein on routine SEP. Approximately 3% of the population older than 70 years

TABLE 68.3 Kidney Pathology in Patients With Myeloma

Histologic Finding	Prevalence (%)
Myeloma kidney (myeloma cast nephropathy)	30–50
Interstitial nephritis/fibrosis without cast nephropathy	20–30
Amyloidosis	10
Light chain deposition disease	5
Acute tubular necrosis	10
Other (urate nephropathy, tubular crystals, hypercalcemia, focal segmental glomerulosclerosis)	5

Spectrum of glomerular and tubulointerstitial renal lesions associated with monotypical immunoglobulin light chain deposition. *Lab Invest*. 1991;64(4):527–537.

BOX 68.1 Histologic Features of Myeloma Cast Nephropathy

- Many eosinophilic, often fractured casts (medullary portion of the distal nephron predominantly)
- Intratubular and interstitial macrophages and giant cells in response to casts
- Interstitial inflammation, fibrosis, tubular atrophy, crystalline inclusions
- Minimal glomerular abnormality
- Minimal or no vascular changes

will have a serum M-protein, most consistent with MGUS. A diagnosis of MGUS is more likely if the serum level of the M-protein is low (<3 g/dL), there is absent or very low urinary LC (<1 g/24 h), and the absence of end-organ injury (no lytic lesions, <10% plasma cells on bone marrow aspirate).[31] The FLC ratio should be normal using an extended reference range (0.82–3.6) for patients with eGFR less than 55 mL/min.[32] This distinction is important because most patients with MGUS will die of an unrelated disease, and only 1% a year progress to myeloma.[33] Previously it was considered that most kidney disease in patients with MGUS was unrelated to the M-protein.[34] However, it is now recognized that the spectrum of paraprotein and LC disorders associated with specific kidney diseases histologically noted on biopsy is extensive and heterogeneous, but most are not associated with the malignant clonal expansion characteristic of myeloma. These disorders are now described as MGRS (see Chapter 22).[2] Evidence suggesting an alternative cause of the kidney disease (most commonly diabetes or vascular disease), along with a period of observation, may clarify the significance of the M-protein, although kidney and/or bone marrow biopsy is often required when diagnostic uncertainty persists.[35]

NATURAL HISTORY

Most patients with reduced eGFR at presentation will show resolution of these predominantly functional changes with therapeutic measures that include withdrawal of nephrotoxins, rehydration, treatment of hypercalcemia, treatment of sepsis, and reduction in LC load with chemotherapy. Response to treatment with improvement in kidney function is associated with better clinical outcomes.[36] Reversibility occurs more frequently with higher GFR at presentation, lower LC excretion, and presentation with hypercalcemia. The number of casts and degree of interstitial fibrosis/tubular atrophy present at biopsy are independently associated with kidney recovery, itself associated with improved patient survival.[18] Although GFR improves in the majority of patients, approximately 10% of patients presenting with reduced GFR at diagnosis may require dialysis. Before the introduction of modern chemotherapy strategies, patients requiring dialysis had reported rates of recovery of kidney function as low as 5% to 15%. However, the introduction of specific LC reduction strategies has increased kidney recovery in up to 80% of patients if a significant reduction in the FLC level is achieved by day 21, with improvement in GFR and independence from dialysis being associated with improved patient outcomes.[37,38]

TREATMENT

There are three key issues in the management of MCN. The first is to suspect and diagnose myeloma in the differential diagnosis of AKI. The inclusion of serum FLC measurement for routine evaluation of otherwise unexplained AKI in the appropriate clinical circumstances is essential. This is because kidney injury in myeloma is directly related to FLC excess and the increased sensitivity and specificity of FLC measurement, along with its rapid availability, may implicate or refute myeloma as a likely diagnostic possibility well in advance of results from SPE/IFE or kidney biopsy. Early diagnosis is crucial to allow implementation of the second strategy, which is to prevent or reverse oliguria by rapid identification and management of possible contributing factors to kidney impairment, which are present in around 50% of patients. Hypercalcemia, sepsis, and nonsteroidal antiinflammatory agents (NSAIDs) are the most common precipitants. Intravenous volume expansion is helpful to increase glomerular filtration, reduce single-nephron LC concentration, and increase tubular flow. The use of furosemide to promote diuresis should be avoided because it may favor cast formation. There is no clinical evidence of the superiority of volume expansion with sodium bicarbonate over sodium chloride, although prevention of urinary acidification is in theory desirable and in severe kidney failure may be necessary for management of metabolic acidosis. The maintenance of a high fluid intake (3 L/d) with water after initial volume correction and restoration of urine output with intravenous crystalloid is recommended to maintain high urine flow rates.

The third key requirement is the rapid reduction of FLC in the serum by chemotherapy. The immediate initiation of high-dose dexamethasone 40 mg/d is recommended, because plasma cells are highly responsive to corticosteroids, which induce rapid apoptosis and lowering of LC concentration. The addition of newer chemotherapy strategies (see later discussion) with high immediate LC-lowering effects in combination with corticosteroids is critical to achieving a rapid response.[30] Reducing the LC load with plasma exchange did not improve either recovery from kidney failure or patient survival.[39] The large volume of distribution of LC (which freely cross cell membranes) is not well suited to plasma exchange. The use of high cutoff dialysis membranes (molecular cutoff up to 50 kDa), in conjunction with chemotherapy, was initially shown to be associated with a reversal of kidney failure and the rapid reduction in circulating FLC in patients with cast nephropathy.[38,40] However, two randomized controlled trials did not confirm an independent benefit of high cutoff membranes when combined with bortezomib chemotherapy, confirming that early response to chemotherapy is the more important factor.[41,42] A suggested algorithm for management of myeloma with AKI is shown in Fig. 68.5.

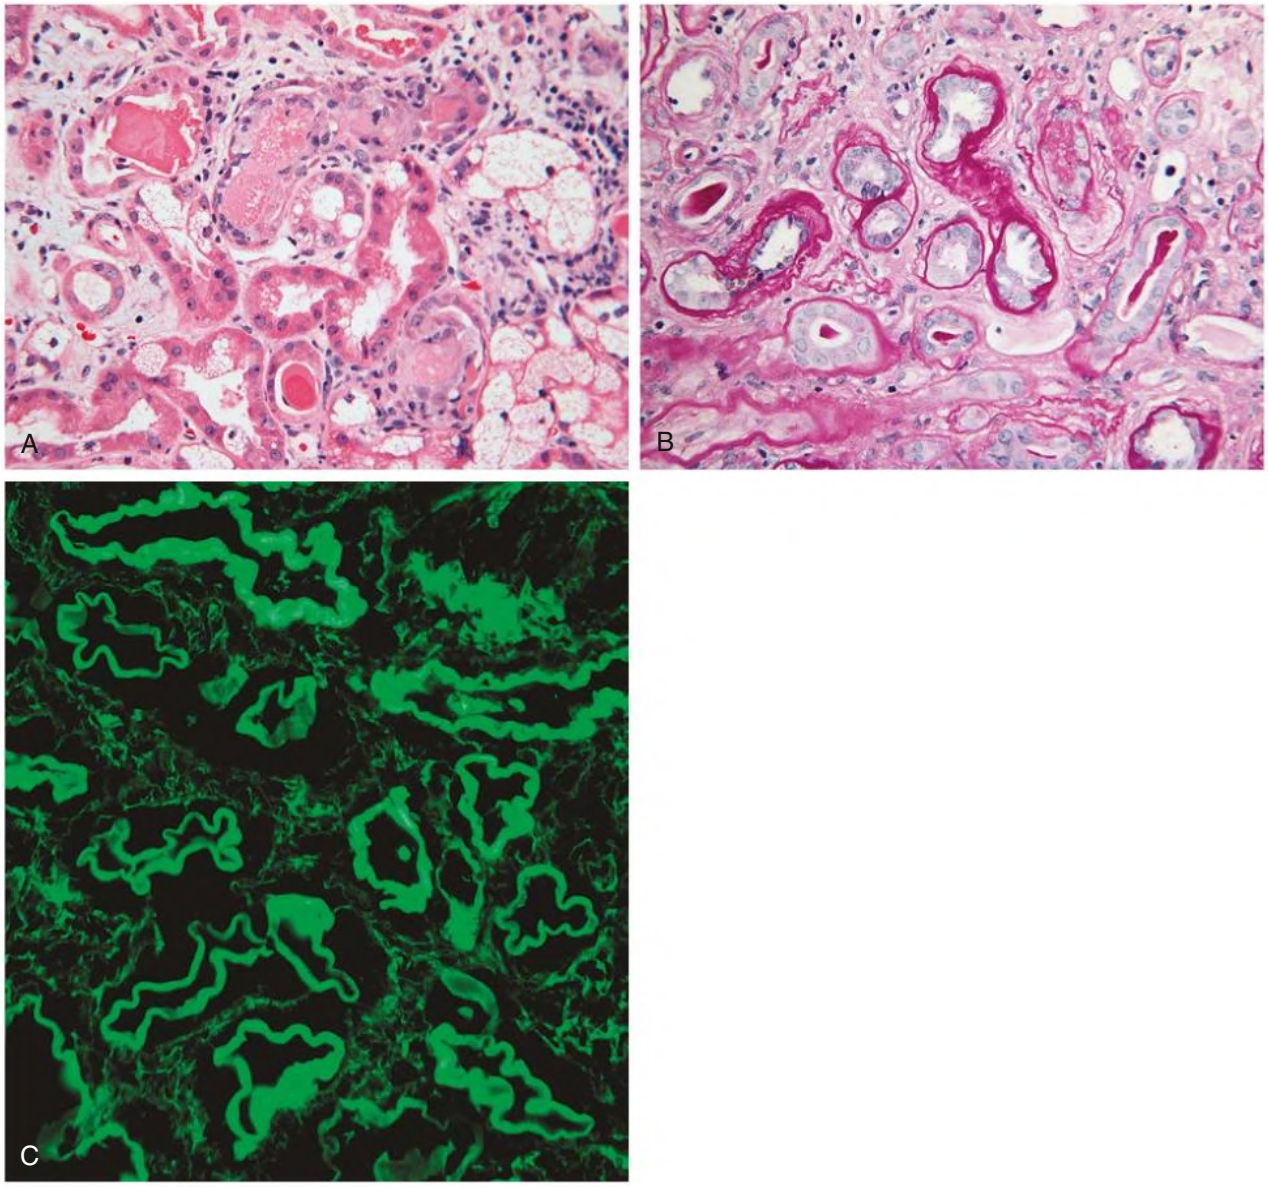

Fig. 68.3 Myeloma Cast Nephropathy. (A) Myeloma kidney. Many dilated tubules are obstructed by densely eosinophilic hard casts, with giant cell reaction and inflammatory cell infiltrates. There is also vacuolation and degeneration of tubules (hemoxylin and eosin stain; ×160). (B) Light chain deposition along tubular basement membrane (TBM) in myeloma kidney without casts. There is marked thickening of the TBM by periodic acid–Schiff (PAS)-positive deposits and interstitial fibrosis and mild chronic inflammation (PAS stain; ×160). (C) Light chain deposition along TBM. Strong linear deposition of κ light chain in the thickened TBM (direct immunofluorescence anti-κ light chain; ×160). (Courtesy R. Sinniah, Perth, Australia.)

Chemotherapy

Although myeloma is incurable, chemotherapy will induce clinical improvement by control of the underlying disease in most patients. Chemotherapy involves an immediate induction treatment followed by consolidation strategy after disease control. Bortezomib, a reversible proteasome inhibitor whose clearance is independent of kidney function, has been successfully and safely used in patients with kidney failure and myeloma without significant toxicity and is the agent of choice for rapid reduction of LCs in combination with dexamethasone.[30] Bortezomib lowers the LC load by direct effects on plasma cells and also may protect kidney proximal tubular cells by inhibiting activation of IL-6 and NF-κB induced by LC endocytosis.[43] Immunomodulatory drugs such as thalidomide, lenalidomide, and pomalidomide are also frequently used for induction (triple therapy), as consolidation therapy, or for relapsed disease in conjunction with dexamethasone.[3] Agents used for management of myeloma in patients with AKI are summarized in Table 68.4.[44] Autologous stem cell transplantation (ASCT) significantly extends survival and is now the treatment of choice for eligible patients.[30] Patients on dialysis are suitable for ASCT, which is associated with kidney recovery and freedom from dialysis, although with greater toxicity and increased morbidity and mortality.[45-47] For patients unsuited for ASCT, chemotherapy selection depends on comorbidity, and dexamethasone/lenalidomide may be useful. Close multidisciplinary management and discussion with hematology and oncology staff is required to individualize decision-making because of the continuous advances in this area.

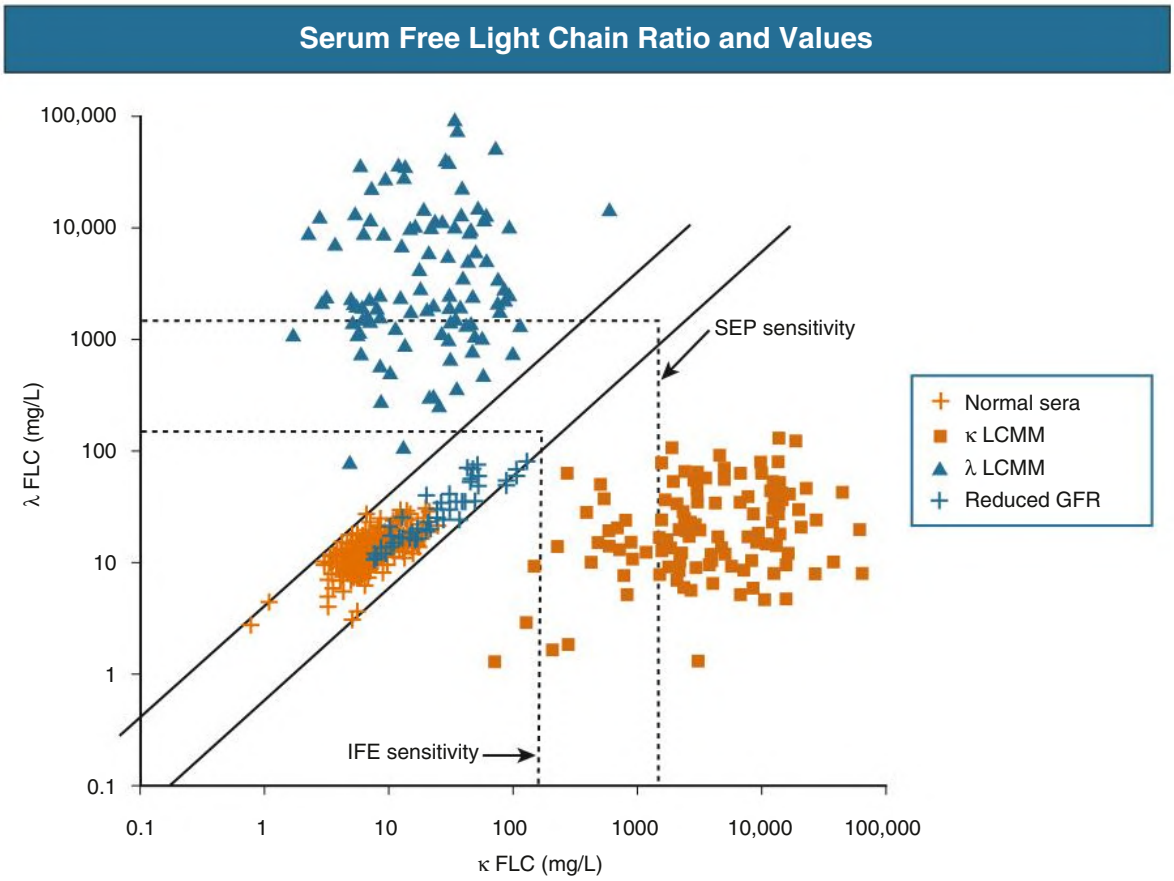

Fig. 68.4 Serum free light chain ratio and values in normal individuals, patients with reduced glomerular filtration rate (GFR) and light chain myeloma. *FLC,* free light chain; *IFE,* Immunofixation; *LCMM,* light chain multiple myeloma; *SEP,* serum protein electrophoresis.

Infection and progression of disease remain the major impediments to long-term survival in myeloma, especially within the higher-risk end-stage kidney disease (ESKD) group. Median survival in recent ESKD series with conventional chemotherapy before ASCT was only 4 to 8 months; however, survival of up to 7 years is reported in selected cases of ESKD managed with ASCT, and overall patient survival has improved with the advent of newer treatment strategies.[48,49] The improved overall management of myeloma with prolonged survival of patients will increase the referral of patients with relapsed and treatment-refractory disease presenting with MCN. The management of this patient group is challenging and must be individualized based on overall prognosis and potential for salvage chemotherapy and likelihood of benefit from dialysis.

Adjunctive Therapies

Patients with myeloma and chronic kidney disease or kidney failure respond to erythropoiesis-stimulating agents (although may require higher doses), and these should be used along with other hematopoietic agents, including granulocyte colony-stimulating factor (G-CSF) as required, although early in the disease frequent transfusion may be necessary. Intravenous bisphosphonates rapidly correct hypercalcemia and are preferred to furosemide (which may aggravate tubular LC injury) and in the longer term reduce bone fracture.[50] However, there are several reports of toxicity (acute tubular necrosis, proteinuria) with full dose and/or rapid infusion of pamidronate and zoledronic acid; the use of reduced doses (pamidronate 30–60 mg, zoledronic acid 4 mg) and slower infusion rates is recommended.[51,52] Alternatively, bisphosphonates could be avoided in patients with eGFR less than 30 mL/min/1.73 m^2 by using denosumab to manage hypercalcemia.[53]

DIALYSIS AND TRANSPLANTATION

Where kidney replacement therapy is required in the long term, both hemodialysis and peritoneal dialysis have been successfully used and there are no data to indicate that outcome is influenced by dialysis modality. Choice of long-term therapy requires individual assessment of patient circumstances. Aggressive measures to reduce the risk for systemic infection (antibiotic catheter locking solutions; mupirocin at exit sites) should be routinely considered because initially central venous catheters are often required for dialysis and chemotherapy. The timing of arteriovenous fistula placement requires an individualized risk assessment because it may be several months before irreversibility of kidney failure or a response to chemotherapy is proven. Kidney transplantation has a high risk for disease recurrence in the allograft and patient mortality, and given the incurability of the disease, has rarely been appropriate.[54] Current advances in chemotherapy and prolonged patient survival have prompted reconsideration of the role, timing, and management of kidney transplant.[55] The use of kidney transplant after successful induction therapy and ASCT may be considered for younger patients when disease remission by standard criteria and normalization of the serum FLC ratio is achieved. Allogeneic bone marrow and kidney allograft transplant have been reported, demonstrating the ability to induce allograft tolerance in haploidentical pairs.[56] This treatment is limited in availability and is not suitable for the majority of patients.

TABLE 68.4 Chemotherapeutic Drugs Used in Myeloma and Kidney Failure

Class	Agent	Route of Administration	Dose Reduction for CrCl <30 mL/min/1.73 m^2	Side Effects
Corticosteroids	Dexamethasone, Prednisone	PO/IV	None	Standard
Alkylating agents	Melphalan	PO/IV	Yes	Bone marrow suppression, infection
	Cyclophosphamide	PO/IV	No	
Immunomodulatory drugs	Thalidomide	PO	No	Neuropathy, venous thrombosis, hyperkalemia, cytopenias
	Lenalidomide	PO	Yes	
	Pomalidomide	PO	No	
Proteasome inhibitors	Bortezomib	IV/SC	None	Neuropathy, cytopenias, TMA
	Carfilzomib	IV	No	
	Ixazomib	PO	Yes	
Anti-CD38 monoclonal antibodies	Daratumumab	IV	No	Cytopenias
	Isatuximab			

CrCl, Creatinine clearance; *IV,* intravenously; *PO,* orally; *SC,* subcutaneously; *TMA,* thrombotic microangiopathy.

SELF-ASSESSMENT QUESTIONS

1. Kidney injury in patients with myeloma is most usually due to an excess of which of the following?
   A. Calcium
   B. Uric acid
   C. Light chains
   D. Immunoglobulins
   E. β_2-Microglobulin
2. What is the most common histologic lesion noted in patients with acute kidney injury and myeloma?
   A. Amyloidosis
   B. Light chain deposition disease
   C. Cast nephropathy
   D. Urate nephropathy
   E. Tubular crystals
3. In addition to corticosteroids, which therapy should be commenced urgently for the management of myeloma cast nephropathy?
   A. Vincristine
   B. Adriamycin
   C. Melphalan
   D. Cyclophosphamide
   E. Bortezomib
4. A 72-year-old man has a 3-month history of back pain and is managed with nonsteroidal antiinflammatory agents. He presents with anemia, hypercalcemia, and acute kidney injury. You suspect myeloma. What is the most appropriate investigation to rapidly confirm the diagnosis?
   A. Urine Bence Jones protein
   B. Serum protein electrophoresis
   C. Serum immunoglobulins
   D. Serum free light chains
   E. Kidney biopsy

Kidney Disease in Liver, Cardiac, Lung, and Hematopoietic Stem Cell Transplantation

Amanda DeMauro Renaghan, Claire Kennedy, Colm C. Magee

Kidney disease can complicate all forms of nonrenal solid organ transplantation (SOT) and is associated with longer hospitalization, higher morbidity and mortality, and greater expense. Although there are organ-specific factors that impact on the incidence and severity of kidney disease, some useful generalizations can be made.

GENERIC KIDNEY ISSUES IN NONRENAL SOLID ORGAN TRANSPLANTATION

Estimation of Glomerular Filtration Rate

Transplant candidates and recipients often have low muscle mass and low creatinine generation. Hence, a mildly elevated creatinine concentration may represent a markedly reduced glomerular filtration rate (GFR). Such patients should have their GFR estimated by 24-hour urinary creatinine clearance (which will tend to overestimate because of tubular secretion) or, preferably, measured directly by iothalamate or other radioisotopes. Of the various creatinine-based equations that estimate GFR, the Chronic Kidney Disease Epidemiology Collaboration (CKD-EPI) and Modification of Diet in Renal Disease (MDRD) equations appear to correlate best with true posttransplantation GFR.[1]

Calcineurin Inhibitor Nephrotoxicity

Calcineurin inhibitors (CNIs; e.g., cyclosporine, tacrolimus) are the cornerstone of immunosuppression in SOT recipients, but also directly contribute to acute kidney injury (AKI) and CKD. CNIs also exacerbate posttransplantation hypertension and diabetes, both of which can cause CKD in the long term. It is probable that CNI nephrotoxicity is more severe in nonrenal (than kidney) transplantation because higher blood concentrations of CNIs may be used; furthermore, the denervated transplanted kidney may be protected from early sympathetic-mediated injury.[2]

Acute CNI nephrotoxicity is mainly a prerenal syndrome caused by reversible vasoconstriction of the afferent glomerular arteriole; tubular damage and microvascular disease may occur in severe cases. Acute CNI-induced thrombotic microangiopathy (TMA) is rare after SOT but is associated with a poor prognosis. In many cases TMA is precipitated by excessively elevated blood levels of CNI, or by infection, allograft rejection, or addition of a mammalian target of rapamycin (mTOR) inhibitor to CNI-based immunosuppression. Treatment usually involves discontinuation of the CNI (and/or mTOR inhibitor).

Electrolyte and other metabolic disturbances may be seen with acute and/or chronic CNI toxicity. Hyperkalemia, hyperuricemia, metabolic acidosis, and hypomagnesemia have been described, due to effects on renal tubular function.

Chronic CNI nephrotoxicity is probably the result of prolonged kidney ischemia and other effects, such as direct stimulation of kidney fibrogenesis. The patient is typically hypertensive with a steady fall in GFR, most marked in the first 6 to 12 months after transplantation (Fig. 69.1).[2,3] Urinalysis usually shows minimal/no hematuria and minimal/mild proteinuria. In practice, biopsies are often reserved for those with clinical features suggestive of a kidney disorder other than CNI toxicity.

Histologic examination shows changes in all compartments with "striped" interstitial fibrosis and tubular atrophy, arteriolar hyalinosis, arteriosclerosis, and secondary focal glomerulosclerosis.[2] There may also be features of chronic TMA.[2] However, these "typical" histologic findings of CNI toxicity are nonspecific, making it difficult to estimate the actual contribution of CNI toxicity to posttransplant CKD.

The presumed high prevalence of chronic CNI nephrotoxicity has generated interest in low- or zero-dose CNI protocols (discussed later).[2] There remains reluctance to pursue these protocols because CNIs are such effective immunosuppressants, and organ replacement therapy analogous to dialysis is not available for other SOT recipients if severe rejection occurs. Another strategy is to preferentially use tacrolimus over cyclosporine, given that tacrolimus provides equivalent or superior immunosuppression with less nephrotoxicity.[4] The roles of calcium channel blockers, renin-angiotensin system (RAS) blockers, and spironolactone in ameliorating CNI nephrotoxicity remain controversial. Control of hypertension is probably more important than the use of a particular antihypertensive agent.

Pretransplant Acute Kidney Injury

AKI is common in the days to weeks immediately before liver, heart, or (less commonly) lung transplantation and is typically prerenal (e.g., kidney hypoperfusion or hepatorenal syndrome), intrarenal (ischemic or toxic tubular injury), or a combination. Management focuses on treatment of the underlying cause and provision of dialytic support according to standard criteria. Because the patients are critically ill, continuous renal replacement therapy (CRRT) may be preferred to intermittent hemodialysis (HD), but there are no randomized controlled trials (RCTs) showing better outcomes with CRRT.

When severe or prolonged AKI occurs before anticipated transplantation, estimation of reversibility becomes very important, because presumed irreversible severe AKI shifts the management toward simultaneous dual-organ (e.g., liver plus kidney) transplantation. Kidney biopsy may help prognosticate but is not commonly performed because of technical difficulties in critically ill patients, who often also have coagulopathy.

The advantages and disadvantages of dual-organ transplantation are shown in Box 69.1. There is uncertainty about whether dual organ transplantation represents the best use of scarce donor organs, and some suggest prioritizing kidney transplantation after SOT instead. Liver, lung, and heart allocation is based on medical urgency, whereas kidney allocation is generally based on waiting time and immunologic factors. As a result, multiorgan transplants assume the priority of the

Changes in Measured Iothalamate GFR in Individual Patients After Lung Transplantation

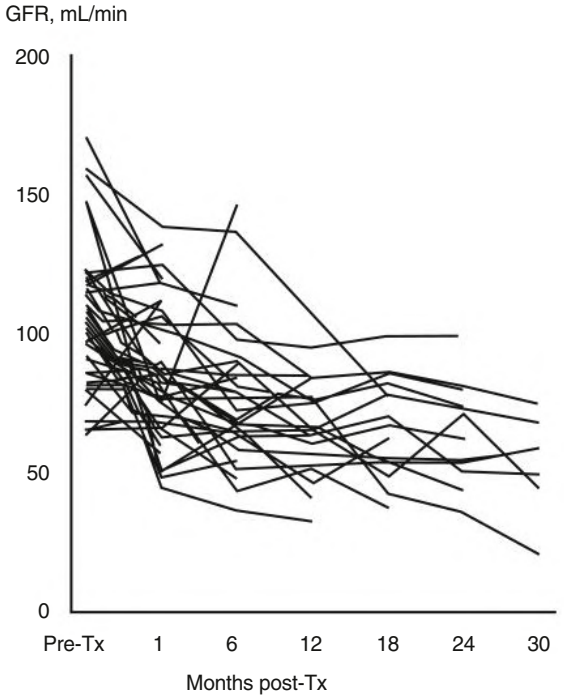

Fig. 69.1 Changes in Measured Iothalamate Glomerular Filtration Rate (GFR) in Individual Patients After Lung Transplantation. Note the variation in GFR before transplant and the large fall in GFR in many patients within the first 6 months. *Tx,* Transplantation. (Modified from Navis G, Broekroelofs J, Mannes GP, et al. Renal hemodynamics after lung transplantation. A prospective study. *Transplantation.* 1996;61[11]:1600–1605.)

BOX 69.1 Advantages and Disadvantages of Simultaneous Kidney and Nonrenal Transplantation

Advantages
- Potentially provides much better kidney function over the short and long term
- Single donor: potential for lower cumulative dose of immunosuppression (as opposed to kidney transplantation later)

Disadvantages
- Surgery is more technically complex and prolonged
- Deprives patients with "definite" end-stage kidney disease of a kidney transplant
- Not needed when the acute kidney injury is reversible

nonkidney organ and may therefore divert kidneys from those with "definite" end-stage kidney disease (ESKD), who may wait a long time for a kidney-only transplant. The kidney in a multiorgan transplant typically has a low kidney donor profile index (KDPI), again diverting these kidneys from the kidney-only wait list, where they would have likely been offered to pediatric recipients or other priority groups.[5] Recent guidelines and policy updates have tried to address some of these controversies and are discussed later.[5,6]

BOX 69.2 Causes of Acute Kidney Injury After Solid Organ Transplantation

Prerenal
- Hypovolemic shock (e.g., aggressive diuresis)
- Cardiogenic shock (e.g., severe cardiac allograft dysfunction)
- Distributive shock (e.g., sepsis)
- Cyclosporine or tacrolimus

Intrarenal (Acute Tubular Injury)
- Prolonged shock
- Cyclosporine or tacrolimus
- Aminoglycosides, amphotericin
- Intravenous contrast
- Massive hemolysis

Postrenal
- Rare

Posttransplant Acute Kidney Injury

AKI is common in the days to weeks after transplant and is often multifactorial (Box 69.2). It is associated with higher mortality and increased risk for CKD in survivors.[7] Delayed introduction or reduced doses of CNIs may be used, usually under the cover of induction antibody immunosuppression.[7]

Passenger lymphocyte syndrome is uncommon but can occur in the early weeks after transplant (usually liver, but also other SOT) in the setting of a minor ABO or other blood group system mismatch. Donor lymphocytes ("passengers" with the transplant) produce anti–blood group antibodies, which cause hemolysis. Severe cases may be complicated by AKI.

Severe rhabdomyolysis has been reported, typically when a statin is prescribed with cyclosporine and an inhibitor of the cytochrome P-450 system, such as diltiazem or an azole-based antifungal agent.

BK polyomavirus nephropathy should be considered in the differential diagnosis of unexplained kidney dysfunction after SOT, especially in the context of intensive immunosuppression. However, the absolute risks of BK viremia and nephropathy remain low, and routine screening is not recommended.[8]

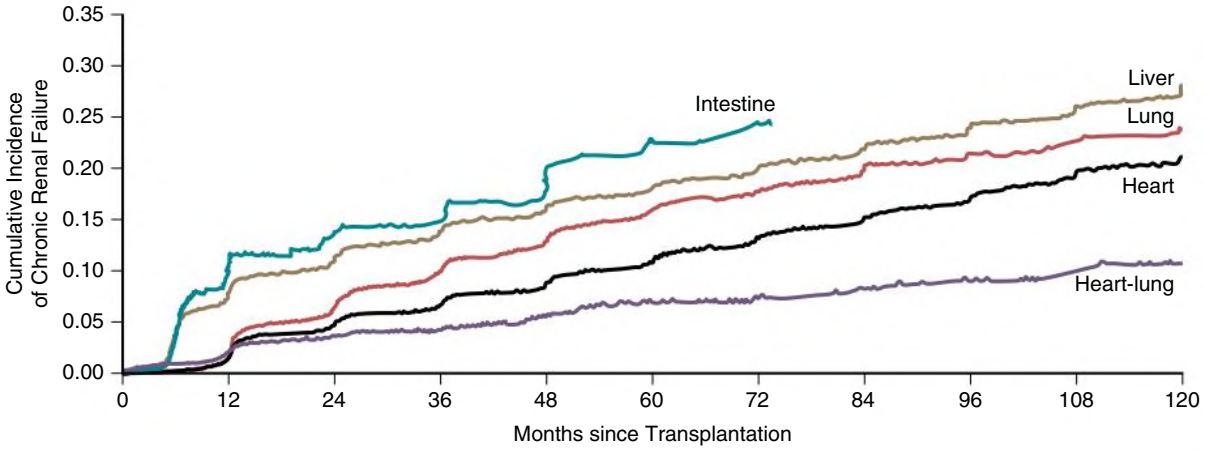
Chronic Kidney Disease

With the growing number and longer survival of transplant recipients worldwide, the absolute number of recipients with CKD has increased. The CKD-EPI equation (despite its limitations) is useful in identifying CKD in this setting.

In the most comprehensive study to date, the cumulative incidence of posttransplant CKD (defined as estimated GFR < 30 mL/min/1.73 m^2) at 5 years varied according to organ transplanted, from 6.9% (heart-lung) to 21.3% (intestinal) (Fig. 69.2).[7] Pretransplant variables that increase the risk for CKD include older age, female sex, lower GFR, diabetes, hypertension, hepatitis C virus, and need for dialysis. Posttransplant variables were also implicated: postoperative AKI and initial use of cyclosporine (as opposed to tacrolimus). Minimizing posttransplantation AKI and controlling hypertension and diabetes are therefore likely to prevent or slow CKD. Many studies have confirmed that CKD (particularly ESKD) after SOT portends a poor prognosis (Fig. 69.3), as well as increased hospitalization and infection rates.

Referral to a nephrologist should be considered in those with progressive decline in eGFR. The initial evaluation should include a thorough review of kidney function pre- and peritransplant, as well as exposure to nephrotoxins. If urinalysis shows moderate/severe

Cumulative Incidence of Stage 4 or 5 Chronic Kidney Disease in Nonrenal Organ Transplant Recipients



No. at Risk

Mortality Associated With Chronic Kidney Disease in Organ Transplant Recipients

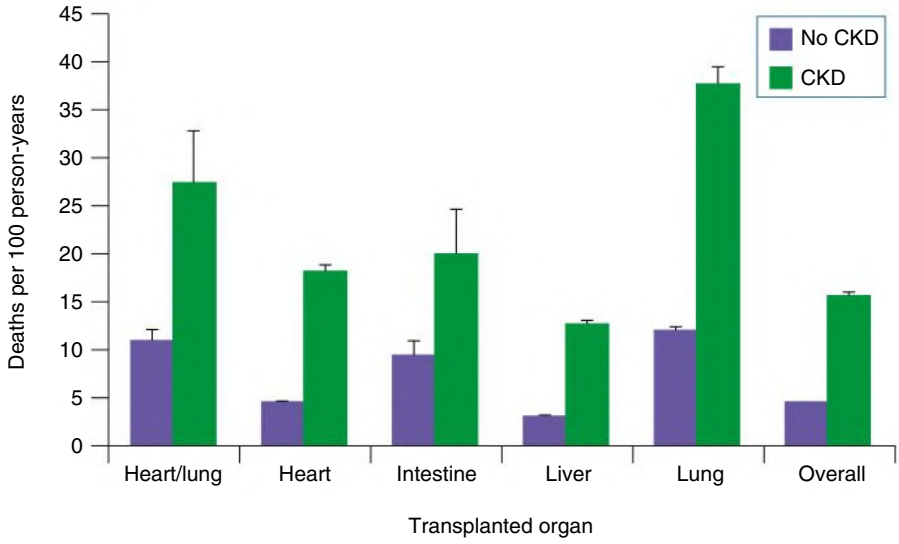

Fig. 69.3 Mortality associated with stage 4 and 5 chronic kidney disease (CKD) in organ transplant recipients. (From Scientific Registry of Transplant Recipients.)

proteinuria or hematuria or both, biopsy should be considered, as it may identify pathologies other than CNI nephrotoxicity.

Close consultation with the primary transplant team is important. When CNI toxicity is deemed the main cause of CKD, several approaches can be taken to reduce ongoing CNI toxicity and CKD progression.

A reduction in CNI dosage with a compensatory increase in antimetabolite dosing for patients at low immunologic risk should be considered. If the patient is on a cyclosporine-based regimen, a switch from cyclosporine to tacrolimus may be beneficial. An alternative strategy (one that we favor less) is to substitute an mTOR inhibitor for the CNI. This approach is not recommended in the early posttransplant period because of the impact of mTOR inhibitors on wound/anastomosis healing. The mTOR inhibitors themselves have some important kidney adverse effects: experimental models demonstrate delayed recovery from AKI due to effects on tubular cell proliferation. The mTOR inhibitors also potentiate the nephrotoxicity of cyclosporine when coadministered and can induce or exacerbate proteinuria.

CKD complications may be exacerbated by other posttransplant factors. For example, antiproliferative immunosuppressants may exacerbate anemia, and corticosteroids may exacerbate CKD-related mineral and bone disorder (CKD-MBD). In the absence of specific studies, it seems reasonable to apply standard guidelines to manage these and other CKD complications. Although there is experimental evidence that RAS blockers may have antifibrotic effects in nonrenal transplant CKD, there are no trials showing improved kidney outcomes with these compared with other antihypertensive agents.

End-Stage Kidney Disease

There is little doubt that kidney transplantation is the best form of RRT in SOT recipients with advanced CKD who are fit enough for the procedure. Where feasible, a preemptive living donor transplant is the best option. Maintenance immunosuppression is typically increased in the perioperative period; induction immunosuppression is not without risk and is not used in all cases.[9] In the immediate posttransplant period, mortality is higher than remaining on the waiting list (reflecting the complications of surgery and more immunosuppression), but mortality in the medium to long term is much lower.[7] The number of patients with a nonrenal transplant subsequently wait-listed for a kidney transplant in the United States has increased dramatically over the last 15 years.[10] Mortality is much higher in SOT recipients wait-listed for kidney transplant than in wait-listed controls.[10]

Patients who do not receive a preemptive kidney transplant start dialysis for the usual indications. Home dialysis (home hemodialysis and peritoneal dialysis) should be explored and modality choice individualized for each patient.[11]

KIDNEY DISEASE IN LIVER TRANSPLANTATION

AKI in cirrhosis has been defined as an absolute rise in serum creatinine of 0.3 mg/dL or greater (≥26.5 μmol/L) within 48 hours or a 50% or greater increase from baseline over 7 days.[12] AKI is common before liver transplantation and is usually due to hepatorenal syndrome (HRS), acute tubular necrosis (ATN), or both. Prolonged HRS may cause ATN.

If RRT is required in patients with severe HRS, CRRT is often preferred, in part because it may have less effect on intracranial pressure than intermittent dialysis. The need for dialysis in liver transplant candidates portends a very poor prognosis if liver transplantation does not occur.[13] Some centers use intraoperative CRRT during liver transplantation in patients with severe preoperative AKI who are predicted to tolerate the surgery poorly from a volume or electrolyte perspective. This practice remains somewhat controversial.[14]

The Model for End-Stage Liver Disease (MELD) scoring system measures severity of liver dysfunction based on international normalized ratio, serum creatinine and bilirubin, and predicts 90-day mortality risk. The MELD-Na score includes sodium to further refine the short-term prognosis and has become the tool of choice to guide allocation of deceased donor liver allografts in many jurisdictions. As both tools include serum creatinine, patients with severe AKI are prioritized.

Posttransplantation AKI occurs in over 60% of recipients of donation after circulatory death (DCD) grafts and approximately 40% of recipients of donation after brain death (DBD) grafts or living donor grafts.[15] Requirement for RRT is associated with higher mortality rates.

Although relatively low doses of CNIs are traditionally used in liver transplantation (because rejection is less of a concern than in other SOT), CKD remains common, suggesting other factors (such as diabetes and hepatitis virus-associated glomerulonephritis) play an important role.

Various protocols involving reduction or cessation of CNIs have been studied with mixed results. Induction with interleukin-2 (IL-2) receptor blockers, and maintenance with mycophenolate mofetil (MMF), corticosteroid, and delayed (day 5) introduction of low-dose tacrolimus was less nephrotoxic than other regimens while maintaining excellent allograft and patient outcomes.[16] Conversion to sirolimus does not have clearly proven benefits and is associated with certain risks, and so is not routinely performed. CNI withdrawal to MMF monotherapy was shown to be a reasonable option for selected patients who were several years out from transplant.[17]

The number and percentage of simultaneous liver-kidney (SLK) transplants in the United States have increased since the MELD score was adopted into allocation policy, such that over 700 SLK transplants are performed annually (>8% of all liver transplants).[6] This is much higher than in many other jurisdictions (e.g., Canada, United Kingdom), where SLK accounts for fewer than 2% of all liver transplants.

Although selected patients with severe pretransplant kidney disease benefit from SLK transplant, it can be difficult to predict which patients are likely to have meaningful kidney recovery without kidney transplant. Prognostication is further complicated by the risk of kidney biopsy in this patient cohort.

In the United States the Organ Procurement and Transplantation Network (OPTN) has provided updated clinical recommendations (which do not mandate a kidney biopsy) as to who should receive SLK transplants (Box 69.3).[6] This policy also includes a safety net of priority for kidney transplant in those patients who have advanced CKD following liver transplantation (eGFR ≤ 20 mL/min/1.73 m^2 or dialysis dependent and registered on the kidney transplant wait list in the first year post–liver transplant). The Canadian Forum guidelines suggest that patients are eligible for SLK if they are dialysis dependent for more than 3 months. They are "possibly eligible" (determined on a case-by-case basis) if they are on dialysis for a shorter time or if they have an eGFR less than 30 mL/min/1.73 m^2 for more than 1 month.[5]

BOX 69.3 UNOS and OPTN Policy Regarding Candidacy for Simultaneous Liver-Kidney Transplant in Patients Listed for Liver Transplant

- CKD defined as GFR ≤60 mL/min/1.73 m^2 for >90 consecutive days and one of the following:
  - Dialysis dependence (ESKD)
  - GFR ≤30 mL/min/1.73 m^2 at transplant wait-listing
- AKI defined as ≥6 weeks of one or a combination of the following:
  - GFR ≤25 mL/min/1.73 m^2 at least once every 7 days
  - Dialysis at least once every 7 days
- Specific metabolic diseases
  - Hyperoxaluria
  - Atypical hemolytic uremic syndrome (from factor H or I deficiency)
  - Methylmalonic aciduria
  - Familial nonneuropathic systemic amyloidosis

Modified from Boyle G. Simultaneous Liver Kidney (SLK) Allocation Policy. https://optn.transplant.hrsa.gov/media/1192/0815-12_SLK_Allocation.pdf.

KIDNEY DISEASE IN CARDIAC TRANSPLANTATION

Preoperative AKI is common, and approximately 1% of heart transplant recipients require RRT before transplantation.[7] The main cause of AKI is kidney hypoperfusion from severe congestive heart failure (type 1 cardiorenal syndrome). In some patients there may also be a component of CKD for a variety of reasons, including chronic hypoxia, renovascular disease, hypertension, and atheroembolism. Ventricular assist devices are increasingly used as a bridge to cardiac transplantation and may improve kidney perfusion and function in this setting.

Postoperative AKI is also common, with 5% to 30% of cardiac transplant recipients requiring dialysis, depending on patient- and center-specific characteristics.[18] There is a strong association between the severity of postoperative AKI and both mortality and kidney dysfunction at 1 year.[18] In addition to the causes shown in Box 69.2, risk factors for AKI after cardiac transplant surgery are prolonged aortic cross-clamping, large fluid volume shifts, prolonged cardiac allograft ventricular dysfunction, postoperative bleeding, and reexploration.

CKD is an important complication in the medium to long term and portends a worse prognosis[19] (see Fig. 69.2). The cumulative incidence of stage 4 or stage 5 CKD in cardiac transplant recipients has been reported as 11% at 5 years, which is lower than in bowel, liver, or lung transplant recipients.[7]

The principal cause of CKD after cardiac transplantation is CNI toxicity. A number of studies have assessed the impact of CNI modification, reduction, or withdrawal after cardiac transplantation. A small RCT compared tacrolimus to cyclosporine and reported a favorable side effect profile (including kidney function) with tacrolimus, with similar survival and rejection rates.[20] Since this study, tacrolimus use has continued to increase (and the use of cyclosporine greatly decreased), such that more than 95% of cardiac transplant recipients now receive tacrolimus-based immunosuppression.[21] Despite some encouraging short- and medium-term results with everolimus and reduced CNI dosing in patients at low immunologic risk, fewer than 10% of cardiac transplant recipients receive an immunosuppression regimen that includes everolimus or sirolimus.[22]

The absolute number of simultaneous heart-kidney transplants remains low but is steadily increasing in the United States (in 2018 approximately 7% of total heart transplants).[23] The criteria for simultaneous heart-kidney transplant eligibility are generally less well-defined than in the case of SLK, and the SLK criteria (Box 69.3) are often used as a reference point.[8]

KIDNEY DISEASE IN LUNG TRANSPLANTATION

Preoperative AKI is less common, with 0.1% of lung transplant recipients requiring dialysis before transplantation.[7] Postoperative AKI is common and associated with significantly reduced survival. A systematic review and meta-analysis showed that approximately 53% of patients had postoperative AKI (KDIGO criteria), and 9.3% required RRT after lung transplantation.[24]

AKI can occur for the usual reasons (see Box 69.2), but factors specific to lung transplantation include aggressive diuresis and nephrotoxic antimicrobial agents for resistant infections (e.g., aminoglycosides, amphotericin). Acute oxalate nephropathy leading to irreversible kidney failure has been described. It is thought that enteric hyperoxaluria is caused by either prolonged antibiotic administration (which interferes with colonic flora) and/or cystic fibrosis–related pancreatic exocrine insufficiency.[25] Although probably rare, this "new disease" emphasizes the importance of maintaining a broad differential diagnosis for kidney disease occurring after SOT and the importance of biopsy when the clinical manifestation is unusual.

CKD, although often underappreciated, is common in the first year after lung transplantation, and the incidence increases thereafter. As with other forms of posttransplantation CKD, the most common cause is probably CNI toxicity. CNI dosages tend to be higher because of the increased risk for rejection in lung transplantation. Although CNI withdrawal is poorly tolerated in this setting, a few studies have reported improvements in GFR when doses of CNIs were reduced. CNI reduction should be accompanied by addition/optimization of MMF. De novo use of mTOR inhibitors is not recommended because they may be associated with breakdown of the bronchial anastomosis; later use is associated with pneumonitis. Simultaneous lung-kidney transplantation is very rarely performed.

KIDNEY DISEASE IN HEMATOPOIETIC STEM CELL TRANSPLANTATION

Hematopoietic stem cell transplantation (HSCT) involves the administration of chemotherapy with or without radiotherapy, followed by bone marrow engraftment of stem or progenitor cells.[26,27] Most commonly, HSCT is used to treat hematologic malignancies; however, other indications include certain solid tumors, nonmalignant hematologic conditions (e.g., aplastic anemia, sickle cell disease), genetic immunodeficiencies, and inborn errors of metabolism.[28] Stem and progenitor cells may be harvested from peripheral blood, bone marrow, or umbilical cord blood, and may come from the affected patient (*autologous*) or a related or unrelated donor (*allogeneic*). In both *myeloablative* autologous and allogeneic HSCT, intensive pretransplant conditioning regimens using high-dose chemotherapy and radiation are given to eradicate the bone marrow and underlying cancer; the hematopoietic system is then reconstituted by infusion and engraftment of transplanted cells. Patients not eligible for aggressive myeloablative therapy because of older age or comorbidities may be candidates for *nonmyeloablative* (low-intensity) or *reduced-intensity conditioning* (RIC; intermediate intensity) regimens. These less toxic conditioning regimens provide sufficient immunosuppression to permit the engraftment of transplanted cells, which then target tumor cells (the graft-versus-tumor effect).[29] Both myeloablative and nonmyeloablative allogeneic transplantation (but not autologous transplantation) require posttransplant immunosuppression to prevent acute and chronic graft-versus-host disease (GVHD); CNIs are often prescribed for this purpose.

Acute Kidney Injury After Hematopoietic Stem Cell Transplantation

Epidemiology

AKI is a common complication of HSCT, with reported incidence and severity varying by the conditioning regimen (myeloablative > nonmyeloablative), type of transplant (allogeneic > autologous), and definition of AKI used (Table 69.1). It is most common (>70% of patients in some series) after myeloablative allogeneic HSCT, likely reflecting the longer period of profound immunosuppression (with associated risk of sepsis) and much greater risk of hepatic sinusoidal obstruction syndrome (SOS), previously called venoocclusive disease (VOD) of the liver, compared with nonmyeloablative allogeneic regimens.[27,30] Autologous transplantation carries the lowest risk of AKI (approximately 20%); this has been attributed to more rapid engraftment, the absence of GVHD, and lack of CNI exposure.[31] AKI after HSCT confers poor short- and long-term prognoses.

The incidence of dialysis-requiring AKI ranges from 0% (autologous) to 33% (myeloablative allogeneic), with approximately 5% of patients requiring RRT overall. The prognosis is very poor for those

TABLE 69.1 Three Types of Hematopoietic Stem Cell Transplantation and Their Associated Kidney Complications

	Myeloablative Allogeneic	Myeloablative Autologous	Nonmyeloablative Allogeneic
Diseases treated	Many leukemias, lymphomas, myelodysplastic syndromes, myeloproliferative neoplasms, multiple myeloma, marrow failure states (e.g., aplastic anemia), select inherited immunodeficiencies, metabolic disorders, and hemoglobinopathies	Multiple myeloma, lymphomas, germ cell tumors, neuroblastoma	As for myeloablative allogeneic type
Used in patients >60 years	Rarely	Sometimes	Often
Comorbidities permissible before HSCT	Minimal	Minimal	Some
Intensity of conditioning regimen	High	High	Low (intermediate for RIC regimens)
GVHD after HSCT	Common	None	Common
CNIs used routinely	Yes	No	Yes
Mortality	Moderate-high	Low	Moderate-high
Risk of relapse	Lower	Higher	Lower
Incidence of AKI[36]	Very common (19%–66%)	Common (12%–50%)	Common (29%–54%)
Causes of AKI	Hepatic SOS, shock syndromes, nephrotoxic drugs, CNIs, acute TMA	Shock syndromes, nephrotoxic drugs, occasionally hepatic SOS	Shock syndromes, nephrotoxic drugs, CNIs, acute TMA
Incidence of CKD	Common	Common	Mild forms probably common
Causes of CKD	Irreversible AKI, kidney TMA, CNIs, GVHD	Irreversible AKI, pretransplant CKD (e.g., kidney involvement by amyloidosis or multiple myeloma)	Pretransplant mild CKD, irreversible AKI, CNIs, GVHD

requiring dialysis (early mortality >80%).[27,31] Fortunately, rates of post-HSCT AKI are decreasing, likely due to multiple improvements in peritransplant care.

Etiology

It is helpful to consider the causes of AKI according to the period after HSCT (Box 69.4).[26] *Tumor lysis syndrome* is an immediate but rare complication after HSCT, as the cancer is often eliminated by the time of transplant. *Marrow infusion syndrome* occurs within 24 to 48 hours of stem/progenitor cell infusion when patients are exposed to products of red blood cell lysis (released during cryopreservation), as well as the cryoprotectant dimethyl sulfoxide (DMSO), leading to intratubular pigment cast formation and/or toxic ATN.[32] This complication is now infrequent, likely related to advances in cell preservation.

Within the first few weeks of HSCT, when intense conditioning regimens have caused pancytopenia, mucositis, vomiting, and liver damage, recipients are at high risk of many forms of AKI. These include prerenal syndromes (e.g., hypovolemia, capillary leak syndrome, engraftment syndrome, hepatic SOS) and acute tubular injury from sepsis. Medication-induced nephrotoxicity may take the form of acute tubular injury (aminoglycosides, amphotericin B, intravenous iodinated contrast), crystal-induced tubular toxicity (acyclovir, sulfonamides), or acute interstitial nephritis (many antibiotics, allopurinol, proton pump inhibitors).[31,33] CNIs have toxicities as outlined previously.

Obstructive uropathy is much less common but can be caused by severe hemorrhagic cystitis or fungal infection of the collecting system. Causes of hemorrhagic cystitis include high-dose cyclophosphamide and viral infections (e.g., adenovirus, BK virus). Adenovirus and BK nephropathies have also been described.[31]

In addition to the prerenal AKI that occurs in the context of gastrointestinal GVHD, moderate and severe acute and chronic GVHD are correlated with intrarenal AKI and CKD, attributed in part to excessive release of proinflammatory cytokines.[33] Animal models of GVHD have demonstrated infiltration of donor-type leukocytes into the kidneys, with associated cell-mediated injury to the kidney microvasculature and kidney tubules.[34]

Capillary Leak Syndrome and Engraftment Syndrome

Capillary leak syndrome and engraftment syndrome are caused by endothelial cell injury and the release of proinflammatory cytokines and are characterized by fluid retention and fever. Both lead to AKI due to intravascular volume depletion, and possibly by a direct inflammatory effect.[33] Capillary leak syndrome presents within 2 weeks of HSCT and is seen most often in haploidentical transplants as a component of cytokine release syndrome (CRS). Engraftment syndrome presents similarly to capillary leak syndrome but occurs at the time of neutrophil regeneration, and is seen most commonly after autologous HSCT.[33]

Hepatic Sinusoidal Obstructive Syndrome (Previously Venoocclusive Disease of the Liver)

Hepatic SOS is an important cause of severe AKI after myeloablative HSCT, particularly myeloablative allogeneic HSCT (see Table 69.1 and Box 69.4). The incidence ranges from 2% (by updated European Society for Blood and Marrow Transplantation criteria) to 30%.[30] Pathophysiology is thought to involve radio- and chemotherapy-induced damage to the endothelium of hepatic venules with subsequent venular thrombosis and sinusoidal and

BOX 69.4 Causes of Kidney Disease According to Time After Hematopoietic Stem Cell Transplantation

Immediate (Very Rare)
- Tumor lysis syndrome
- Marrow infusion syndrome

Early (AKI in First 3 Months)
- Prerenal
  - Hypovolemia (gastrointestinal GVHD, drug-induced nausea and vomiting, salt and water losses due to diuretics or other tubular injury)
  - Capillary leak syndrome, engraftment syndrome
  - Hepatic SOS (early)
  - Heart failure
  - CNI toxicity (early)
- Intrarenal
  - Ischemic acute tubular injury (prolonged prerenal ischemia, sepsis/septic shock, hepatic SOS [late], calcineurin inhibitor toxicity [late], intravenous iodinated contrast)
  - Toxic acute tubular injury (aminoglycosides, amphotericin B, foscarnet, cidofovir)
  - Crystal-induced tubular toxicity (acyclovir)
  - Allergic interstitial nephritis (penicillins, cephalosporins, fluoroquinolones, macrolides, trimethoprim-sulfamethoxazole, allopurinol, proton pump inhibitors)
- Postrenal
  - Hemorrhagic cystitis (cyclophosphamide, BK virus, adenovirus)

Late
- Thrombotic microangiopathy
- Calcineurin inhibitor toxicity
- Irreversible AKI
- Membranous nephropathy or other glomerular diseases
- Recurrence of original disease, which then affects the kidneys (e.g., amyloidosis, multiple myeloma)
- Retroperitoneal fibrosis (malignancy, radiotherapy)
- GVHD (?)

AKI, Acute kidney injury; *CNIs,* calcineurin inhibitors; *GVHD,* graft-versus-host disease; *SOS,* sinusoidal obstruction syndrome.

portal hypertension that in turn decreases kidney perfusion. Independent risk factors include the use of antithymocyte globulin, myeloablative conditioning regimens (total body irradiation based and busulfan based), busulfan exposure (pediatric population), 2 or more HSCTs, and increased tacrolimus trough blood concentrations (>5–10 ng/mL).[30] The use of gemtuzumab ozogamicin and inotuzumab ozogamicin, novel antibody-drug conjugates sometimes administered prior to HSCT, have also been implicated.[30,31]

Clinically, SOS presents as a form of hepatorenal syndrome during the first 30 days after HSCT. There is frequently a precipitating factor such as sepsis. Initial symptoms and signs include weight gain, edema, and ascites, followed by right upper quadrant abdominal pain, jaundice, and abnormal liver function tests. Oliguria and rising creatinine follow.[33] In mild to moderate cases, patients may recover with supportive care alone. Severe SOS complicated by liver and kidney failure (and frequently respiratory failure) carries a mortality approaching 80%.[35] The differential diagnosis includes acute GVHD of the liver, sepsis, drug-induced cholestasis, gallstone disease, and hepatotoxic effects of parenteral nutrition.

The diagnosis of hepatic SOS is usually based on characteristic clinical and laboratory features, though liver biopsy is occasionally performed. Urine sodium concentration is low (<10 mEq/L). Urinalysis and urine sediment are typically bland; granular casts may be seen with progression to ATN. Kidney biopsy specimens have not revealed intrinsic kidney lesions, consistent with the understanding that SOS is most likely hemodynamic in pathophysiology.[36]

Transplant-Associated Thrombotic Microangiopathy

Transplant-associated thrombotic microangiopathy (TMA) is associated with subclinical kidney disease, AKI, and (most commonly) CKD. Recent studies reveal an incidence of 2.3% to 30%, with widely varying definitions of transplant-associated TMA and study populations.[37] Transplant-associated TMA is characterized by endothelial cell injury leading to microangiopathic hemolytic anemia, thrombocytopenia, and end-organ damage; the kidneys are thought to be vulnerable to microvascular injury due to their extensive glomerular circulation.[36] Patients typically present 4 to 12 months after HSCT with slowly rising creatinine, although some patients demonstrate a more fulminant presentation with severe nephritic syndrome. Clues to the diagnosis include disproportionate hypertension and progressive anemia. Urinalysis shows variable proteinuria and hematuria. Careful review of prior test results may show evidence of an intermittent or persistent low-grade TMA, although the classic laboratory findings (e.g., elevated serum lactate dehydrogenase, decreased haptoglobin, schistocytes) may not all be present. Diagnostic criteria (and their limitations) are summarized elsewhere.[38] Histopathology reveals endothelial cell swelling, fibrin thrombi within capillary loops and arterioles, fragmented red blood cells, mesangiolysis, and thickened arteriolar vasculature. Chronic injury leads to glomerular capillary wall remodeling, double contour formation of the basement membrane, and tubular injury with interstitial fibrosis (Fig. 69.4).[37]

It is unclear if transplant-associated TMA is a direct complication of HSCT or a consequence of endothelial injury precipitated by GVHD or other exposures.[31,37] Acute GVHD (especially grades 2–4) is a major risk factor for transplant-associated TMA, with emerging data suggesting that transplant-associated TMA might be an "endothelial complication" of GVHD.[36,39] Other significant risk factors include unrelated donor type and CNI use. Transplant-associated TMA has also been associated with advanced primary malignancy, nonmyeloablative transplant, high-dose busulfan administration, total body irradiation (TBI), mTOR inhibitor use, and infections (e.g., systemic infections, *Aspergillus* species, BK virus, cytomegalovirus, parvovirus B19, and adenovirus).[37] Recent studies demonstrate that complement activation and genetic susceptibility to complement dysregulation play major roles in the endothelial injury that drives transplant-associated TMA, with potential implications for therapy[37,40] (Fig. 69.5).

Prevention, Detection, and Management of Acute Kidney Injury After Hematopoietic Stem Cell Transplantation

General Considerations

Strict control of fluid balance is essential for the prevention of posttransplant AKI. Weight, blood pressure, intake, and output (urine and stool) should be monitored regularly in all HSCT patients.[31] Nephrotoxic medications and iodinated contrast should be used judiciously. Infections and gastrointestinal GVHD should be treated promptly. If CNI trough concentrations are high, dose reduction should be considered. Promising developments that may lower the risk of AKI include the use of CNI-free (e.g., cyclophosphamide-based) regimens for GVHD prophylaxis and personalized drug dosing protocols.[31]

As previously discussed, serum creatinine has limitations as an AKI biomarker in this context. Novel AKI biomarkers (e.g., urine

neutrophil gelatinase-associated lipocalin [NGAL]) have been evaluated in the research setting but are not yet in routine clinical use.[36]

Posttransplant AKI should be evaluated as for any patient with hospital-acquired AKI but with particular focus on the patient's cancer diagnosis, type of transplant, and conditioning regimen. Complications specific to HSCT, such as capillary leak syndrome/engraftment syndrome, hepatic SOS, and transplant-associated TMA, should be considered in the appropriate clinical context. Nephrotoxic medications should be stopped where possible, and medications dose adjusted for eGFR.[31] Urinalysis, urine microscopy, urine protein/creatinine ratio, and kidney ultrasound should be performed. Clinicians should have a low threshold to evaluate for TMA, BK virus, and adenovirus. Kidney biopsy may be considered in the following situations: (1) AKI of unclear etiology, (2) failure of kidney function to recover as anticipated after initial modifications in therapy, or (3) presence of nephrotic-range proteinuria. As many HSCT patients are thrombocytopenic and/or coagulopathic, biopsies should be performed with caution and appropriate transfusion support.[31]

The choice of RRT modality is usually based on hemodynamic stability and volume status; daily obligate fluid intake in this context is frequently massive, and fluid balance may be controlled most easily with continuous RRT. There is evidence in the pediatric literature that continuous convective therapies may be preferred, perhaps related to differences in the removal of small- and middle-sized molecules compared with diffusive therapies.[41]

Data supporting earlier (versus later) initiation of RRT after HSCT comes primarily from the pediatric population, with a small recent study demonstrating good outcomes in patients with SOS, AKI, and fluid overload treated with a standardized fluid balance protocol and early initiation of RRT.[42] In the absence of consensus guidelines, some experts advocate for initiation of RRT when there is radiologic and clinical evidence of pulmonary edema, worsening oxygenation, poor response to high-dose diuretics, evidence of systemic inflammation, and ongoing oliguria.[36]

Importantly, vascular access can be problematic in these patients because of thrombocytopenia and neutropenia, predisposing to bleeding and infection, respectively.

Disease-Specific Considerations

Hepatic sinusoidal obstruction syndrome. Current strategies for preventing hepatic SOS are based on inconclusive evidence and include avoiding precipitating factors where possible and using ursodeoxycholic acid (UDCA) or low-dose heparin.[43] Ursodeoxycholic acid alters the bile acid milieu, rendering bile less hydrophobic and toxic to parenchymal cells if cholestasis is present; it also exerts local cytokine-mediated immunomodulatory effects. Defibrotide, an oligonucleotide with antithrombotic and fibrinolytic effects on the microvascular endothelium but with apparently few systemic adverse effects, has demonstrated efficacy in both preventing and treating SOS.[44] As discussed earlier, continuous RRT may have less effect on intracranial pressure than intermittent HD.

Transplant-associated thrombotic microangiopathy. Patients with suspected or confirmed transplant-associated TMA should be supported with transfusions, blood pressure control, and dialysis as indicated.[37] All patients should be promptly evaluated for precipitating viral infections and acute GVHD. In patients receiving CNIs or mTOR inhibitors for GVHD prophylaxis, replacement with alternative agents (corticosteroids, MMF, IL-2 inhibitors, and anti-CD20 agents) may be appropriate, although not extensively studied.[38] Plasma exchange has not been proven to be beneficial.[37,38] Limited reports in pediatric and adult patients have demonstrated response rates of 80% (12 of 15 patients) with the use of rituximab.[37] Given the complement pathway abnormalities described previously, there is interest in the C5 inhibitor eculizumab. Data for its use comes primarily from the pediatric literature, with a relatively large study of 64 children with high-risk transplant-associated TMA demonstrating 66% 1-year post-HSCT survival compared with 16.7% in a previously reported untreated cohort.[45] Of course, the risks and benefits of any extra immunosuppression in patients after HSCT must be very carefully considered.

Chronic Kidney Disease After Hematopoietic Stem Cell Transplantation

Epidemiology

CKD is an important long-term complication of HSCT, particularly allogeneic HSCT.[27] The reported cumulative incidence of CKD after HSCT ranges from 7% to 48%, with approximately 4% of these patients progressing to ESKD and experiencing worse survival on dialysis compared with non-HSCT controls.[27,38,46] The incidence of CKD after HSCT is expected to rise as the age of patients undergoing transplantation increases.[31] Some causes of CKD are shown in Table 69.1.

Risk factors for posttransplant CKD include age 45 years or older at time of transplantation, baseline GFR less than 90 mL/min/1.73 m^2, acute and chronic GVHD, prior AKI, and survival more than 1 year after transplantation.[27] Exposure to high-dose total body irradiation has also been implicated, possibly by contributing to subacute or chronic transplant-associated TMA.[28,31] Hypertension is a well-recognized late complication of HSCT, with incidence linked to the development of CKD. Albuminuria has been associated with CKD progression and decreased posttransplant survival.[31]

CNIs are routinely prescribed after allogeneic HSCT to prevent and treat GVHD. They are often stopped after 3 to 6 months (unless there is ongoing GVHD), and so their contribution to CKD is thought to be limited.[27] The contribution of CNIs to chronic kidney TMA is unclear, as transplant-associated TMA can certainly occur in patients on non-CNI protocols.[46]

Glomerular Disease

Nephrotic syndrome has been described after both allogeneic (particularly nonmyeloablative) and autologous HSCT. Nephrotic syndrome after allogeneic HSCT tends to occur more than 6 months after transplantation and appears to be strongly associated with tapering of immunosuppression and the presence of GVHD; de novo membranous nephropathy is the most common biopsy finding, followed by minimal change disease.[47,48] Importantly, the original hematologic disease (e.g., amyloidosis, multiple myeloma) may recur with kidney involvement.

Management of Hematopoietic Stem Cell Transplantation–Related Chronic Kidney Disease

Proteinuria and hypertension should be monitored and controlled. There is limited evidence regarding the superiority of RAS blockade, but its use seems reasonable.[49] Management of chronic transplant-associated TMA is discussed earlier. Clinical response in patients with post-HSCT membranous nephropathy or minimal change disease is usually seen with increased immunosuppression (typically corticosteroids and/or CNI); there are also limited reports of success with rituximab (particularly in membranous nephropathy).[47,48]

Suitability for kidney transplantation should be judged on a case-by-case basis. On occasion, the allogeneic stem cell donor can donate a kidney; the benefit of this approach is that tolerance to the kidney allograft should exist; hence minimal or no additional immunosuppression is required.[50] If this option is not available and the patient receives a conventional kidney transplant, low-dose immunosuppression should generally be prescribed because HSCT recipients may not have normal immunity and remain at higher risk for infection. Good outcomes after kidney transplantation have been reported in carefully selected patients.[50,51]

SELF-ASSESSMENT QUESTIONS

1. A 28-year-old woman is referred to the nephrology clinic with serum creatinine 2.3 mg/dL (200 µmol/L). Six years ago she underwent lung transplantation because of respiratory failure associated with cystic fibrosis. The lung transplant is working well. However, her serum creatinine has increased slowly over the last 5 years from 1.1 mg/dL (97 µmol/L). Her medications are cyclosporine, azathioprine, prednisolone, simvastatin, and pancreas enzyme supplements. The main findings on examination are finger clubbing and blood pressure (BP) 148/84 mm Hg. The urine dipstick shows trace protein only. Which of the following is *true?*
   - **A.** The underlying cause of her CKD is most likely cyclosporine toxicity.
   - **B.** An urgent kidney biopsy is indicated.
   - **C.** Switching azathioprine to sirolimus is indicated.
   - **D.** If her CKD progresses, kidney transplant is contraindicated because of underlying cystic fibrosis.
   - **E.** Diltiazem should be added to control the hypertension.
2. A 30-year-old man is referred to the nephrology clinic because of rising serum creatinine and worsening hypertension. Eight months ago he underwent an allogeneic stem cell transplant for acute myeloid leukemia (AML). His conditioning regimen included total body irradiation and cyclophosphamide. His early posttransplant course was relatively uncomplicated. However, he remained on cyclosporine because of GVHD of the skin. Recent cyclosporine trough concentrations have been 60 to 90 ng/mL. His medications are low doses of cyclosporine, prednisolone, valacyclovir, and sulfamethoxazole-trimethoprim. The main findings on examination are BP 166/98 mm Hg (148/86 mm Hg, 3 weeks ago), mild GVHD of the skin, and mild leg edema. The urine dipstick shows 3+ blood and 3+ protein. Other test results are as follows: white blood cells 4.2×10^9/L, hematocrit 26.0 (32.0, 3 weeks ago), platelets 82×10^9/L (130×10^9/L, 3 weeks ago), creatinine 2.3 mg/dL (200 µmol/L) (1.2 mg/dL [105 µmol/L], 3 weeks ago), albumin 3.2 g/dL, and 24-hour urine protein 3.2 g. The prothrombin time and activated partial thromboplastin time are normal. Which of the following is *true?*
   - **A.** The main cause of the kidney disease is probably cyclosporine toxicity.
   - **B.** The patient has nephritic syndrome, most likely caused by membranous nephropathy.
   - **C.** The plasma lactate dehydrogenase, serum haptoglobin, and blood film should be checked urgently.
   - **D.** The main cause of the kidney disease is recurrence of AML, with infiltration of the kidneys.
   - **E.** Computed tomography with intravenous contrast should be performed urgently to exclude obstruction of the urinary tract.
3. A 30-year-old man is referred urgently to the nephrology clinic because of an increase in creatinine from baseline 2.0 mg/dL (176 µmol/L) to 2.9 mg/dL (255 µmol/L). One week ago he was diagnosed with community-acquired pneumonia and treated with antibiotics. His breathlessness and cough have improved, but he reports mild headache and pain in the right big toe. Ten years ago he underwent a heart transplant for severe heart failure caused by idiopathic dilated cardiomyopathy. The heart transplant is apparently working well. His medications are cyclosporine, azathioprine, prednisolone, ramipril, atorvastatin, and (in the last week) cefuroxime plus clarithromycin. Examination shows fine hand tremor, pulse 90/min and regular, BP 142/84 mm Hg, oxygen saturation 98% on room air, normal breath sounds with no added sounds, and no leg edema. The right big toe is inflamed, consistent with acute gout. The urine dipstick shows trace protein only. Tests show serum creatinine 2.9 mg/dL (255 µmol/L), potassium 5.9 mmol/L, white blood cells 4.9×10^9/L (with normal differential), hematocrit 30, and platelets 189×10^9/L. Which of the following is *true?*
   - **A.** The most likely cause of the acute kidney dysfunction is allergic interstitial nephritis resulting from cefuroxime.
   - **B.** The main underlying cause of the CKD is cardiac failure (of the transplanted organ).
   - **C.** If the patient's CKD progresses to a glomerular filtration rate below 15 mL/min, the treatment of choice would be peritoneal dialysis.
   - **D.** Allopurinol should be added to treat the gout.
   - **E.** The most likely cause of the acute kidney dysfunction is acute cyclosporine nephrotoxicity caused by impairment of cyclosporine metabolism by clarithromycin.
4. A 44-year-old woman is admitted to the intensive care unit with severe, decompensated liver disease. The underlying cause is cirrhosis from hepatitis C (HCV) infection. Over 1 week she becomes oliguric; serum creatinine increases from 1.0 mg/dL (88 µmol/L) to 2.5 mg/dL (221 µmol/L). The urine dipstick shows trace blood and trace protein only. The fractional urine excretion of sodium is 0.2%. Low-dose noradrenaline is started, causing the mean arterial pressure to increase to 65 mm Hg and the urine output to increase to 800 mL/24 h. A decision is made to list her for an emergency liver transplant. Which of the following is *true?*
   - **A.** The baseline serum creatinine of 1.0 mg/dL likely reflects normal eGFR.
   - **B.** The clinical picture is consistent with hepatorenal syndrome.
   - **C.** The acute renal dysfunction is a result of HCV-related glomerulonephritis.
   - **D.** At this time, a simultaneous liver-kidney rather than a liver-alone transplant should be performed.
   - **E.** After successful liver transplantation, her risk for developing stage 4 or 5 CKD over the long term is negligible.
5. A 39-year-old woman is referred for opinion regarding kidney transplantation. She has a background of complex congenital cyanotic heart disease and has undergone several procedures for this. However, her cardiac function is worsening; therefore, she is being considered for cardiac transplantation. Her serum creatinine has steadily increased over the last 3 years. Medications are furosemide, digoxin, bisoprolol, omeprazole. She reports poor appetite and breathlessness on minimal exertion. On examination she is thin, pulse is 114 beats/min and regular, BP 152/92 mm Hg, and respiratory rate 22/min at rest. The fingertips are cyanosed. The jugular venous pressure is increased. There are reduced breath sounds in the left lung base. The liver edge is palpable; the femoral pulses are strong with no bruits. There is trace leg edema. Tests show urine dipstick 3+ protein and trace blood, plasma creatinine 4.0 mg/dL, potassium 5.1 mmol/L, albumin 3.1 g/dL, and 24-hour urine protein 4.2 g. Which of the following is *true?*
   - **A.** The kidney dysfunction is mainly a result of the severe heart failure and thus should improve significantly after successful cardiac transplantation.
   - **B.** Because of the risk that cyclosporine or tacrolimus will worsen kidney function after cardiac transplantation, you should advise the cardiologists to avoid using these drugs after transplantation.
   - **C.** Simultaneous heart-kidney transplant is a relatively common procedure and should be considered here.
   - **D.** Simultaneous heart-kidney transplant is an uncommon procedure but should be considered here.
   - **E.** You should recommend that a kidney transplant be performed first and only later consider cardiac transplantation.

Pathophysiology and Etiology of Acute Kidney Injury

Cary H. Paine, J. Ashley Jefferson, Juan Carlos Q. Velez

DEFINITION

Acute kidney injury (AKI) is defined as an abrupt decline in glomerular filtration rate (GFR) sufficient to decrease the elimination of nitrogenous waste products and other uremic toxins. This has traditionally been referred to as *acute renal failure* (ARF) but has been replaced with the term *acute kidney injury*, and standardized definitions of AKI have been developed (see Table 72.1) with stages based upon the magnitude of the rise in serum creatinine and changes in the urine output over 1 week.[1]

ETIOLOGY

AKI is caused by a broad range of etiologies, and the differential diagnosis must be considered in a systematic fashion. The traditional paradigm divides AKI into prerenal, renal, and postrenal causes. Prerenal causes may be due to hypovolemia or a decreased effective arterial volume. Postrenal kidney failure is usually due to obstruction. Intrinsic renal causes of AKI should be considered under the different anatomic components of the kidney (vascular supply, glomerular, tubular, and interstitial disease; Fig. 70.1). Major extrarenal artery or venous occlusion must also be considered (see Chapter 43). Disorders of the small intrarenal vasculature can also result in AKI (e.g., vasculitis, thrombotic microangiopathy, malignant hypertension, eclampsia, postpartum states, disseminated intravascular coagulation [DIC], scleroderma; see Chapters 26, 30, 38, 42, and 65). All forms of acute glomerulonephritis can present as AKI, as can acute inflammation and space-occupying processes of the kidney interstitium (e.g., drug-induced, infectious, and autoimmune disorders, leukemia, lymphoma, sarcoidosis).

Among inpatients, prerenal azotemia and acute tubular injury (ATI) account for most AKI cases[2] (Fig. 70.2), often in the setting of AKI superimposed on chronic kidney disease (CKD), so-called acute-on-chronic kidney disease. The term ATN (acute tubular necrosis), although commonly used, is a misnomer because the alterations are not limited to the tubular structures, and true cellular necrosis in human ATN is often minimal. ATN should be reserved for cases of AKI in which a kidney biopsy (if performed) shows the characteristic changes of tubular cell injury (Fig. 70.3), or for patients with findings of tubular injury (e.g., renal tubular epithelial cells in the urine sediment) in an appropriate clinical setting. There are also geographic differences in the causes of AKI, with the spectrum of causes in tropical countries described in Chapter 71.

PATHOPHYSIOLOGY AND ETIOLOGY OF PRERENAL AKI

Impaired kidney perfusion with a resultant fall in glomerular capillary filtration pressure is a common cause of AKI. In this setting, tubular function is typically normal, whereas kidney reabsorption of sodium and water is increased, so the urine exhibits low sodium concentration (<20 mmol/L) and high osmolality (>500 mOsm/kg), presuming a diuretic has not been administered. A marked reduction in kidney perfusion may overwhelm autoregulation and precipitate an acute fall in GFR. With lesser degrees of kidney hypoperfusion, glomerular filtration pressures and GFR are maintained by afferent arteriolar vasodilation (mediated by vasodilatory eicosanoids) and efferent arteriolar vasoconstriction (mediated by angiotensin II) that increases the filtration fraction. In this setting, AKI may be precipitated by agents that impair afferent arteriolar dilation (nonsteroidal antiinflammatory drugs [NSAIDs]) or efferent vasoconstriction (angiotensin-converting enzyme [ACE] inhibitors and angiotensin receptor blockers [ARBs]).

The hemodynamic mechanisms that drive the reduction in GFR and an adaptive increase in proximal tubular reabsorption in hypovolemic states originate from an interplay between hydraulic and oncotic pressures (Fig. 70.4). Under normal physiologic conditions, the glomerular capillary hydraulic pressure (P_{GC}) is greater than the glomerular capillary oncotic pressure (ϖ_{GC}), and hydraulic pressure in Bowman's space that opposes filtration and the oncotic pressure in Bowman's space are negligible. Thus, the sum of these forces leads to the generation of ultrafiltrate (see Chapter 2). The directionality of fluid flow reverses in the proximal tubule, where the peritubular capillary oncotic pressure (ϖ_{TC}) is greater than the peritubular capillary hydraulic pressure (P_{TC}), thus favoring reabsorption. As kidney perfusion falls beyond compensatory limits, P_{GC} falls. When volume loss is pronounced, ϖ_{GC} may rise as a result of hemoconcentration and rise in serum total protein concentration. Those processes lead to a fall in GFR. Concomitantly, the dominance of ϖ_{TC} over P_{TC} becomes more pronounced primarily as a result of further drop in $P_{TC.}$ This avid proximal tubular reabsorption in prerenal azotemia partly explains the increased reabsorption of molecules like sodium, urea, and calcium observed in this disease state.

Prerenal AKI is often secondary to gastrointestinal losses (diarrhea, vomiting, prolonged nasogastric drainage), renal losses (diuretics, osmotic diuresis in hyperglycemia), dermal losses (burns, extensive sweating), or sequestration of fluid, sometimes known as third spacing (e.g., acute pancreatitis, muscle trauma). Kidney perfusion may also be impaired in the setting of normal or increased extracellular fluid, when

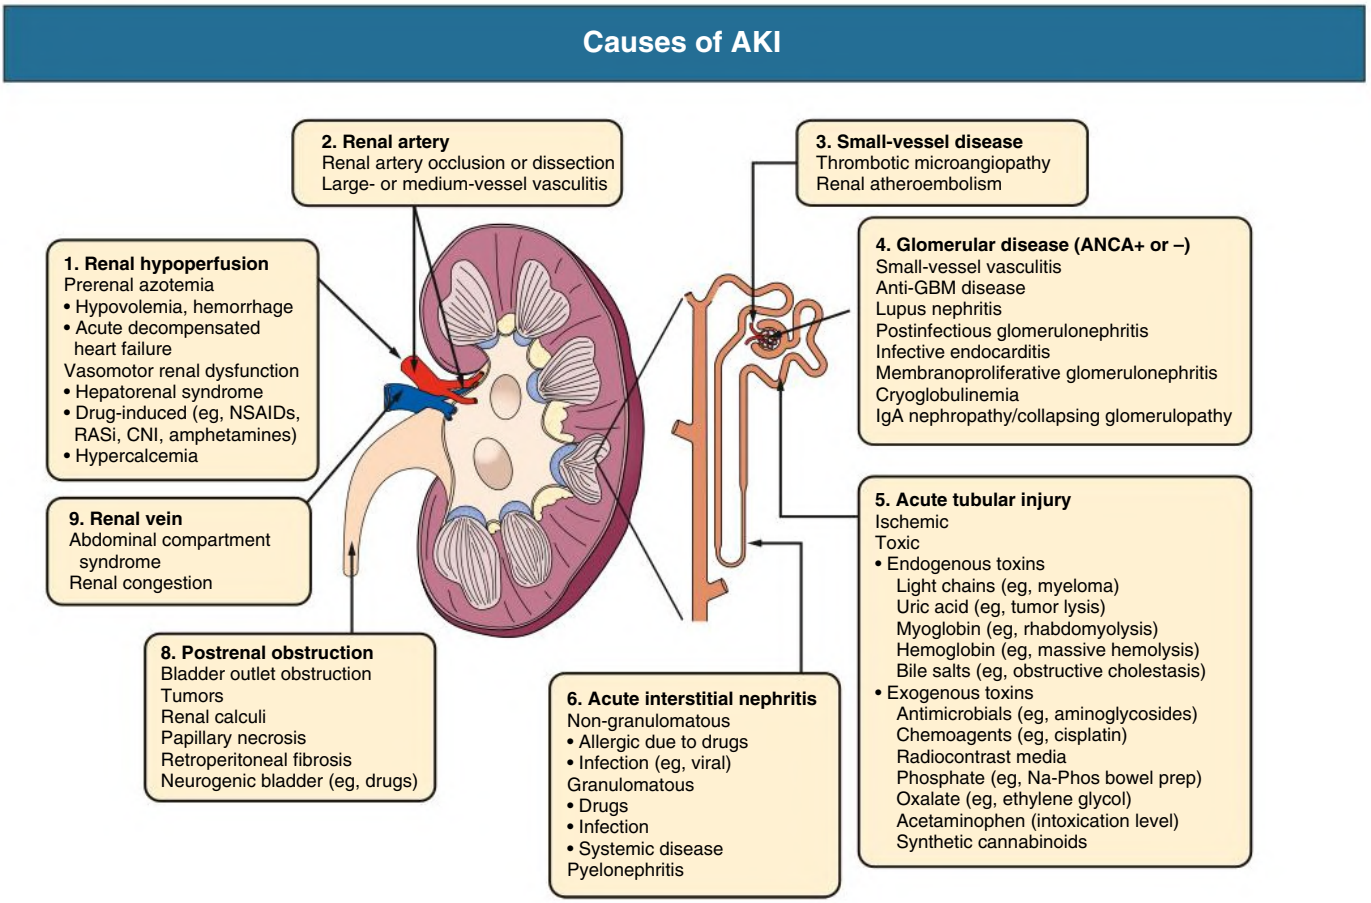

Fig. 70.1 Causes of Acute Kidney Injury (AKI). AKI is classified into prerenal, renal, and postrenal causes. Renal causes of AKI should be considered under the different anatomic components of the kidney (vascular supply, glomerular, tubular, and interstitial disease). *ANCA,* Antineutrophil cytoplasmic antibody; *CNI,* calcineurin inhibitor; *GBM,* glomerular basement membrane; *IgA,* immunoglobulin A; *Na-Phos,* sodium-phosphate; *NSAID,* nonsteroidal antiinflammatory drug; *RASi,* renal-angiotensin system inhibitor.

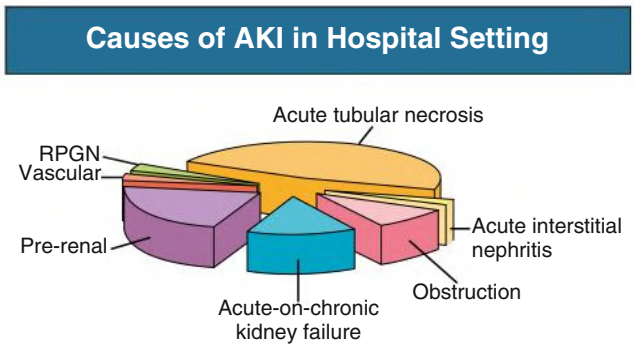

Fig. 70.2 Causes of acute kidney injury *(AKI)* in the hospital setting. Madrid acute renal failure study (1996). *RPGN,* Rapidly progressive glomerulonephritis.

cardiac output is reduced (heart failure), or when there is systemic arterial vasodilation with redistribution of cardiac output to extrarenal vascular beds (e.g., sepsis, liver cirrhosis) (see Chapters 8 and 76). An unusual cause of prerenal AKI is the infusion of large quantities of osmotically active substances such as mannitol, dextran, or protein, which can increase the glomerular oncotic pressure enough to exceed the capillary hydrostatic pressure stopping filtration.

Prerenal AKI can be corrected if the extrarenal factors causing the kidney hypoperfusion are rapidly reversed. Failure to restore renal blood flow (RBF) during the functional prerenal stage will ultimately lead to tubular cell injury.

PATHOPHYSIOLOGY OF ATI

ATI commonly occurs in patients with trauma, vascular and cardiac surgery, severe burns, pancreatitis, sepsis, and chronic liver disease. ATI is responsible for most cases of hospital-acquired AKI and is usually due to ischemic or nephrotoxic injury, or a combination of both. In the intensive care unit, two-thirds of cases of AKI are due to the combination of impaired kidney perfusion, sepsis, and nephrotoxic agents. The importance of combined injury is highlighted by animal studies, in which severe and prolonged hypotension or a single nephrotoxic agent may not cause ATI. Fever may exacerbate ATI by increasing the renal tubular metabolic rate, thereby increasing adenosine triphosphate (ATP) consumption. The typical course of uncomplicated ATI is recovery over 2 to 3 weeks; however, superimposed kidney insults (e.g., episodes of hypotension induced by hemodialysis) or multiple comorbidities often alter this pattern.

Histology

The typical features of ATI include vacuolization and loss of brush border in proximal tubular cells. Sloughing of tubular cells into the lumen leads to cast obstruction, manifested by tubular dilation. Interstitial edema can produce widely spaced tubules, and a mild leukocyte infiltration may be present (see Fig. 70.3). Despite the term acute tubular

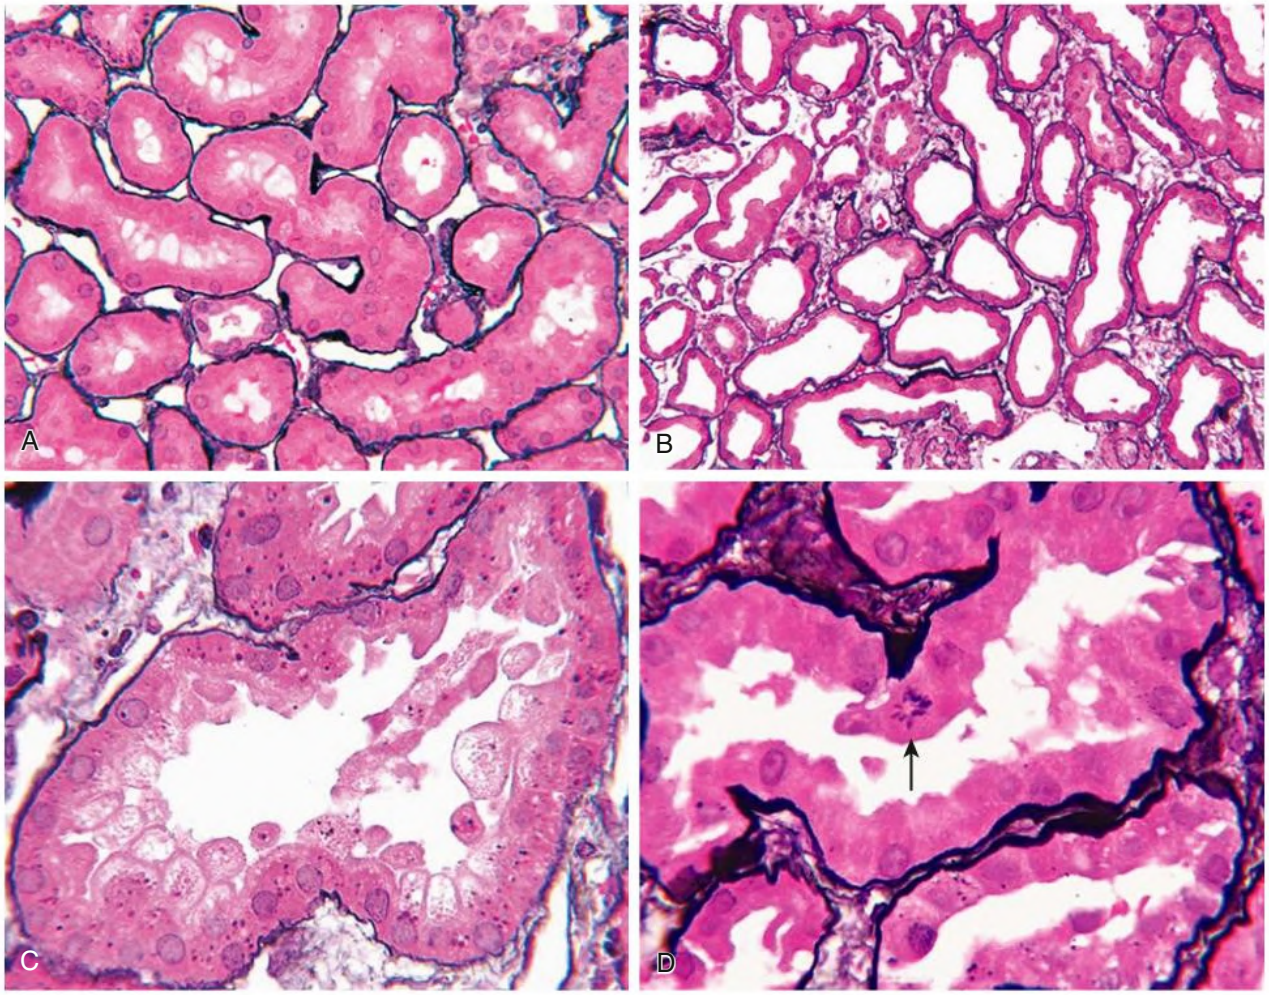

Fig. 70.3 Kidney Pathology in Acute Tubular Necrosis (ATN). (A) Normal cortical renal tubules. (B–C) ATN. Note the flattened epithelium, bare basement membranes, and intraluminal cellular debris. "necrosis," frankly necrotic cells are uncommon on kidney biopsy. Histologic evidence of injury frequently only involves 10% to 15% of the tubules despite marked functional impairment, implying that additional factors such as vasoconstriction and tubular obstruction are important in the loss of GFR.

Site of Tubular Damage in ATI

Tubular damage is usually due to a combination of ischemic injury resulting in depletion of cellular ATP and direct tubular epithelial cell injury by nephrotoxins. The S3 segment of the proximal tubule and the medullary thick ascending limb (mTAL) are particularly vulnerable to hypoxic injury (Fig. 70.5) for several reasons:

1. *Blood supply:* Most blood flow to the kidney is directed to the kidney cortex for glomerular filtration, where tissue Po_2 is 50 to 100 mm Hg. By contrast, the outer medulla and medullary rays are watershed areas receiving their blood supply from vasa rectae. Countercurrent oxygen exchange occurs, leading to a progressive fall in Po_2 from cortex to medulla. This results in medullary cells living on the "brink of hypoxia" (Po_2 as low as 10–15 mm Hg). The S3 segments of proximal tubule cells and distal mTALs are thus exposed to chronic borderline oxygen deprivation.
2. *High tubular energy requirements:* The cells of the S3 region and mTAL have high metabolic activity due to sodium reabsorption driven by basolateral membrane Na^+,K^+-ATPase. Blocking sodium reabsorption in the mTAL with loop diuretics raises the medullary tissue Po_2 from about 15 to 35 mm Hg. The low GFR in AKI may be renoprotective by diminishing sodium filtration and hence limiting the need for ATP-dependent sodium reabsorption. The drop in GFR in this setting has been called acute renal success. However, there is no clinical evidence that loop diuretics foster AKI recovery.
3. *Glycolytic ability of tubular cells:* Proximal tubular cells have minimal glycolytic machinery and rely almost solely on oxidative phosphorylation for the generation of ATP. In contrast, mTAL cells have a large glycolytic capacity and are more resistant to hypoxic or ischemic insults.

Hemodynamic Factors in the Development of ATI

Impaired Kidney Autoregulation

Autoregulation between systolic blood pressures of 80 and 150 mm Hg allows maintenance of RBF, glomerular pressures, and GFR in a stable range. Below 80 mm Hg, this autoregulation fails, and ischemic injury may result. In certain conditions, such as aging or CKD, autoregulation is impaired, and ischemic injury may occur more easily with reductions in perfusion pressure. In settings of low kidney perfusion (e.g., volume depletion, left ventricular failure, renal artery stenosis, chronic liver disease), GFR may be dependent on autoregulation mediated by vasodilatory prostaglandins acting on the afferent arteriole and angiotensin II–mediated efferent arteriolar vasoconstriction to maintain glomerular pressure. Any interference with these mechanisms (e.g., administration of ACE inhibitors or NSAIDs) may produce a precipitous fall in GFR.

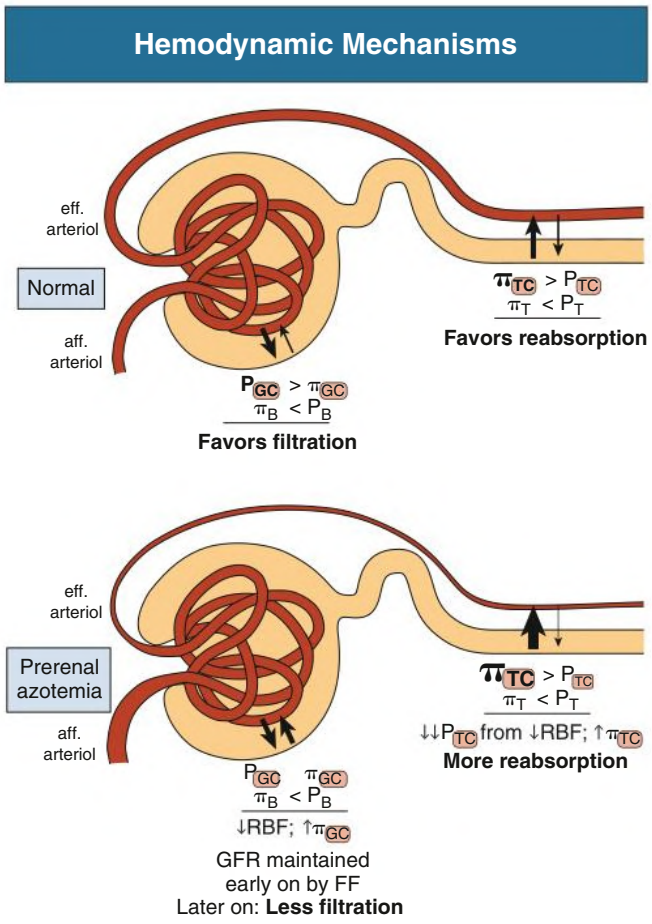

Fig. 70.4 Hemodynamic Mechanisms That Drive the Reduction in Glomerular Filtration Rate (GFR) and an Adaptive Increase in Proximal Tubular Reabsorption in Hypovolemic States Originate From an Interplay Between Hydraulic and Oncotic Pressures. Under normal physiologic conditions, the glomerular capillary hydraulic pressure (P_{GC}) that drives fluid from the capillary tuft into Bowman's space is greater than the glomerular capillary oncotic pressure (π_{GC}) that drives fluid into the glomerular capillary. The hydraulic pressure in Bowman's space (P_B) that opposes filtration and the oncotic pressure in Bowman's space (π_B) are of lesser magnitude or negligible. Thus, the sum of these forces leads to the generation of ultrafiltrate. The directionality of filtration fraction (FF) reverses in the proximal tubule where the peritubular capillary oncotic pressure (π_{TC}) is greater than the peritubular capillary hydraulic pressure (P_{TC}), thus favoring reabsorption. The hydraulic pressure inside the tubular lumen (P_T) and the oncotic pressure inside the tubular lumen (π_T) are of lesser magnitude. As kidney perfusion falls beyond compensatory limits, P_{GC} falls. When volume loss is pronounced, π_{GC} may rise as a result of hemoconcentration and rise in serum total protein concentration. Those processes lead to a fall in GFR. Concomitantly, the dominance of π_{TC} over P_{TC} becomes more pronounced primarily as a result of further drop in P_{TC}. This avid proximal tubular reabsorption in prerenal azotemia partly explains the increased reabsorption of molecules like sodium, urea, and calcium observed in this disease state. *RBF,* Renal blood flow.

Intrarenal Vasoconstriction

In established ATI, RBF is decreased by 30% to 50%. Indeed, in AKI, rather than the normal autoregulatory renal vasodilation that occurs in response to decreased perfusion pressure, there is evidence of renal vasoconstriction. Vasoconstrictors implicated in this response include angiotensin II, endothelin-1, adenosine, thromboxane A_2, prostaglandin H_2, leukotrienes C_4 and D_4, sympathetic nerve stimulation (Fig. 70.6), and tubuloglomerular feedback (TGF). Some of these vascular abnormalities may be mediated by increased cytosolic calcium content in afferent arterioles as a result of ischemia.

Tubuloglomerular Feedback

The role of TGF (see Chapter 2) in the setting of AKI may be partly beneficial because the resultant decrease in GFR limits sodium chloride delivery to damaged tubules. This in turn leads to reduced ATP-dependent tubular reabsorption of sodium, which protects against intracellular ATP depletion and thus kidney injury.

Tubular Epithelial Cell Injury and the Development of ATI

The tubular cell may be injured because of ischemia (depletion of cellular energy stores [ATP]) or from direct cytotoxic injury. Following acute kidney ischemia, tubular cell injury may also result from the restoration of RBF (reperfusion injury). Mediators of tubular cell injury include reactive oxygen species (ROS), intracellular calcium influx, nitric oxide, phospholipase A2, complement, and cell-mediated cytotoxicity.[3] Mitochondrial injury can be caused by ROS, depletion of antioxidants, and increased intracellular calcium. Disruption of mitochondrial function exacerbates cellular injury due to disrupted energy metabolism and release of proapoptotic proteins. Autophagy is a mechanism by which cells degrade self-proteins, and it is a central part of the cellular response to stress and injury. Experimental work has shown that autophagy is important for removal of damaged mitochondria and the recovery of tubular epithelial cells from ischemic injury. ROS may be derived from local sources (including xanthine oxidase and cyclooxygenases secondary to mitochondrial injury) or from infiltrating leukocytes. In models of ischemic ATN, a variety of methods that inhibit ROS protect against kidney injury. Hypoxia inducible factor (HIF) and downstream mediators such as heme oxygenase 1 may serve to protect cells against ischemic injury.[4]

Factors that affect the integrity and function of the renal tubular epithelial cells and contribute to the reduction in GFR include (Fig. 70.7):

1. *Cell death:* Most tubular cells undergo cell death by apoptosis rather than necrosis. In animal models, kidney injury is ameliorated using caspase inhibitors and p53 inhibitors that decrease apoptosis.[5]
2. *Disruption of actin cytoskeleton:* A characteristic feature of sublethally injured cells is the disruption of the actin cytoskeleton. Activation of the cysteine protease calpain (partly due to increased intracellular calcium) can degrade actin-binding proteins such as spectrin and ankyrin. This leads to abnormal translocation of Na^+K^+-ATPase and other proteins from the basolateral membrane to the cytoplasm or apical membranes. In the proximal tubular cell, this loss of polarity results in impaired proximal reabsorption of filtrate with resultant increased distal NaCl delivery, which activates tubuloglomerular feedback.
3. *Cast obstruction:* Tubular cells are attached to the tubular basement membrane by α3β1 integrins, which recognize RGD (arginine-glycine-aspartate) sequences in matrix proteins. Disruption of the actin cytoskeleton results in movement of integrins from basolateral positions to the apical membrane, leading to impaired cell matrix adhesion and cell detachment. Many of these detached cells are still viable and can be cultured from urine of patients with ATN. Sloughed proximal tubular cells can bind to RGD sequences in Tamm-Horsfall protein, resulting in cast formation and intratubular obstruction. In models of ischemic AKI, the elevation in tubular pressures may be inhibited by synthetic RGD peptides mitigating the obstructive process. Both increased sodium concentration in the tubular lumen resulting from lack of sodium reabsorption or back-leak (see below), as well as acidic pH observed in ATI, favor dimerization of uromodulin and cast formation. Casts seen in ATI include granular casts, waxy casts, and renal tubular epithelial cell casts.

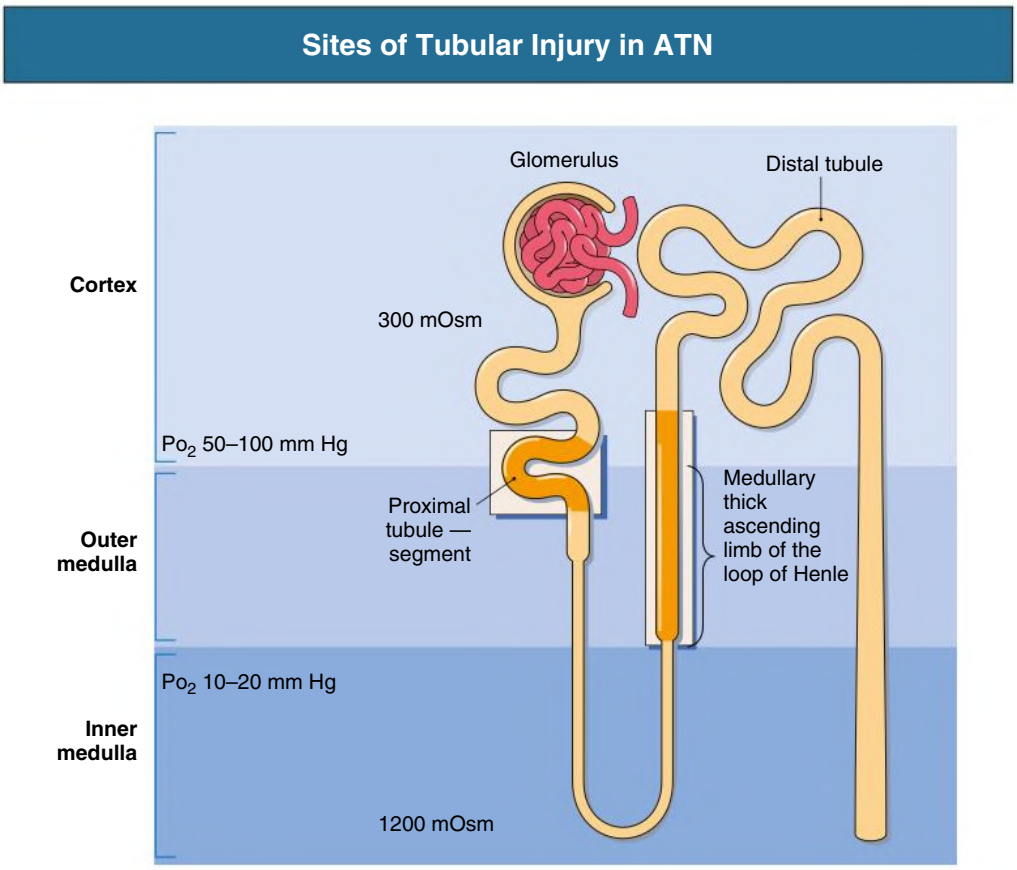

Fig. 70.5 Sites of Tubular Injury in Acute Tubular Necrosis (ATN). The S3 segment of the proximal tubule and the medullary thick ascending limb are particularly vulnerable to ischemic injury because of the combination of borderline oxygen supply and high metabolic demands.

4. *Back-leak:* The loss of adhesion molecules (E-cadherin) and tight junction proteins (ZO-1, occludin) weakens junctions between cells, allowing filtrate to leak back into the kidney interstitium. Although this does not alter the actual GFR at the level of the glomerulus, the net effect is a reduction in the measured GFR. Earlier dextran sieving experiments suggest only a modest effect of back-leak on the decrement of GFR in AKI (about 10%); however, in the kidney allograft with severe ATI, back-leak has been calculated to account for up to 50% of the GFR reduction.

Endothelial Cell Injury and the Development of ATN

Endothelial cell injury occurs partly as a result of acute kidney ischemia and oxidant injury.[3] Endothelial injury is characterized by cell swelling, upregulation of adhesion molecules (with recruitment of inflammatory neutrophils and monocytes), and impaired vasodilation (decreased endothelial nitric oxide synthase and vasodilatory prostaglandins) and may mediate some of the impaired autoregulation and intrarenal vasoconstriction described earlier. Endothelial injury within the peritubular capillaries (vasa rectae) may produce congestion in the outer medulla, exacerbating interstitial edema and worsening hypoxic injury to the S3 segment of the proximal tubule and the thick ascending loop of Henle.

Inflammatory Factors in The Development of ATN

Although ischemia causes direct kidney cytotoxicity, tissue inflammation during reperfusion also contributes to kidney injury and may cause some of the systemic effects of AKI. Components of both the innate and the adaptive immune systems contribute to the pathogenesis of ATN.[6] The innate immune system is activated by cellular injury and certain pattern recognition molecules. Toll-like receptor 2 (TLR2) and TLR4 are upregulated within the ischemic kidney, activated by molecules released from injured cells, and induce renal epithelial cells to produce chemokines. The complement system is also activated within the tubulointerstitium after ischemia/reperfusion, predominantly by the alternative pathway. It can directly induce nearby epithelial cells to produce proinflammatory cytokines (e.g., tumor necrosis factor-α [TNF-α], interleukin-6 [IL-6], IL-1β), and chemokines (e.g., MCP-1, IL-8, RANTES) that promote the infiltration of leukocytes and are also directly vasoactive.

A network of dendritic cells extends throughout the kidney interstitium, which help shape the inflammatory response within the kidney after ischemia/reperfusion, likely through their interactions with other inflammatory cell types. Neutrophils and mononuclear cells are seen in peritubular capillaries. Neutrophil activation and the release of proteases and ROS can exacerbate injury. By contrast, neutrophil depletion or the inhibition or genetic deletion of neutrophil adhesion molecules (ICAM-1) ameliorates injury in ischemic ATN. Monocytes infiltrate the kidney after reperfusion and differentiate into the M1 (proinflammatory) type exacerbating kidney injury after ischemia. These macrophages may later convert to an M2 (reparative) phenotype. Cells of the adaptive immune system, including T and B lymphocytes, also contribute to kidney injury in models of ATN, and their depletion ameliorates injury. It is not known whether these responses are antigen specific. Furthermore, some B and T cell subsets, such as T regulatory cells, help limit kidney injury.

AKI may have systemic effects on other organs.[7] The injured kidney may prime and activate leukocytes, which produce proinflammatory cytokines that can mediate remote organ injury (Fig. 70.8). The lungs may be particularly vulnerable from the combined effects of volume

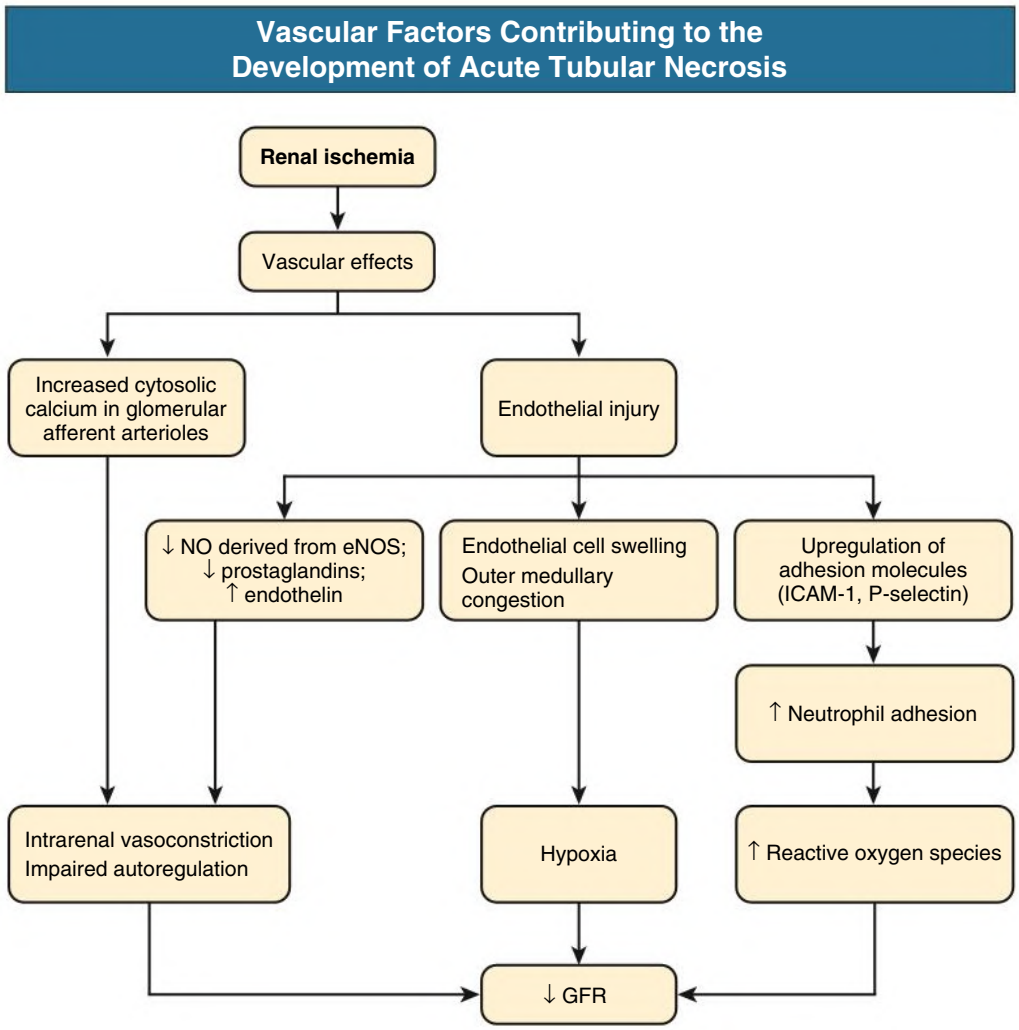

Fig. 70.6 Vascular Factors Contributing to the Development of Acute Tubular Necrosis. Renal vasoconstriction and endothelial injury promote kidney ischemia and tubular injury. *eNOS,* Endothelial nitric oxide synthase; *GFR,* glomerular filtration rate; *ICAM-1,* intercellular adhesion molecule 1; *NO,* nitric oxide.

overload, increased vascular permeability and proinflammatory environment. These effects may partly account for the increased mortality in patients with AKI (see Chapter 73).

Recovery Phase

Recovery from ATI requires the restoration of tubular cell number and coverage of denuded tubular basement membrane. Marked cell proliferation occurs in recovering human ATI (see Fig. 70.3). The restoration of tubular cell number is due to the dedifferentiation and proliferation of surviving tubular cells rather than from a mesenchymal stem cell source.[8] After tubular epithelial cell proliferation, the dedifferentiated cells must migrate to areas of denuded tubular basement membrane, attach to the basement membrane, and differentiate into mature polar tubular epithelial cells. The early inflammatory infiltrates of neutrophils and M1 monocytes are replaced by M2 monocytes, which support epithelial cell repair, after which their numbers decline by migration or apoptosis. When the injury process is persistent or severe, maladaptive repair may occur, leading to CKD.[9]

ACUTE CORTICAL NECROSIS

The same pathophysiological processes that lead to ATN can lead to bilateral acute cortical necrosis, but this only accounts for less than 2% of cases of ischemic ATN. If cortical necrosis is extensive, kidney failure often is irreversible. About 20% of the cases have reversible bilateral acute cortical necrosis.

In cortical necrosis, there is microvascular and glomerular thrombosis with extensive death of kidney tissue. The process is distinct from that seen with infarction caused by arterial occlusion because some blood supply to the medulla is preserved. The type of shock, in particular placental abruption, rather than severity seems to predict the risk for cortical necrosis. Other causes include thrombotic microangiopathy, snakebite envenomation, and trauma-related hemorrhagic shock.

The diagnosis of cortical necrosis is most often considered when recovery from AKI attributed to ATN is delayed. Contrast-enhanced computed tomography (CT) may reveal characteristic anatomic distortion of the kidneys (Fig. 70.9), but the use of radiocontrast in this setting has to be considered judiciously. Calcification detected radiologically is a late and unreliable sign. Contrast angiography may show patchy loss of perfusion. Kidney biopsy may not be informative because cortical necrosis may be patchy.

PATHOPHYSIOLOGY AND ETIOLOGY OF POSTRENAL AKI

Obstruction must be excluded in any patient with AKI because prompt intervention can result in improvement or complete recovery of kidney function (see Chapter 61). Most causes of obstructive nephropathy

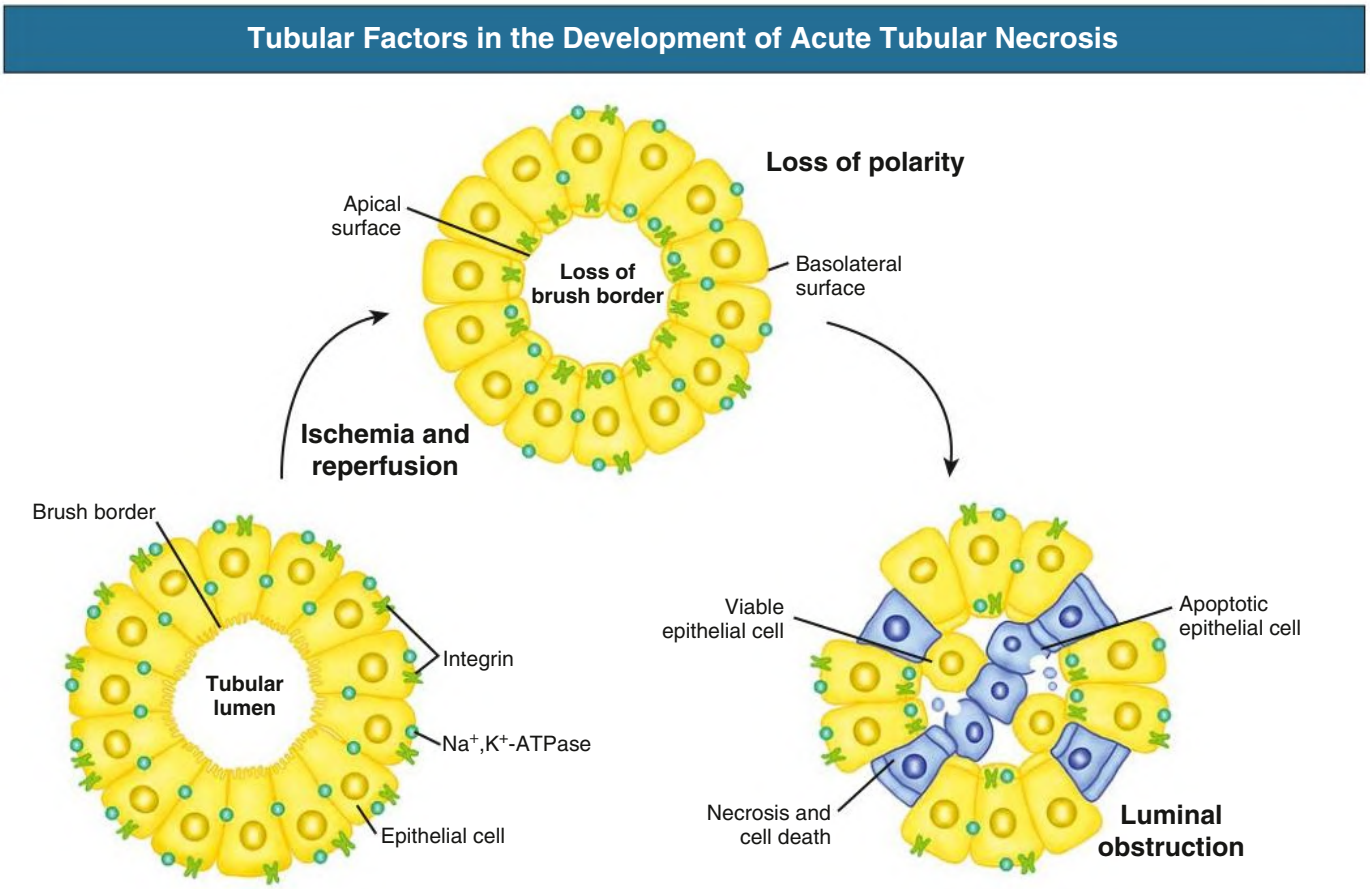

Fig. 70.7 Tubular Factors in the Development of Acute Tubular Necrosis. Loss of cell polarity results in weakening of cell-to-cell and cell matrix adhesion resulting in cast obstruction and back-leak of tubular fluid. (Modified from Schrier RW, Wang W, Poole B, Mitra A. Acute renal failure: definitions, diagnosis, pathogenesis, and therapy. *J Clin Invest.* 2004;114[1]:5–14.)

are amenable to therapy, and the prognosis is often good if treatment or intervention is early (Chapter 61).

NEPHROTOXIC AGENTS AND MECHANISMS OF TOXICITY

The identification and avoidance of nephrotoxic agents in AKI is critical because AKI may be rapidly reversible upon removal of the offending agent. The mechanisms of nephrotoxicity include alterations in kidney hemodynamics, induction of direct tubular injury, allergic reactions resulting in interstitial nephritis, and intratubular obstruction. The list is extensive, but the more common agents are presented in Fig. 70.10.

Nonsteroidal Antiinflammatory Drugs

NSAIDs commonly cause AKI in the community because of the large amounts of these drugs either prescribed or purchased over the counter. COX-2–specific NSAIDs have similar effects on kidney function as the nonselective NSAIDs and are not safer with respect to AKI. NSAID-related AKI is most often due to a hemodynamically mediated reduction in GFR that occurs in patients who are particularly dependent on vasodilatory prostaglandins to maintain kidney perfusion. These include elderly patients with atherosclerotic disease, volume-depleted patients, and those in sodium avid states such as cirrhosis, nephrotic syndrome, and congestive heart failure. This form of AKI is usually reversible in 2 to 7 days upon discontinuation of the drug and rarely occurs in otherwise healthy individuals. Concurrent use of diuretics, ACE inhibitors, ARBs, and calcineurin inhibitors has been associated with an increased incidence of NSAID-related AKI. Less frequently, NSAIDs induce ATN or, even more rarely, papillary necrosis. NSAIDs may also cause an acute interstitial nephritis (AIN), often with significant proteinuria (see Chapter 64). Other renal side effects of NSAIDs include fluid and electrolyte disturbances such as sodium retention exacerbating hypertension and congestive heart failure, hyponatremia, and hyperkalemia.

Acetaminophen (Paracetamol)

Isolated ATN with acetaminophen may occur in rare cases, but kidney injury is more typically associated with acute hepatitis. Kidney and liver toxicity usually occurs when more than 15 g have been taken, but in alcoholics, normal doses may be toxic. Acetaminophen is conjugated in the liver and undergoes renal excretion. Less than 5% undergoes metabolism by P-450 (CYP2E1) enzymes to form a toxic metabolite, N-acetylimidoquinone, which is inactivated by the thiol group of glutathione. With high levels of acetaminophen, glutathione becomes depleted, and N-acetylimidoquinone can bind to thiol groups on intracellular proteins, resulting in cell injury. Because glutathione is a major intracellular antioxidant, its loss may predispose to oxidative injury of the tubular cells.

Clinically, acute liver failure and ATN only begin once glutathione levels are depleted, and clinical manifestations usually present 3 to 4 days after ingestion. N-acetylcysteine, which substitutes for glutathione by providing a free thiol group, can be protective if administered early.

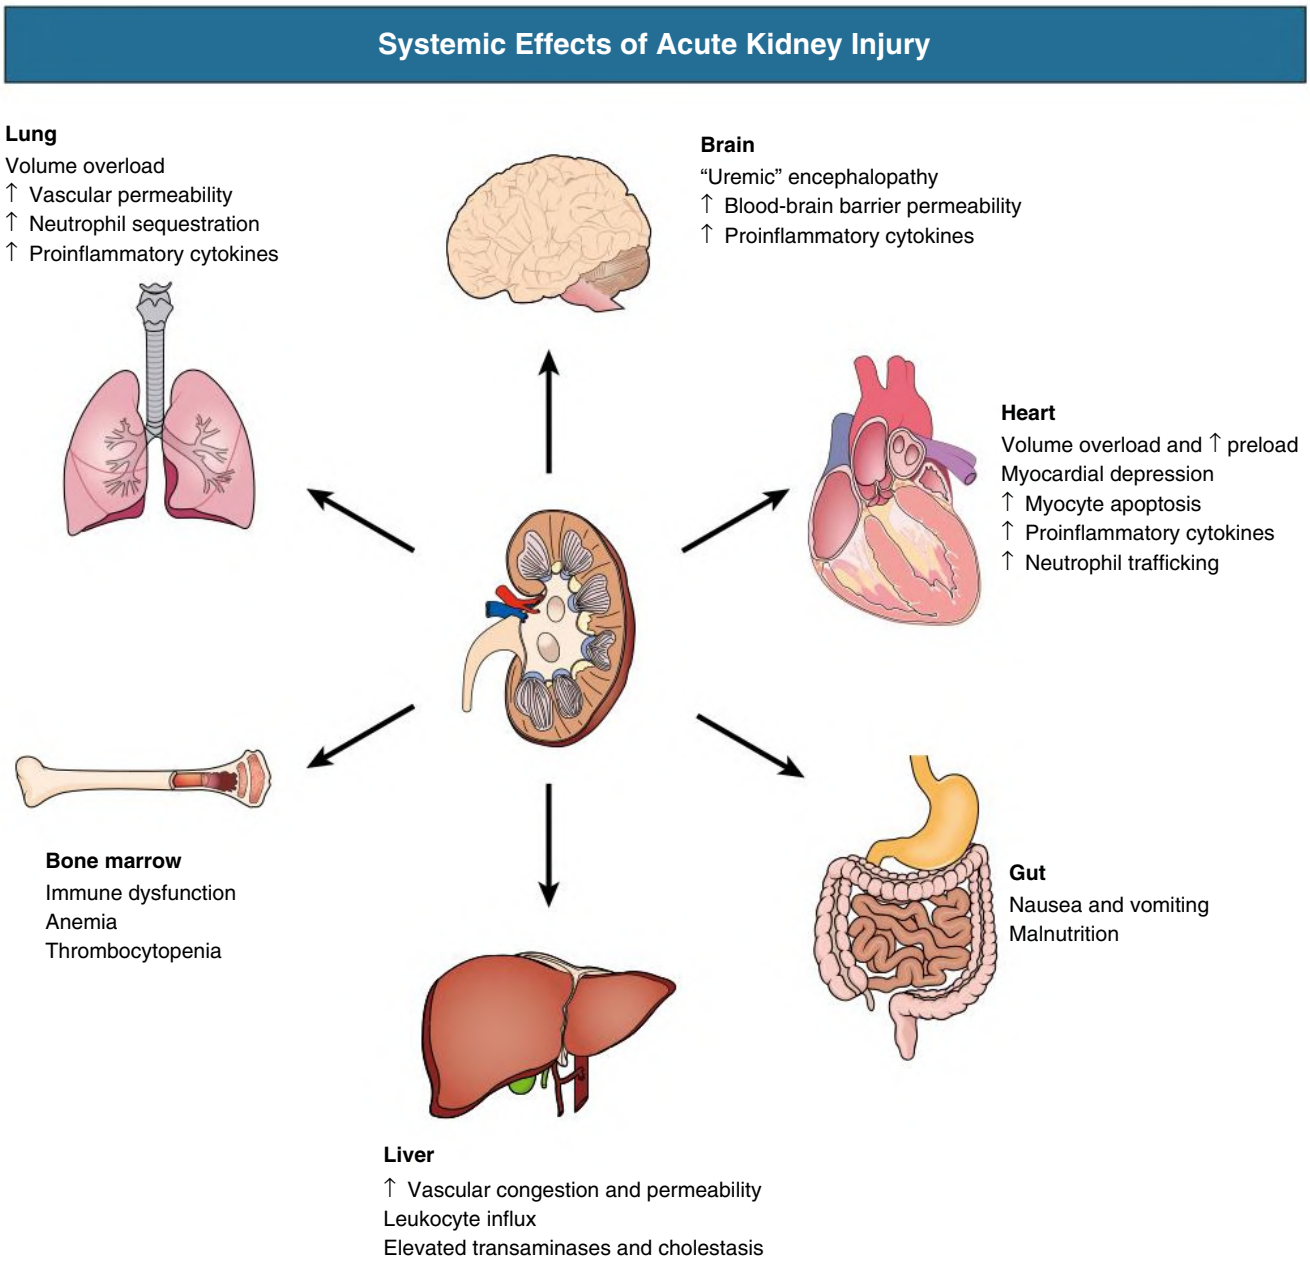

Fig. 70.8 Systemic Effects of Acute Kidney Injury. Acute kidney injury may contribute to remote organ injury, partly due to abnormalities in inflammatory and immune function from renal tubular dysfunction. (Modified from Grams ME, Rabb H. The distant organ effects of acute kidney injury. *Kidney Int.* 2012;81[10]:942–948.)

ACE Inhibitors and ARBs

Initiation of therapy with an ACE inhibitor or an ARB is commonly associated with a functional decrease in GFR that is not considered AKI. Indeed, it is well established that use of these medications is associated with improved kidney outcomes despite the initial drop in GFR that is often seen. ACE inhibitors and ARBs may also cause hemodynamically induced AKI in the setting of reduced kidney perfusion by impairing compensatory vasoconstriction of the efferent arteriole. These drugs may directly impair kidney perfusion by their antihypertensive effects. Patients in whom kidney perfusion is compromised due to dehydration, renovascular disease, or functionally impaired autoregulation are at particular risk for developing AKI after initiation of therapy. Patients chronically treated with ACE inhibitors or ARBs have an increased risk for postoperative kidney dysfunction, probably as a consequence of intraoperative hypotensive episodes.

Aminoglycosides

Aminoglycoside toxicity may occur if the dose is not adjusted to the GFR. Cationic amino groups (NH_3^+) on the drugs bind to anionic megalin on the brush border of proximal tubular epithelial cells. Following endocytosis aminoglycosides accumulate in proximal tubular cell lysosomes and can reach 100 to 1000 times their serum concentration. These drugs interfere with cellular energetics, impair intracellular phospholipases, and induce oxidative stress.[10]

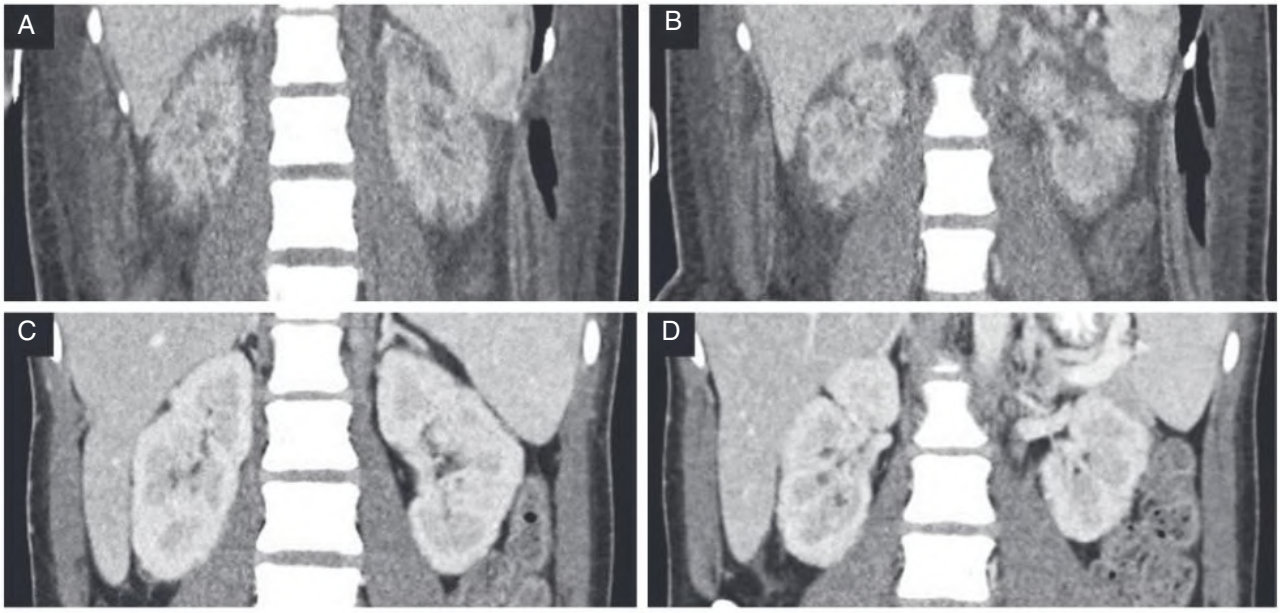

Fig. 70.9 Imaging Showing Bilateral Acute Cortical Necrosis of the Kidneys. (A–B) Contrast-enhanced computed tomography (CT) scanning coronal images disclose remarkable distortion of the anatomic appearance of both kidneys, including irregular margins, presence of hypodensity of the renal cortices and patchy medullary enhancement. (C–D) After 60 days, repeat CT scanning (coronal view) shows complete resolution of previously observed kidney abnormalities. (From Luo X, Cielo AG, and Velez JCQ. Abnormal imaging findings of the kidneys in a patient with shock. *Kidney360.* 2020;1[12]:1462–1463.)

Nonoliguric AKI usually occurs after 5 to 10 days of treatment with gentamicin. Involvement of distal tubular segments may produce polyuria, potassium, and magnesium wasting. The risk for AKI correlates with the accumulation of gentamicin in proximal tubular cells and is related to the daily dose and duration of therapy. Prolonged accumulation in proximal tubular cells may allow development of AKI even after the drug has been discontinued. Additional risk factors for gentamicin toxicity include increasing age, preexisting kidney disease, hypotension, concurrent liver disease, sepsis, coadministration of vancomycin, and concurrent nephrotoxins. Aminoglycoside serum levels should be monitored to minimize nephrotoxicity. When possible, the drug should be administered in a single daily total dose, which leads to lower renal proximal tubular cell accumulation. Gentamicin, tobramycin, and netilmicin appear to have similar nephrotoxic effects. Amikacin, which has fewer amino groups per molecule, and plazomicin, a next-generation aminoglycoside, may be less nephrotoxic.

Vancomycin

The extent to which vancomycin is directly nephrotoxic is controversial.[11] The recommendation for higher vancomycin trough levels to target methicillin-resistant *Staphylococcus aureus* has led to recognition that vancomycin can be nephrotoxic. Vancomycin is excreted primarily by glomerular filtration, but accumulation in proximal tubule cells via basolateral secretion is thought to underlie nephrotoxicity. Experimentally, high-dose vancomycin causes oxidative stress and triggers intrarenal apoptotic pathways. In humans, high initial vancomycin trough levels greater than 15 μg/mL have been associated with nephrotoxicity in a graded fashion. Additional risk factors include total dose of more than 4 g daily, long duration of therapy, concurrent nephrotoxin or diuretic exposure, and critical illness. Vancomycin coadministration with piperacillin-tazobactam appears to increase risk for AKI, though the mechanism for this is unclear.[12] A precipitous rise in serum creatinine could be observed in a subset of cases of vancomycin-associated AKI.[13] ATN is the predominant lesion seen in experimental models of vancomycin nephrotoxicity, but case reports of human biopsies have shown both interstitial nephritis and ATN. Vancomycin can cause a drug reaction with eosinophilia and systemic symptoms (DRESS syndrome) with inflammatory kidney injury. Treatment is generally conservative. High-flux hemodialysis can be used for drug removal when levels are very high. Kidney injury from vancomycin is generally reversible.

Amphotericin B

This polyene macrolide antibiotic binds to sterols in the cell membranes of both fungal walls (ergosterol) and mammalian (cholesterol) cell membranes, resulting in the formation of aqueous pores that increase membrane permeability. Within the renal tubular cell, the subsequent sodium influx leads to increased Na^+,K^+-ATPase activity and depletion of cellular energy stores.[14] Additionally, the standard amphotericin B formulation is suspended in the bile salt deoxycholate, which has a detergent effect on cell membranes. Nephrotoxicity relates to cumulative dosage, usually occurring after administration of 2 to 3 grams.

Early signs of nephrotoxicity include a loss of urine-concentrating ability, followed by a decrease in GFR. Hypokalemia and hypomagnesemia due to distal tubular wasting are common. A distal renal tubular acidosis may be present due to proton back-leak in the cortical collecting duct.

Prevention of nephrotoxicity requires the maintenance of high urine flow rates by saline loading during amphotericin administration. The more expensive liposomal amphotericin B preparations reduce the incidence of AKI by approximately 50%. As amphotericin B binds more avidly to fungal ergosterol than to cholesterol, delivering the drug as a cholesterol liposome diminishes binding to tubular epithelial cell membranes without altering fungicidal activity. Additionally,

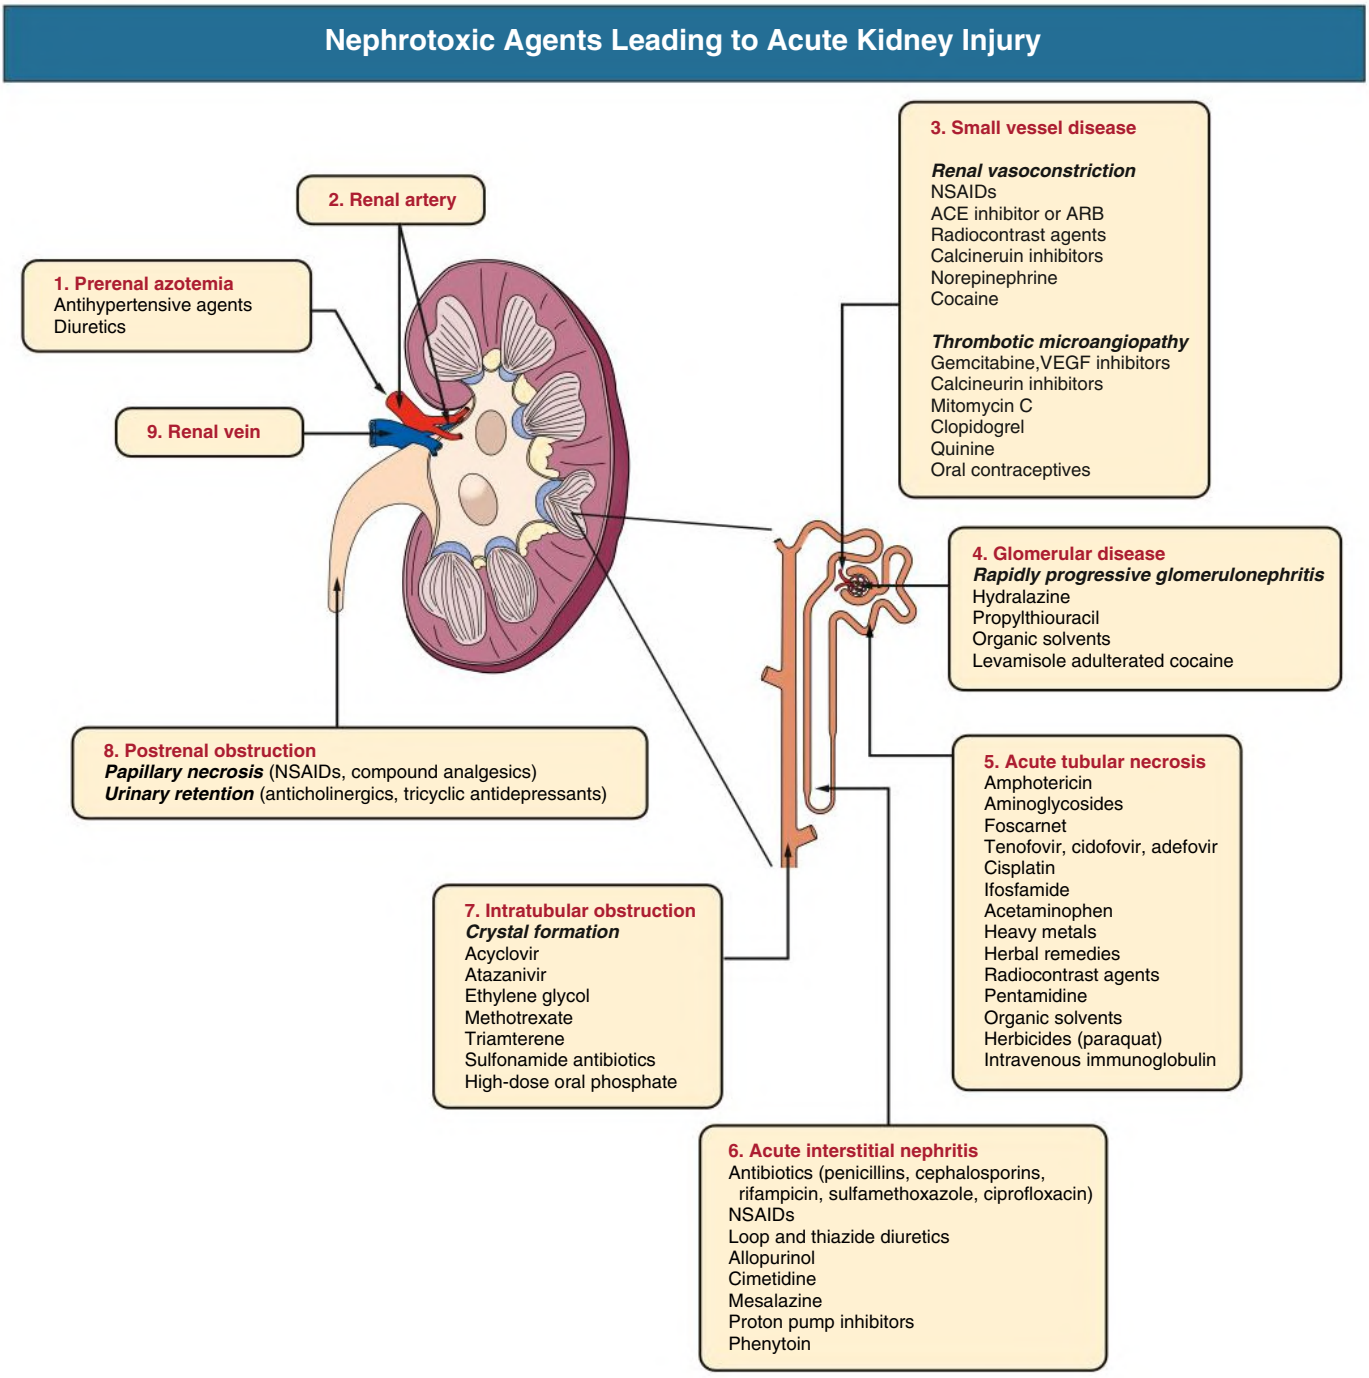

Fig. 70.10 Common nephrotoxic agents leading to acute tubular necrosis. *ACE,* Angiotensin-converting enzyme; *ARB,* angiotensin receptor blocker; *NSAID,* nonsteroidal antiinflammatory drug; *VEGF,* vascular endothelial growth factor.

liposomal preparations do not contain deoxycholate. Amphotericin B–induced AKI is usually reversible with discontinuation of the drug, although distal tubular injury as manifested by magnesium wasting may persist.

Antiviral Therapy

Acyclovir

Nephrotoxicity is typically seen after intravenous (IV) acyclovir administration and may be due to direct tubular cell toxicity and the formation of intratubular, birefringent needle-shaped acyclovir crystals. However, kidney biopsy data suggest that AIN may be the predominant mechanism of toxicity.

Oliguric AKI typically occurs within a few days of treatment and may be associated with abdominal or loin pain. High serum levels of acyclovir due to decreased kidney clearance may produce neurologic toxicity. The AKI is usually mild and recovers on stopping the drug. Maintaining a high urine flow rate and avoiding IV bolus administration of acyclovir may be preventative.

Tenofovir

Tenofovir is a nucleoside reverse transcriptase inhibitor used to treat both HIV and hepatitis B infection. The prodrug, tenofovir disoproxil fumarate (TDF), is the most widely used therapy for HIV in the world. Tenofovir is secreted into proximal tubule cells via organic anion transporters (OATs), where it can interfere with mitochondrial DNA synthesis and upset the energy supply, resulting in characteristic enlarged, dysmorphic mitochondria. Manifestations of tenofovir nephrotoxicity include subclinical tubular defects (e.g., normoglycemic glycosuria), Fanconi syndrome, ATN, and CKD.[15] Kidney manifestations can develop within weeks of drug initiation or can occur after years, but reversibility is common. Risk factors include preexisting CKD, advanced age, low CD4 count, and total dose and duration of TDF use. HIV patients exhibit a variety of kidney diseases (see Chapter 58), and biopsy should be strongly considered when kidney dysfunction does not improve after drug cessation or when resistance patterns make tenofovir critical for patient care. Tenofovir alafenamide (TAF) is a newer prodrug of tenofovir, the use of which has increased in recent years such that it is now included in many first-line drug regimens. TAF concentrates in mononuclear cells, resulting in lower plasma concentrations and reduced drug delivery to the kidney. TAF is less nephrotoxic than TDF, but cases of TAF-associated AKI have been reported.[16]

Other Antiviral Agents

Among antivirals used to treat HIV infection, both cobicistat and dolutegravir inhibit proximal tubular secretion of creatinine, causing a false elevation in serum creatinine. A small rise in creatinine is considered acceptable and generally occurs within 2 weeks of starting these drugs. Atazanavir, a protease inhibitor, can cause urolithiasis, crystalline-induced kidney injury, AIN, or a granulomatous interstitial nephritis. Acute presentations are largely reversible, but long-term use can lead to CKD.[17]

Adefovir, a second-line drug used to treat hepatitis B, was frequently nephrotoxic when prescribed at high doses, but current low-dose regimens appear safe for most patients. Foscarnet and cidofovir are well-recognized nephrotoxic antivirals.

Sodium-Glucose Cotransporter-2 Inhibitors

Sodium-glucose cotransporter-2 (SGLT2) inhibitors can be associated with a functional decrease in GFR that is likely the result of direct renovascular effects, similar to that seen with initiation of ACE inhibitors and ARBs, and is not considered to represent AKI. In fact, the risk of AKI as a direct result of treatment with SGLT2 inhibitors is low.[18] There are rare case reports of AKI due to osmotic nephrosis following initiation of an SGLT2 inhibitor. The use of SGLT2 inhibitors in CKD is covered in Chapters 32 and 33.

Immunosuppressive Agents

Calcineurin Inhibitors

Cyclosporine and tacrolimus may cause AKI due to afferent arteriolar vasoconstriction, partly mediated by endothelin. This is usually reversible upon dose reduction. Persistent injury may lead to chronic interstitial fibrosis in a striped pattern along medullary rays reflecting both the ischemic nature of the insult, as well as the development of arteriolar hyalinosis. Associated clinical features include hypertension, hyperkalemia, hyperuricemia, and wasting of phosphorus and magnesium from tubular injury. Calcineurin inhibitors also cause reversible tubular dysfunction, and are associated with the development of thrombotic microangiopathy, likely due to their effects on the endothelium (see Chapter 30).

Other Immunosuppressive Agents

The monoclonal anti-CD3 antibody (OKT3) or polyclonal antilymphocyte and antithymocyte preparations (ALG, ATG) may cause a first-dose cytokine release syndrome and prerenal azotemia secondary to capillary leak. Intravenous immunoglobulin (IVIG) can cause AKI, which may be partly mediated by the high sucrose concentration in these products. Tubular uptake of sucrose may result in osmotic cell swelling and injury. Although it does not typically cause AKI, sirolimus delays the recovery from AKI in kidney transplant patients with delayed graft function.

Anticoagulation-Related Nephropathy

AKI has been described in patients taking anticoagulants who develop an acute rise in the international normalized ratio (INR), usually to greater than 3. Most cases of anticoagulation-related nephropathy (ARN) appear within the first 8 weeks of initiating therapy in patients with underlying CKD. AKI results from glomerular hematuria with obstruction of renal tubules by red blood cell casts. The risk of ARN is thought to be highest in patients treated with warfarin, but cases in patients treated with direct acting oral anticoagulants have also been reported.[19]

Acute Phosphate Nephropathy

Oral sodium phosphate has been widely used as a bowel preparation for colonoscopy procedures, but recent cases of AKI have limited the use of this purgative.[20] AKI associated with oral sodium phosphate is believed to be caused by phosphaturia and acute calcium-phosphate deposition within the renal tubules. Risk factors for this condition include older age, volume depletion, and underlying CKD. A similar phenomenon has been reported with use of sodium phosphate–containing enemas.

Drugs of Abuse

AKI is a common condition in those who abuse drugs and may be due to nephrotoxicity of the drug, coexistent viral infection (HIV, HCV), sepsis, infective endocarditis, or rhabdomyolysis.[21]

Cocaine induces intense vasoconstriction, which may lead to AKI due to severe hypertension or rhabdomyolysis. Mechanisms for rhabdomyolysis include coma and pressure necrosis, vasospasm leading to ischemic muscle injury, and adrenergic stimulation with hyperpyrexia leading to increased cellular metabolism. Cocaine may also exert direct toxic effects on the myocyte.[22] Most cocaine entering the United States is contaminated by levamisole, an immunomodulator and antihelminthic agent. In humans, levamisole has been reported to cause an antineutrophil cytoplasmic antibody (ANCA)-positive vasculitis with a necrotizing crescentic glomerulonephritis and prominent skin lesions.

Other illicit drugs associated with AKI include opiates (coma-associated, pressure-induced rhabdomyolysis); phencyclidine (rhabdomyolysis secondary to hyperpyrexia and vasoconstriction); and methamphetamines (AKI secondary to rhabdomyolysis, AIN, or acute necrotizing angiitis). Recently, synthetic cannabinoids have been implicated as a cause of AKI, although the culprit component is unclear. When available, kidney biopsy has shown ATN and more rarely AIN. In most cases, no other cause for AKI could be identified.[21]

Ethylene Glycol

Ethylene glycol, found in antifreeze, is a cause of both deliberate and accidental overdose. It is rapidly metabolized by alcohol dehydrogenase to glycoaldehyde and glyoxylate, which are toxic to tubular cells. Further metabolism generates oxalic acid, which can precipitate, leading to intratubular obstruction.

The diagnosis is suggested by the presence of a severe anion gap metabolic acidosis and an elevated serum osmolal gap. Calcium oxalate crystals are often seen on the urine microscopy (see Chapter 4, Fig. 4.4). Management includes inhibition of alcohol dehydrogenase with fomepizole, or IV ethanol if this agent is not available. Although

there is no specific ethylene glycol level above which extracorporeal removal is mandated, hemodialysis is the quickest way to remove both parent alcohol and toxic metabolites. Methanol intoxication may present with similar metabolic abnormalities but rarely causes AKI (see Chapter 13).

Occupational Toxins

Heavy Metals

Lead intoxication usually causes a chronic nephropathy (see Chapter 65). Rarely, ATI occurs that may be associated with Fanconi syndrome. AKI may also occur in cadmium and mercury poisoning.

Organic Solvents

Organic solvents may cause ATI due to peroxidation of membrane lipids. Subacute kidney failure due to anti–glomerular basement membrane (anti-GBM) antibody disease has also been reported with exposure to halogenated hydrocarbons.

Herbal Remedies

AKI has been reported with the use of herbal remedies; however, nephrotoxicity is most often due to impurities found in unregulated formulations of these substances (e.g., lead, NSAIDs) and not the herbs specifically. Some herbs used in traditional African medicine (e.g., Cape aloes, *Callilepis laureola*) are common causes of AKI in parts of Africa. Aristolochic acid (found in certain traditional Chinese medicines) can cause subacute kidney failure (see Chapters 65 and 79).

Contrast-Induced Nephropathy

It is generally agreed that iodinated contrast can be nephrotoxic but that the risk of AKI with contrast administration is frequently overstated. AKI typically occurs in patients with underlying CKD and is rarely seen in patients with preserved estimated glomerular filtration rate (eGFR). In hospitalized patients, it is often difficult to determine whether a contrast CT is the primary cause of AKI, as imaging is often obtained in the setting of other potential kidney insults (e.g., infection, antibiotics). Recent studies have questioned the link of IV contrast CT with nephrotoxicity, suggesting minimal risk of AKI when low or isoosmolar contrast is administered intravenously to patients with eGFR greater than 30 mL/min/1.73 m^2.[23-25] Indeed, in these studies, the risks of AKI associated with contrast administration were similar among well-matched hospitalized patients who received noncontrast CT scans.

Intraarterial contrast administration, required for cardiac catheterization or renal angiography, poses a greater risk for AKI because a larger dose of iodinated material is required and is then delivered to the renal arteries in a concentrated manner. Risk factors for the development of AKI from contrast nephropathy include diabetic nephropathy, advanced age (>75 years), congestive heart failure, volume depletion, hyperuricemia, and high or repetitive doses of radiocontrast agents. Concurrent use of NSAIDs, ACE inhibitors, or diuretics may increase the risk (see Chapter 74).

Both kidney ischemia and direct tubular epithelial cell toxicity are implicated in the pathogenesis of contrast nephrotoxicity. Typically, a biphasic hemodynamic response is seen. Initial vasodilation (lasting a few seconds to minutes) is followed by more prolonged renal vasoconstriction. The resultant medullary hypoxia may be exacerbated by low flow in the vasa recta as a result of a contrast-induced rise in blood viscosity. An osmotic diuresis, leading to increased sodium delivery to the medullary thick ascending loop, may result in increased oxygen consumption for sodium reabsorption. Uricosuria, as well as a hyperosmolar activation of the aldose reductase-fructokinase system in the kidney, has also been proposed to play a role. Radiocontrast agents also cause direct tubular epithelial cell injury. Human studies have demonstrated low-molecular-weight proteinuria, suggestive of proximal tubular injury, partly mediated by ROS. The administration of antioxidants ameliorates contrast nephrotoxicity in animals.

OTHER SPECIFIC ETIOLOGIES OF AKI

Heme Pigment Nephropathy

Heme pigment nephropathy is a common cause of AKI and is usually secondary to the breakdown of muscle fibers (rhabdomyolysis), which release potentially nephrotoxic intracellular contents (particularly myoglobin) into the systemic circulation. Less commonly, heme pigment nephropathy may occur due to massive intravascular hemolysis. Prevention and therapy of heme pigment nephropathy are discussed in Chapter 74.

Causes of Rhabdomyolysis

Muscle trauma is the most common cause of rhabdomyolysis. The initial description was by Bywaters and Beall during the bombing of London in World War II.[26] Other common causes of muscle injury include marked exercise, seizures, pressure necrosis secondary to coma, substance abuse, and limb ischemia (Table 70.1). In skeletal muscles confined to rigid compartments, cell swelling after injury may result in increased intracompartmental pressures that can impair local microvascular circulation and lead to compartment syndrome (Fig. 70.11). In the patient with substance or alcohol abuse, rhabdomyolysis is often multifactorial. Contributing causes include pressure necrosis from coma ("found down"), direct myotoxicity from ethanol, seizures, and electrolyte abnormalities (hypokalemia and hypophosphatemia). Therapy with statins may be associated with rhabdomyolysis, especially when fibrates, cyclosporine, or erythromycin are used concurrently. The risk of rhabdomyolysis appears to be highest with simvastatin and lower with newer statins such as atorvastatin and rosuvastatin. Familial myopathies such as McArdle syndrome and carnitine palmitoyl transferase deficiency should be suspected in patients with

TABLE 70.1 Causes of Rhabdomyolysis

Muscle injury/ischemia	Trauma; pressure necrosis, electric shock, burns, acute vascular disease
Myofiber exhaustion	Seizures, excessive exercise, heat exhaustion
Toxins	Alcohol, cocaine, heroin, amphetamines, ecstasy, phencyclidine, snakebite
Drugs	Statins, fibrates, zidovudine, neuroleptic malignant syndrome, azathioprine, theophylline, lithium, diuretics
Electrolyte disorders	Hypophosphatemia, hypokalemia, hyperosmolar states
Infections	Viral: Influenza, HIV, coxsackievirus, Epstein-Barr virus, COVID-19 Bacterial: *Legionella, Francisella, Streptococcus pneumoniae, Salmonella, Staphylococcus aureus*
Familial	McArdle disease, carnitine palmitoyl transferase deficiency, malignant hyperthermia
Other	Hypothyroidism, polymyositis, dermatomyositis

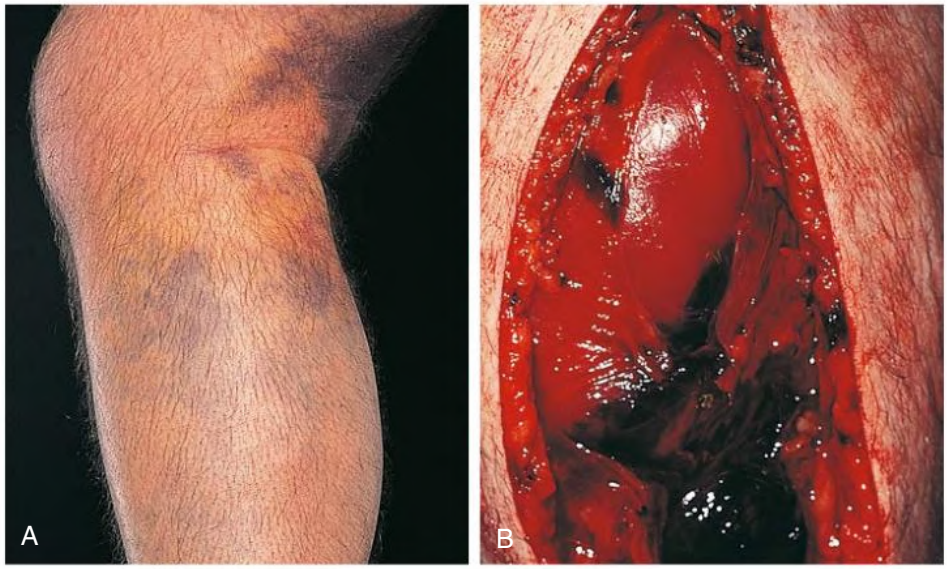

Fig. 70.11 Compartment Syndrome. (A) Severe calf swelling due to anterior and posterior compartment syndromes after ischemia-reperfusion. (B) Appearance after emergency fasciotomy: note edematous muscle and hematoma. (Courtesy Mr. M.J. Allen, FRCS.)

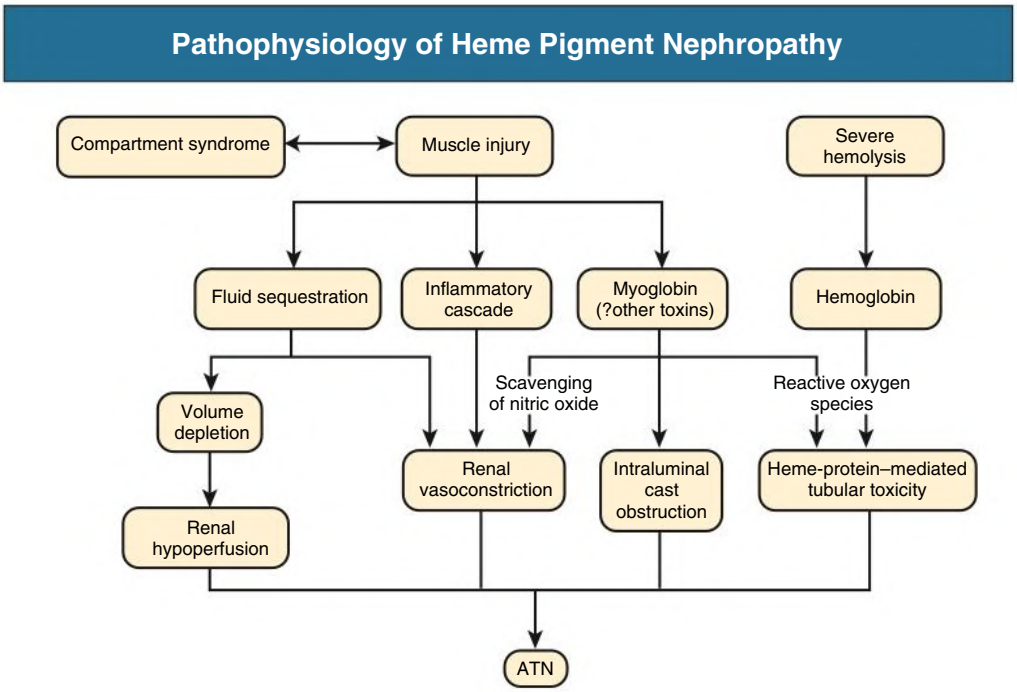

Fig. 70.12 Pathophysiology of Heme Pigment Nephropathy. *ATN,* Acute tubular necrosis.

recurrent episodes of rhabdomyolysis associated with muscle pain, positive family history, onset in childhood, and the absence of other identifiable causes. In developing countries, ingestion of hair dye containing paraphenylene-diamine as a means of self-harm may cause AKI secondary to rhabdomyolysis. Snake and spider bites, bee stings and venomous caterpillar bites may all cause rhabdomyolysis (see Chapter 71). There have been several reports of rhabdomyolysis associated with COVID-19 infection and recreational exposure to bath salts (3,4-methylenedioxypyrovalerone).

Causes of Hemoglobinuria

Intravascular hemolysis results in circulating free hemoglobin. If the hemolysis is mild, the released hemoglobin is bound by circulating haptoglobin. With massive hemolysis, however, haptoglobin stores become exhausted. Hemoglobin (69 kDa) then dissociates into α-β dimers (34 kDa), which are small enough to be filtered, resulting in hemoglobinuria, hemoglobin cast formation, heme uptake by proximal tubular cells, ATN, and filtration failure. Causes of hemoglobinuric AKI include incompatible blood transfusion, autoimmune hemolytic anemia, malaria (blackwater fever), glucose-6-phosphate dehydrogenase deficiency, paroxysmal nocturnal hemoglobinuria, march hemoglobinuria, and toxins (dapsone, venoms).

Pathogenesis of Heme Pigment Nephropathy

The kidney injury is due to a combination of factors including volume depletion, renal vasoconstriction, direct heme-protein–mediated

cytotoxicity, and intraluminal cast formation (Fig. 70.12).[27] Volume depletion is often prominent in patients with rhabdomyolysis owing to the sequestration of up to 15 to 20 L of fluid in injured muscle. Volume depletion activates the sympathetic nervous system and renin-angiotensin system, resulting in renal vasoconstriction. This may be exacerbated by the scavenging of nitric oxide by circulating heme proteins.

Myoglobin (17 kDa) is freely filtered at the glomerulus and is toxic to tubular epithelial cells. The heme center of myoglobin may directly induce lipid peroxidation and kidney injury, and liberated free iron catalyzes the formation of hydroxyl radical through the Fenton reaction, inducing free radical–mediated injury. It has recently been demonstrated that myoglobin released from damaged skeletal muscle activates platelets, which, in turn, induce macrophages in the kidney to produce macrophage extracellular traps (METs).[28] METs have been implicated in the development of kidney injury in mice, though it remains unclear exactly which components of METs are responsible. Renoprotection has been demonstrated in animal models with free iron scavengers and various antioxidants. Finally, the precipitation of myoglobin with uromodulin (Tamm-Horsfall protein) and sloughed proximal tubular cells may result in obstructing casts in the distal nephron, especially when tubular flow rates are low due to volume depletion. The binding of myoglobin to uromodulin is enhanced in acidic urine.

Atheroembolic Kidney Disease

This underrecognized condition occurs predominantly in older patients with atherosclerotic vascular disease (see also Chapter 43). It can occur spontaneously but is most commonly precipitated by arteriography, vascular surgery, thrombolysis (streptokinase and tissue plasminogen activator), or anticoagulation. Destabilization of atherosclerotic plaques primarily in the aorta above the level of the renal arteries results in showers of cholesterol that lodge in small arteries in the kidneys (see Fig. 43.12) and the lower extremities (see Fig. 43.11). Characteristic needle-shaped clefts may be seen on kidney or skin biopsy, denoting the localization of cholesterol plaques before dissolution during tissue fixation (Fig. 43.12). The cholesterol emboli produce an inflammatory reaction and occlusion of the vasculature.

Renal Artery or Vein Occlusion

AKI can be caused by bilateral renal artery occlusion, or unilateral occlusion in the setting of a single functioning kidney (see also Chapter 43). Thrombosis or embolization (noncholesterol) of the renal artery or its intrarenal branches are more common in elderly patients. Atrial fibrillation is an important risk factor for renal emboli. Aortic dissection may also progress to occlude the renal arteries. Renal vein thrombosis most commonly occurs in the setting of nephrotic syndrome and rarely may cause AKI if bilateral.

Acute Interstitial Nephritis

This is most commonly a drug-induced phenomenon and is an important differential diagnosis in AKI because removal of the offending agent can result in reversal of the condition. Less commonly, interstitial nephritis may be due to infection or immune-mediated diseases (see Chapter 64).

Thrombotic Microangiopathy

Thrombotic microangiopathy (TMA) should be considered when a patient presents with AKI and thrombocytopenia, although the condition may occur in the absence of a low platelet count (see also Chapter 30).

TABLE 70.2 Causes of Pulmonary-Renal Syndrome

Anti-GBM Disease (Goodpasture)	
Systemic vasculitis	ANCA associated: • Granulomatosis with polyangiitis • Microscopic polyangiitis • Eosinophilic granulomatosis with polyangiitis • Drugs (penicillamine, hydralazine, propylthiouracil) Immune complex disease: • Lupus • IgA vasculitis • Mixed cryoglobulinemia • Rheumatoid vasculitis
Infection	Severe bacterial pneumonia, postinfectious glomerulonephritis, legionella, leptospirosis, hantavirus, infective endocarditis
Pulmonary edema and AKI	Volume overload in severe left ventricular failure
Multiorgan failure	Acute respiratory distress syndrome and AKI
Other	Paraquat poisoning, renal vein or inferior vena cava thrombosis with pulmonary emboli

AKI, Acute kidney injury; *anti-GBM,* anti–glomerular basement membrane; *ANCA,* antineutrophil cytoplasmic antibody; *IgA,* immunoglobulin A.

Glomerular Disease

All types of glomerular disease (see Section 4) may present with AKI, but it is more commonly seen with forms of acute glomerulonephritis such as postinfectious glomerulonephritis, ANCA-associated small-vessel vasculitis, anti-GBM disease, lupus nephritis, and immunoglobulin A nephropathy. In nephrotic syndrome, AKI may occur due to volume depletion from diuretic use, superimposed ATN, renal vein thrombosis, or rarely from superimposed acute glomerulonephritis (e.g., anti-GBM disease in membranous nephropathy). Minimal change disease in adults is the most common nephrotic disorder associated with AKI.

Pulmonary-Renal Syndromes

The term pulmonary-renal syndrome usually describes the presence of pulmonary hemorrhage in a patient with acute glomerulonephritis. It can be caused by anti-GBM disease (Goodpasture syndrome), systemic vasculitis, or systemic lupus erythematosus (see Chapters 25–27). Patients with pulmonary-renal syndrome require urgent evaluation, and specific testing for these diseases should be pursued. A similar clinical presentation may occur in patients with pulmonary infection and AKI, or in the setting of pulmonary edema secondary to volume overload from AKI. Other conditions that may masquerade as a pulmonary-renal syndrome are outlined in Table 70.2.

SPECIFIC CLINICAL SITUATIONS

AKI in the Patient With Sepsis

Sepsis accounts for up to 50% of cases of AKI in intensive care unit patients, and septic AKI requiring renal replacement therapy is associated with mortality rates as high as 50% to 60%.[29] The traditional model of hypotension and vasoconstriction leading to ischemic ATN has been challenged because in early sepsis, renal blood flow is often normal or even increased. Moreover, the severe drop in GFR observed with sepsis is out of proportion to the relatively mild histologic injury

seen on kidney biopsies, and on autopsy only 22% of patients with sepsis-associated AKI had histologic features of ATN.[30]

The pathogenesis of sepsis-associated AKI is mediated by molecules released from pathogens (lipopolysaccharide, flagellin, lipoteichoic acid, DNA), or injured cells, which activate the innate immune system.[31,32] This leads to the activation of a wide range of cellular and humoral mediator systems, including the cytokine cascade (TNF-a, IL-1β, IL-6); the complement, coagulation, and fibrinolytic systems; increased oxidative stress; and the release of mediators such as eicosanoids, platelet-activating factor, endothelin-1, and nitric oxide. Renal endothelial cells can be damaged in the procoagulant milieu and upregulate their expression of adhesion molecules, further amplifying the immune response. Disruption of the renal microcirculation ensues, with local areas of cortical ischemia despite maintenance of normal renal arterial blood flow. Ligation of toll-like receptors on tubular cells (TLR-4) leads to mitochondrial dysfunction, oxidative stress, and severe apoptosis. The mechanism for the abrupt GFR decline in early sepsis likely involves *efferent* arteriolar vasodilation. Therapies that promote efferent arteriolar vasoconstriction may be beneficial. Treatment with arginine vasopressin, which constricts the efferent more than the afferent arteriole, was associated with reduced progression to the most severe category of AKI in patients with septic shock.[33] Administration of large volumes of IV fluid is common in the early resuscitation phase of sepsis. Isotonic crystalloid solutions with supraphysiologic concentrations of chloride (e.g., normal saline) are associated with an increased incidence of AKI compared with balanced crystalloid solutions (e.g., lactated ringers and plasmalyte), likely due to intense afferent arteriolar vasoconstriction resulting from increased chloride delivery to the macula densa. Sepsis may lead to multiorgan failure, and affected patients may experience repeated episodes of AKI due to nephrotoxic drug exposure or hospital-acquired infections. Maladaptive repair processes can lead to CKD following AKI in sepsis.

AKI in COVID-19

AKI is a common complication of COVID-19; ATN is the predominant mechanism of injury. Cases of collapsing focal segmental glomerulosclerosis have also been reported; these patients typically present with AKI in addition to nephrotic range proteinuria. Kidney disease in COVID-19 is discussed further in Chapter 59.

AKI in the Trauma Patient

AKI significantly increases mortality among those with severe trauma.[34] Mechanisms for kidney injury include rhabdomyolysis (earthquake victims, crush injuries, burns), ATN from hypovolemic shock, or abdominal compartment syndrome due to massive hemorrhage or aggressive hydration. Direct kidney injury may result from penetrating (gunshot, stab wound) or more commonly blunt trauma (fall, motor vehicle collision, assault, sports injury). Proper diagnosis of these injuries requires a contrast-enhanced CT with delayed imaging, otherwise late extravasation from the kidney pelvis or ureters may be missed. Management is generally conservative, but emergent nephrectomy may be required.

AKI in the Postoperative Patient

Postoperative AKI is commonly due to perioperative hemodynamic instability, volume depletion, and/or nephrotoxin exposure.

After Cardiac Surgery

Risk factors for postoperative AKI include duration of cardiac bypass, preoperative kidney function, hyperuricemia, age, diabetes, valvular surgery, blood transfusions, and poor cardiac function.[35] The surgery is often performed with the patient cooled to less than 30°C to protect cells against ischemic injury; however, systemic hypothermia may cause intravascular coagulation. Aortic instrumentation and cross-clamping may lead to renal atheroembolism. Cardiac bypass causes loss of pulsatile flow and exposure of blood to a nonendothelialized surface, resulting in activation of neutrophils, platelets, complement, and fibrinolytic systems. Significant hemolysis and hemoglobinuria may also occur. Perioperative myocardial infarction or left ventricular dysfunction may impair kidney perfusion postoperatively, although the low cardiac output is often transient (myocardial stunning) and recovers within 24 to 48 hours. Atrial fibrillation is common and may be associated with peripheral embolization. Off-pump coronary artery bypass operations may have a lower risk of AKI than surgeries involving cardiopulmonary bypass.

After Vascular Surgery

AKI is common after abdominal aortic aneurysm repair. The risk appears to be lower with endovascular versus open repair.[36] Mechanisms for AKI include ischemic ATN due to prolonged aortic cross-clamping, renal artery thromboembolism or dissection, and cholesterol atheroemboli. Additional complications specific to endovascular repair include contrast nephropathy and kidney ischemia due to endograft malpositioning or migration. In patients with peripheral vascular disease, there is often ischemic kidney disease. Preoperative reduction in eGFR is the strongest predictor of the risk for postoperative AKI.

Abdominal Compartment Syndrome

Markedly raised intraabdominal pressures (>20 mm Hg) may occur after trauma, after abdominal surgery, or secondary to massive fluid resuscitation and can cause AKI. Particularly vulnerable are patients with low mean arterial pressures, as this further compromises abdominal perfusion pressure.[37] The multifactorial mechanisms of AKI likely include increased kidney venous pressure and vascular resistance, as well as a drop in cardiac output from decreased venous return and reduced ventricular compliance. Intraabdominal pressures are best estimated by measurement of intravesical (bladder) pressures. Efforts to reduce intraabdominal pressures, including paracentesis, nasogastric suction, ultrafiltration, or surgical decompression, may improve kidney function.

AKI and Liver Disease

AKI is common in patients with cirrhosis. The differential diagnosis is typically between prerenal AKI, ATN, and hepatorenal syndrome. The pathophysiology of hepatorenal syndrome is discussed in Chapter 76. Assessment of intravascular volume status can be difficult, and a therapeutic trial of volume replacement is typically undertaken. Risk factors for AKI in this population include hypovolemia, GI bleeding, and infection (particularly spontaneous bacterial peritonitis). Severe malnutrition and decreased muscle mass may be masked by the presence of edema; in these settings, a normal serum creatinine can represent a significant loss of GFR. Rarely, the same etiologic agent may be responsible for both the liver and kidney injury. This occurs with certain infections (e.g., leptospirosis, hantavirus) and nephrotoxic agents (Table 70.3). Cholemic nephropathy, AKI secondary to bile cast mediated tubular injury, has been described in obstructive jaundice.

AKI in Heart Failure (Cardiorenal Syndrome)

The development of AKI in patients with decompensated heart failure is common and is associated with poor prognosis. Reduced kidney perfusion secondary to decreased cardiac output has long been considered the primary cause; however, there are important contributions from right ventricular dysfunction leading to kidney venous hypertension and from activation of renin angiotensin and sympathetic nervous systems.[38]

AKI in the Cancer Patient

Patients with cancer are prone to AKI due to the underlying malignancy and its treatment (see Chapter 67). In a large European population, the incidence of AKI was 18% in the year following cancer diagnosis, and AKI occurs commonly in critically ill cancer patients.[39] Prerenal azotemia is common in cancer patients due to the high frequency of vomiting and diarrhea, and urinary tract obstruction must always be ruled out (Table 70.4). More specific causes of intrarenal AKI are noted in the following sections.

Tumor Lysis Syndrome

Necrosis of tumor cells may release large amounts of nephrotoxic intracellular contents (uric acid, phosphate, xanthine) into the circulation. This usually occurs after treatment of lymphoma (particularly Burkitt lymphoma) and leukemia but may occur with solid tumors. Rarely, a spontaneous form of tumor lysis syndrome occurs in patients with rapidly growing tumors that have outstripped their blood supply. AKI occurs when crystals of uric acid, calcium phosphate, and xanthine precipitate in the renal tubules causing obstruction and inflammation. Hyperuricemia may also contribute to AKI by crystal-independent mechanisms including renal vasoconstriction and oxidative injury.[40] Risk factors for tumor lysis syndrome include preexisting CKD, bulky and rapidly proliferating tumors, volume depletion, and acidic urine. The AKI is typically oligoanuric, and the condition should be suspected in patients with high lactate dehydrogenase levels suggestive of massive cell lysis. Markedly elevated phosphate and urate levels may be found. Hyperkalemia may be prominent and life-threatening. Prevention and therapy of tumor lysis syndrome are discussed in Chapter 67.

TABLE 70.3 Causes of AKI and Liver Disease

Prerenal azotemia	Diuretic use, gastrointestinal loss, large-volume paracentesis, hypoalbuminemia
Hepatorenal syndrome	
Acute tubular necrosis	Hyperbilirubinemia (bile cast nephropathy), sepsis, GI hemorrhage
Drugs	Acetaminophen (paracetamol), NSAIDs, tetracycline, rifampin, isoniazid, anesthetic agents, sulfonamides, anticonvulsants (DRESS syndrome), allopurinol, methotrexate, aspirin (Reye syndrome)
Infections	Hepatitis C and cryoglobulinemia, hepatitis B and polyarteritis nodosa, leptospirosis, hantavirus, Epstein-Barr virus, gram-negative sepsis, spontaneous bacterial peritonitis
Other	Papillary necrosis, inhalation of chlorinated hydrocarbons, mushroom poisoning *(Amanita phalloides)*, carbon tetrachloride

AKI, Acute kidney injury; *DRESS,* drug reaction with eosinophilia and systemic symptoms; *GI,* gastrointestinal; *NSAID,* nonsteroidal antiinflammatory drug.

Hypercalcemia

Hypercalcemia is common in advanced cancer and may result from lytic bone metastases, overproduction of 1,25-dihydoxyvitamin D (predominantly lymphomas), or production of parathyroid hormone–related peptide. Hypercalcemia causes nausea, vomiting, and polyuria, and AKI in this setting is often driven by volume depletion. Additional mechanisms for hypercalcemia-induced AKI include direct intrarenal vasoconstriction and intratubular obstruction.

Chemotherapeutic Agents

Cisplatin is commonly associated with nonoliguric AKI, and nephroxicity is the most common dose-limiting side effect of this drug.[41] Cisplatin accumulates in mitochondria inhibiting oxidative phosphorylation, resulting in excessive reactive oxygen formation and impairment in ATP generation, leading to cell death. Tubular injury affects both the proximal and distal nephrons and clinically may be associated with magnesium wasting, impaired urinary concentration, and rarely salt wasting with volume depletion. Prophylaxis against nephrotoxicity includes volume loading and reducing the dose when possible. Although kidney impairment may persist after treatment, progressive decline in GFR is unusual. When combined with bleomycin and vinca alkaloids, cisplatin is also associated with thrombotic microangiopathy. The alternative agent carboplatin appears to be less nephrotoxic.

Ifosfamide is a cyclophosphamide analog with a nephrotoxic metabolite, chloroacetaldehyde. AKI is usually mild, although

TABLE 70.4 Causes of AKI in Patients With Cancer

Prerenal	Nausea and vomiting, hypercalcemia, cardiomyopathy secondary to chemotherapy
Vascular	Thrombotic microangiopathy (adenocarcinoma of stomach; cancer of the breast, prostate, lung, or pancreas; radiation nephropathy), renal vein thrombosis secondary to hypercoagulability, DIC (acute promyelocytic leukemia)
Glomerular	Rapidly progressive glomerulonephritis
Acute tubular necrosis	Sepsis and antibiotic nephrotoxicity
Malignant infiltration	Lymphoma, acute lymphoblastic leukemia
Intraluminal obstruction	Tumor lysis syndrome, myeloma cast nephropathy
Postrenal obstruction	Transitional cell carcinoma ureters and bladder, prostatic obstruction, extrinsic ureteral compression (tumor, nodes, retroperitoneal fibrosis)
Chemotherapeutic Agents	
Tubular toxicity	Cisplatin, ifosfamide, plicamycin (mithramycin), imatinib, pemetrexed, pentostatin, high-dose bisphosphonates
Thrombotic microangiopathy	Mitomycin C, gemcitabine, cisplatin, CNIs, anti-VEGF therapies
Other mechanisms	Capillary leak syndrome (IL-2 therapy), AIN (interferon α, check point inhibitors, lenalidomide), intraluminal obstruction (methotrexate)

AIN, Acute interstitial nephritis; *AKI,* acute kidney injury; *CNI,* calcineurin inhibitor; *DIC,* disseminated intravascular coagulation; *IL-2,* interleukin-2; *VEGF,* vascular endothelial growth factor.

proximal tubular dysfunction (Fanconi syndrome) and hypokalemia may be prominent and sometimes persistent.

High-dose methotrexate and its metabolites can precipitate within the tubular lumen and cause AKI. Risk factors for drug crystallization include acid urine, volume depletion, impaired GFR, and concurrent nephrotoxin exposure. Aggressive hydration and urinary alkalinization (pH >7) can reduce the risk for nephrotoxicity.

Gemcitabine is a nucleoside analog that causes AKI primarily by damaging the renal endothelium. The most common manifestation is a thrombotic microangiopathy that develops 1 to 2 months following drug completion. AKI is often accompanied by new onset hypertension or worsening of existing hypertension. Laboratory evidence of systemic hemolysis is common. AKI due to thrombotic microangiopathy may also be caused by mitomycin and by drugs that inhibit vascular endothelial growth factor pathways (e.g., bevacizumab, tyrosine kinase inhibitors).[42]

Immune checkpoint inhibitors (e.g., ipilimumab, nivolumab, and pembrolizumab) all increase the risk of AKI. Several case series have identified AIN as the predominant mechanism of AKI, although TMA and immune complex–mediated glomerulonephritis have also been observed. Additional chemotherapeutic agents that may cause AKI are listed in Table 70.4.

SELF-ASSESSMENT QUESTIONS

1. Acute tubular injury predominantly affects which segments of the nephron?
   - **A.** Proximal convoluted tubule and loop of Henle
   - **B.** Proximal tubule and distal convoluted tubule
   - **C.** Loop of Henle and distal convoluted tubule
   - **D.** Distal convoluted tubule and collecting ducts
   - **E.** All tubular segments of the nephron equally
2. What is the most likely mechanism by which nonsteroidal antiinflammatory drugs cause AKI in a patient with systolic heart failure?
   - **A.** Impaired efferent arteriole vasodilation
   - **B.** Impaired efferent arteriole vasoconstriction
   - **C.** Impaired tubuloglomerular feedback
   - **D.** Impaired afferent arteriole vasodilation
   - **E.** Impaired afferent arteriole vasoconstriction
3. Which of the following nephrotoxic agents causes AKI predominantly by the formation of intratubular crystals?
   - **A.** Cisplatin
   - **B.** Methotrexate
   - **C.** Gentamicin
   - **D.** Amphotericin
   - **E.** Tacrolimus
4. How does tubular injury (acute tubular necrosis) cause a drop in glomerular filtration rate?
   - **A.** Efferent arteriole vasoconstriction and increased hydraulic pressure in Bowman's space
   - **B.** Afferent arteriole vasoconstriction and increased hydraulic pressure in Bowman's space
   - **C.** Efferent arteriole vasoconstriction and decreased hydraulic pressure in Bowman's space
   - **D.** Afferent arteriole vasoconstriction and decreased hydraulic pressure in Bowman's space
   - **E.** Efferent arteriole vasodilation and unchanged hydraulic pressure in Bowman's space

Acute Kidney Injury in the Tropics

Emmanuel A. Burdmann, Vivekanand Jha, Nattachai Srisawat

Approximately 40% of the world population lives in the tropics, and this proportion is expected to rise to 60% by 2060. Tropical countries have high sociopolitical-economic heterogeneity, which influences health care. Facilities providing sophisticated care coexist with lack of basic public sector health infrastructure.[1-3]

Acute kidney injury (AKI) epidemiology in the tropics reflects these inequalities. In wealthy areas of the main cities and tertiary hospitals, AKI epidemiology is similar to that found in high-income countries in nontropical areas, and AKI principal causes are ischemia and drug nephrotoxicity. In contrast, in remote small cities, in vulnerable neighborhoods of large cities, and in rural zones, AKI is frequently community acquired, affecting previously healthy younger individuals. In those settings, infectious diarrhea, tropical infectious diseases, poisonous animals, natural medicines, and poor obstetric care are common causes of AKI.[1,2] Poverty, malnutrition, lack of quality sanitation, deficient public health systems, and uncontrolled urbanization are frequent and add significantly to the disease burden. Access to kidney replacement therapy (KRT) may be limited because of nonavailability and costs.[2-4] Epidemiologic data for community-acquired AKI in tropical countries showed a high frequency and high early mortality.[2-3]

There is regional variability in the cause of AKI in the tropics. Malaria, leptospirosis, diarrheal diseases, and venomous snakebite are common causes in South Asia. Malaria, diarrheal diseases, obstetric accidents, and indigenous herbal remedies are frequent in Africa. Malaria, leptospirosis, dengue fever, animal envenomation, and obstetric complications are important in Latin America.[1-4] Acute decreases in glomerular filtration rate (GFR) associated with dehydration from prolonged strenuous work in an unhealthy environment has been described in agricultural workers (see Chapter 66).[5] The long-term morbidity and mortality of tropical disease–associated AKI are nearly unknown.

SNAKEBITE

Snakebite is a neglected public health occupational hazard. Economically deprived populations living in rural communities are affected disproportionately. It has been suggested that snakebite envenomation causes 120,000 global deaths annually, with the highest burden in South and Southeast Asia, Latin America, and sub-Saharan Africa.[6] This is likely an underestimate because the data are based on hospital admissions. In 2019 the World Health Organization (WHO) released a strategy aiming to reduce snakebite-associated death and disability by 50% before 2030.[7]

Snake venoms are complex, with significant inter- and intraspecies variation. AKI is an important complication of snake venoms and may develop after bites by hemotoxic or myotoxic snakes belonging to the Viperidae and Elapidae families, such as Russell's viper, saw-scaled viper, puff adder, rattlesnake, tiger snake, green pit viper, *Bothrops, Lachesis,* South American rattlesnake *(Crotalus),* boomslang, gwardar, dugite, *Hypnale, Cryptophis,* and sea snakes. AKI is more frequent after Russell's viper bites (Fig. 71.1) in Asia and *Bothrops* and *Crotalus* bites in Latin America.[1,8-10] In a single center report from India, 21% of 866 snakebite patients over a 10-year period had developed AKI.[11] AKI prevalence is higher in children, probably because of the higher venom dose in relation to the body size.[1,10]

Clinical and Laboratory Features

Clinical manifestations depend on the nature and injected dose of venom. Local pain, swelling, blistering, ecchymosis and tissue necrosis at the bite site, and coagulation abnormalities leading to bleeding diathesis are frequent in Russell's viper and *Bothrops* bites (Figs. 71.2 and 71.3). Neurotoxicity (paralysis) and rhabdomyolysis (myalgia and cola-colored urine) may occur after sea snake and *Crotalus* bites.[1,8-11] Other uncommon manifestations include myocardial injury and hypopituitarism.[12,13]

AKI develops within a few hours (snake venom concentrates in kidney minutes after the bite) to as late as 96 hours after the accident.[1,8-11] The AKI is usually oliguric and catabolic. Oliguria generally lasts for 1 to 2 weeks, and its persistence suggests the likelihood of acute cortical necrosis, which can be confirmed by kidney biopsy or a contrast-enhanced computed tomography scan.[1,8-11] Although kidney function usually recovers, AKI-associated snakebite has been associated with chronic kidney disease (CKD) in both adults and children on long-term follow-up.[14] AKI after snakebite may aggravate kidney dysfunction in CKD of unknown ethology in agricultural workers.[15]

Laboratory investigation may disclose hemolysis (elevated free serum hemoglobin and lactate dehydrogenase and reduced haptoglobin), along with hypofibrinogenemia, reduced factors V, X, and XIIIA, protein C and antithrombin C, and elevated fibrin degradation products. Rhabdomyolysis may be present. Other findings include leukocytosis and elevated hematocrit as a result of hemoconcentration.[1,8-11] Laboratory features suggestive of thrombotic microangiopathy (TMA) were described in 19% cases,[16] related with severe and prolonged AKI and more likely to be associated with acute cortical necrosis. Elevations in urinary kidney structural biomarkers can predict AKI following Russell's viper bites.[17]

Pathology

Grossly, the kidneys may have petechial hemorrhages. On light microscopy, acute tubular cell injury ranging from mild changes to overt tubular necrosis, with hyaline or pigment casts, variable degree of interstitial edema and infiltration, and scattered hemorrhages are usually found. Mesangiolysis may occur (especially with *Crotalid* envenomation), and vessels may show fibrin thrombi. Electron microscopic findings include dense intracytoplasmic bodies representing degenerated organelles in the proximal tubules and electron-dense mesangial deposits. Less common findings are acute interstitial nephritis, necrotizing vasculitis,

and proliferative and crescentic immune-complex glomerulonephritis (GN). Acute cortical necrosis is seen in about 20% to 25% of cases after Russell's viper and *Echis carinatus* bites and has been described after *Bothrops* bites.[1,8-11]

Pathogenesis

Snake venom is a mixture of enzymes, toxins, peptides, carbohydrates, lipids, metals, biogenic amines, and nucleotides. Factors potentially involved in kidney injury include direct tubular toxicity, hemodynamic instability, hemolysis, rhabdomyolysis, systemic inflammation, glomerular deposition of microthrombi, oxidative stress, hyperuricemia, release of cytochrome c, and apoptosis of tubular epithelial cells.[1,8-11,18-20]

Management

Key steps include early administration of specific monovalent antivenom, appropriate volume replacement, maintenance of adequate urine output, correction of electrolyte abnormalities, administration of tetanus immunoglobulin, and treatment of infections.[1,8-11] Locally available polyvalent antivenom is effective against envenoming by multiple or unknown snakes.[21] Nonavailability of antivenom in rural hospitals and poor infrastructure that hampers transportation to health centers delay antivenom administration and may contribute to high mortality.[1,8-11,22] A recent systematic review highlighted the lack of high-quality evidence supporting the safety and efficacy of antivenom or other interventions in preventing or treating AKI.[23] Limited availability and the risk for side effects have encouraged the exploration of alternatives for antivenom therapies, but none has shown efficacy.[24] Therapeutic plasma exchange in cases with TMA was not effective.[16]

ARTHROPODS

Bees

Hundreds of simultaneous bee stings or multiple stings from wasps, yellow jackets, or hornets cause a multifaceted clinical picture comprising intravascular hemolysis; rhabdomyolysis; bleeding; cardiovascular, hepatic, and pulmonary injury; and severe AKI, with high mortality.[1,25,26] The potential mechanisms include direct venom nephrotoxicity, intrarenal vasoconstriction, hemoglobinuria, myoglobinuria, hypotension, TMA, and inflammatory and oxidative stress pathways activation.[27] Rarely, AKI can develop following a single sting, either due to anaphylactic reaction or secondary to TMA.[28] Kidney histology shows acute tubular necrosis.[1,27] The high morbidity and lethality of massive bee attacks has prompted the development of an antivenom, which was effective in protecting against rhabdomyolysis and hemolysis in mice.[29]

Caterpillars

Accidents with caterpillars of the genus *Lonomia* produce severe hemorrhagic disorders, characterized by both fibrinolytic and disseminated intravascular coagulation–like activity.[1] Severe and prolonged AKI, with some patients evolving to CKD, has been reported after *Lonomia obliqua* (Fig. 71.4) envenomation.[1,30] Early antivenom administration in rats prevented hemorrhagic manifestations and kidney dysfunction.[31] The AKI mechanisms likely involve glomerular deposition of fibrin, intravascular hemolysis, direct venom nephrotoxicity, activation of the endothelial cell inflammatory pathway, increased kidney expression of proteins involved in cell stress, heme-induced oxidative stress, coagulation, complement system activation, and kinin release.[32,33] Kidney histologic findings include acute tubular necrosis, ischemia, and tubular atrophy.[30,32]

Fig. 71.5 *Loxosceles* spp. (Brown Recluse Spider). (Courtesy Katia C. Barbaro, São Paulo, Brazil.)

Loxosceles (Brown Recluse Spider)

Loxosceles genus spiders (Fig. 71.5) cause local necrosis at the bite site (Fig. 71.6), intravascular hemolysis, rhabdomyolysis, coagulation abnormalities, and AKI.[1,34] Even patients with mild cutaneous lesions may develop severe hemolysis and AKI, which is the main cause of death after these accidents. AKI pathogenesis has been related to massive intravascular hemolysis, kidney vasoconstriction, direct nephrotoxicity, and rhabdomyolysis.[1,34,35] Kidney histologic examination shows pigment-induced acute tubular necrosis.[34] Antivenom is likely the most effective therapy against AKI, but its use is frequently delayed because the bite goes unnoticed.

Scorpions

Scorpion venom causes autonomic overactivity and massive discharge of vasoactive substances and inflammatory cytokines and concentrates rapidly in kidney tissue.[36] Scorpion venom–associated AKI is rare.[37,38] AKI mechanisms are probably kidney vasoconstriction, hemodynamic instability, rhabdomyolysis, systemic inflammation, hemoglobinuria, mitochondrial dysfunction, and direct venom nephrotoxicity.[36-39] Kidney structural changes include acute tubular necrosis, glomerular changes, interstitial infiltrates, TMA, and acute cortical necrosis.[36,37,38,40]

NATURAL MEDICINE

Herbs and indigenous remedies are widely used in poor societies living in the tropics and are an important cause of AKI, especially in sub-Saharan Africa. This subject is discussed in Chapter 79.

MALARIA

Five species of *Plasmodium* parasites (*falciparum, vivax, malariae, ovale,* and *knowlesi*) cause malaria. Globally, malaria afflicts over 200 million people annually, causing nearly 500,000 deaths, mostly in children with *P. falciparum.* The contribution of malaria as the cause of AKI among different geographic areas ranges from 2% to 39%. AKI frequency in *P. falciparum* malaria reaches 60%, and in *P. vivax* malaria varies from 10% to 19%.[41] *P. malariae, P. knowlesi,* and *P. ovale*–induced AKI are less common. Malaria-associated AKI frequency using Kidney Disease: Improving Global Outcomes criteria is higher than using the WHO criteria.[42] In this chapter we focus on *P. falciparum* malaria–associated AKI.

Pathophysiology

P. vivax, P. ovale, and *P. knowlesi* infect young erythrocytes, and *P. malariae* infects aging cells. *P. falciparum* infects erythrocytes of all ages, producing a higher number of merozoites (Fig. 71.7). Heavy parasitemia is commonly observed in *P. falciparum* malaria, creating adverse effects on the microcirculation. Parasitized erythrocytes play a major role in the pathophysiologic process of the disease through decreased erythrocyte deformability and sequestration, knobs and rosette formation, cytoadherence, and changes in membrane transport and permeability (Fig. 71.8). The presence of knobs on parasitized erythrocyte membranes and cytoadherence between parasitized erythrocytes and vascular endothelial cells are characteristic of *P. falciparum* malaria. Cytoadherence of mature *P. vivax* parasitized erythrocytes to vascular endothelial cells involves intercellular adhesion molecule-1, CD36, endothelial protein C receptor, platelet endothelial cell adhesion molecule, and chondroitin sulfate A receptors.[43] *P. vivax*–caused cytoadherence is lower than that of *P. falciparum*–infected erythrocytes. Several proinflammatory cytokines (tumor necrosis factor; interleukins 1, 6, and 8; interferon-γ) and vasoactive mediators are released. The renin-angiotensin-aldosterone system is also stimulated. Hemodynamic changes in malaria are similar to those of bacterial sepsis, including decreased systemic vascular resistance, hypervolemia, increased cardiac output, and increased kidney vascular resistance. Because of increased vascular permeability, the initial hypervolemia is followed by hypovolemia and decreased cardiac output, with decreased kidney blood flow and GFR. Increased blood viscosity, intravascular coagulation, hemolysis, rhabdomyolysis, jaundice, fever, lactic acidosis, complement activation, and reactive oxygen species further compromise kidney blood flow. Activation of poly (adenosine diphosphate [ADP]-ribose) polymerase by peroxynitrite and free radicals decreases oxygen utilization.

AKI in malaria is ischemic and hypoxic in origin and usually occurs with heavy parasitemia, intravascular coagulation, intravascular hemolysis, or rhabdomyolysis.[41] Immune responses in malaria involve Th1 and Th2 activation. Immune complex GN can occur (see Chapter 57). Tubular changes vary from cloudy swelling to tubular degeneration (Fig. 71.9). Bile and hemoglobin casts and Tamm-Horsfall protein are present in the tubular lumen. Interstitial mononuclear infiltration and edema can occur. TMA and acute cortical necrosis have been reported.[44,45] Malarial antigens are occasionally seen along the glomerular endothelium and medullary capillaries. Adhesion molecules and proinflammatory cytokines are overexpressed in the vascular endothelium and proximal tubules.[41]

Fig. 71.6 Local Necrotic Injury in the Left Leg of a Female Patient After *Loxosceles* Bite. (A) At 4 days after the bite. (B) At 60 days after the bite. (C) At 3 months after the bite. (Courtesy Carlos A.C. Mendes, São José do Rio Preto, Brazil.)

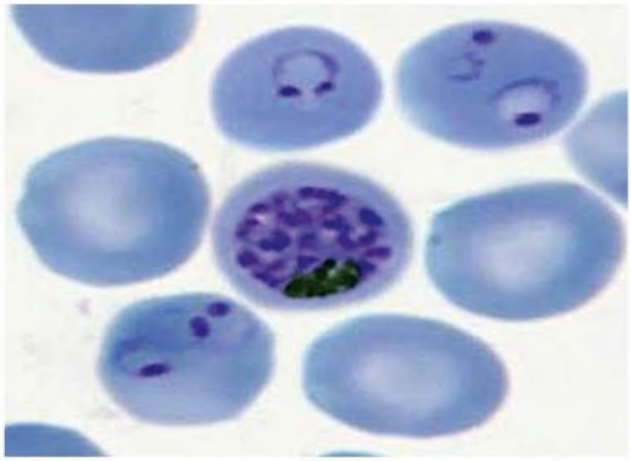

Fig. 71.7 Ring form and merozoites of *Plasmodium falciparum* in infected erythrocytes.

Clinical Manifestations

Malarial AKI affects predominantly nonimmune adults, mostly infected by *P. falciparum.* Reports link *P. vivax* infection with acute respiratory distress syndrome (ARDS), severe AKI, and TMA.[44] Mixed *Plasmodium* infections and comorbidities related to sepsis are likely important contributing factors to AKI. Symptoms include fever, chills, headache, prostration, and occasionally jaundice. The urinalysis usually shows few erythrocytes, leukocytes, and granular casts and proteinuria, often less than 1 g/24 hr. Hemoglobinuria happens in the patient with intravascular hemolysis, frequently associated with glucose-6 phosphate dehydrogenase deficiency. Rhabdomyolysis with myoglobinuria can be observed. Fluid and electrolyte changes are common in malaria.[41,46] Hyponatremia, usually asymptomatic, is observed in 67% of patients, is related to the severity of malaria, and resolves within a few days after antimalarial treatment. The causes of hyponatremia are multiple, including increased antidiuretic hormone with water retention, intracellular shift of sodium as a result of decreased Na^+,K^+-ATPase activity, and sodium depletion. Hypernatremia is uncommon, indicates hypothalamic lesions with diabetes insipidus, and is associated with unfavorable prognosis. Hypokalemia occurs in 20% to 40%

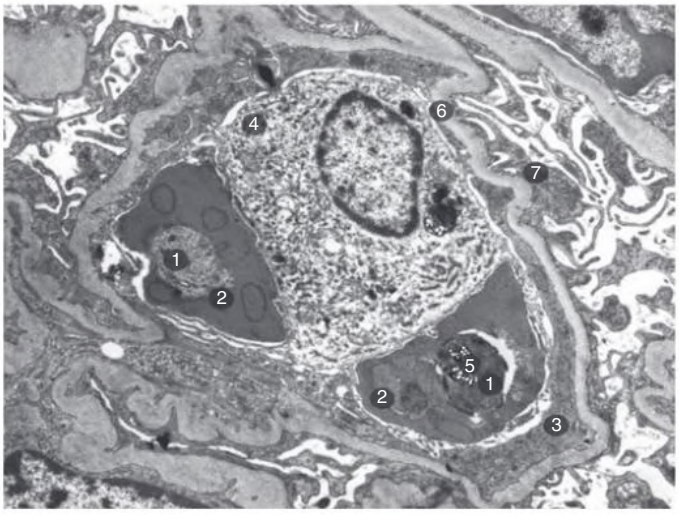

Fig. 71.8 Transmission electron micrograph from the kidney in *Plasmodium falciparum* malaria showing sequestration of two parasitized ed blood cells *(2)* within a glomerular capillary. Fig. 71.9 Acute tubular necrosis in *Plasmodium falciparum* malaria.

of patients with uncomplicated cases. Hyperkalemia is observed in patients with intravascular hemolysis, rhabdomyolysis, and/or AKI. Hypocalcemia with prolonged QTc interval occurs in 45% of severe malaria cases and resolves with infection control.[46] Decreased activities of Na^+,K^+-ATPase, Ca^{2+}-ATPase, and parathyroid hormone are considered the main causes for hypocalcemia. Hypophosphatemia is observed in 6% to 30% and hypomagnesemia in 30% of patients.[46] Downregulation of sodium channels on the apical membrane of alveolar epithelial cells and increased vascular permeability account for the development of pulmonary edema and ARDS.[47]

Malarial AKI is characterized by a rapid increase in serum creatinine and is often associated with cholestatic jaundice. Risk factors for AKI include high parasitemia, jaundice, high liver enzymes, thrombocytopenia, decreased diastolic blood pressure, retinopathy, and ARDS. Hemolytic uremic syndrome has been described. Severe acidosis-associated lactic acidemia, hypoglycemia, and central nervous system symptoms are observed in severe malaria. Malarial AKI with multiple organ involvement and papilledema carries an unfavorable prognosis. AKI duration ranges from one to several weeks and is oliguric in 60% of the patients. Quinine and artesunate are the antimalarial agents most commonly used. The first choice in malarial AKI is artesunate, because it has high efficacy and does not need adjustment for kidney function. Early and frequent KRT (hemodialysis or peritoneal dialysis) is lifesaving.[41] Continuous venovenous hemofiltration yields good results in patients with multiorgan involvement, especially those with pulmonary edema or ARDS.[41] Exchange blood transfusion and erythrocytapheresis are adjunctive for the patient with heavy parasitemia.[48] The mortality rate of malarial AKI ranges from 10% to 50%. Kidney function may not recover completely in severe AKI, evolving to CKD in 7% of malaria-induced AKI.

LEPTOSPIROSIS

Leptospirosis, the world's most common zoonosis, is caused by *Leptospira* genus spirochetes.

The WHO included leptospirosis as a reemerging infectious disease in both higher and lower income areas, and cases have been increasingly reported in wealthy countries. Wild and domestic mammals (rodents, dogs, pigs, cattle, horses) are the disease vectors. The infection is transmitted accidently to humans through broken skin or mucosal membranes exposed to water or soil contaminated with organisms shed in the urine from the natural vectors.[1] Leptospirosis is a job-related threat for rodent exterminators, slaughterhouse workers, farmers, pet traders, veterinarians, garbage collectors, and sewer workers. Human leptospirosis is endemic in many tropical countries and usually reaches epidemic levels after heavy rainfall and flooding, or natural disasters, such as hurricanes or earthquakes. A meta-analysis revealed that flooding, lacerated wounds, and history of contact with livestock were independent risk factors for human leptospirosis.[49] There is an annual global estimate of 1 million cases, with 58,900 fatalities, with about half among young adult males.[50] A high seroprevalence of anti-*Leptospira* antibodies has been found in the general asymptomatic population in tropical countries.[1]

Leptospira interrogans, the only parasitic species, is mobile, aerobic, and unstained by the Gram method. Its endotoxins primarily affect tubulointerstitial cells. The bacterial outer membrane contains lipopolysaccharide, cytotoxic glycolipoprotein (GLP), and lipoproteins (LipL), especially LipL 32, which is immunogenic. Because *Leptospira* have special tropism for the kidneys, the effect of GLPs on tubular Na^+,K^+-ATPase activity is potentially involved in the AKI cellular pathophysiology, in the urinary concentrating defects, and in the paradoxical hypokalemia frequently seen in these patients.[1] Glycocalyx and endothelial injury caused by spirochete membrane proteins also may contribute to AKI (Fig. 71.10).

Kidney involvement is almost universal in leptospirosis but becomes relevant in Weil disease, the most severe form of leptospirosis, which is characterized by multiorgan involvement, with diffuse alveolar hemorrhage, pulmonary edema, ARDS, or a combination of these features, accompanied by AKI and a high mortality rate. Leptospirosis-associated AKI incidence varies from less than 10% to more than 80%, and its severity is associated with increasing mortality. Oliguria, jaundice, arrhythmias, thrombocytopenia, elevated baseline serum creatinine, and urinary neutrophil gelatinase–associated lipocalin levels have been associated with AKI development.[51] AKI is typically nonoliguric and associated with hypokalemia.[1] Tubular changes characterized by high urinary fractional excretion of sodium and potassium precede reduced GFR, which could explain the high frequency of hypokalemia. Long-term follow-up of leptospirosis-associated AKI found late development of CKD and presence of tubular function abnormalities.[52]

Early diagnosis and treatment are pivotal to successful leptospirosis treatment. The symptoms of leptospirosis (fever, myalgia, and headache) are nonspecific, jeopardizing its diagnosis.[53] The THAI

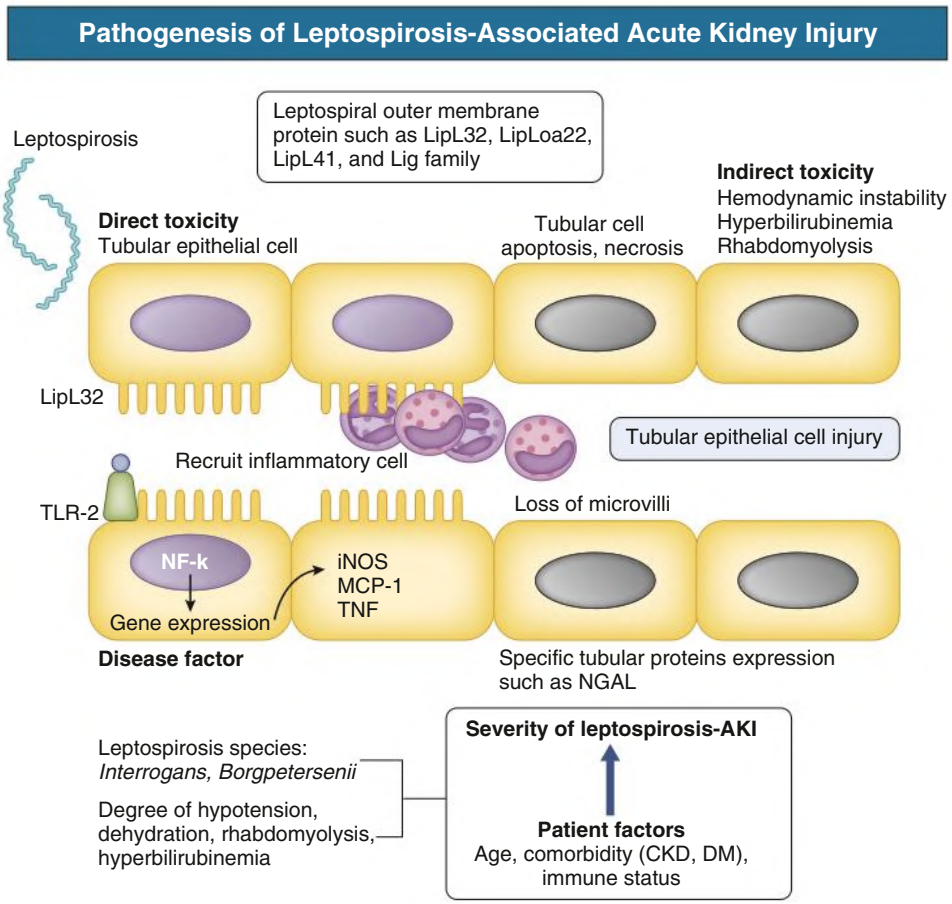

Fig. 71.10 Pathogenesis of leptospirosis associated acute kidney injury (AKI). *CKD,* Chronic kidney disease; *DM,* diabetes mellitus; *NGAL,* neutrophil gelatinase-associated lipocalin.

LEPTO score was proposed as a tool to help distinguish leptospirosis from other diseases in the inpatient setting. It includes hypotension, jaundice, muscle pain, AKI, low hemoglobin, hypokalemia with hyponatremia, and neutrophilia. The score showed a high discriminatory power with area under the curve (AUC) of 0.82.[54] A subsequent report in an outpatient department setting showed that the simplified score (Lepto OPD score) comprising history of exposure to wet ground at workplace, contact with water reservoir used by animal, positive urine dipstick test for protein and blood, and neutrophil count higher than 80% had an AUC of 0.72.[55] Microtranscriptome profiles of patients with severe leptospirosis versus nonsevere were different, suggesting novel biomarkers for severe leptospirosis.[56]

The leptospirosis diagnostic tests recommended by WHO include microscopic agglutination test, direct culture, and polymerase chain reaction technique. These techniques require advanced facilities, which are not universally available. Rapid diagnostic test kits, which mainly test serum immunoglobulin M antibodies, might be an alternative for this situation. However, different test kits have diversity of accuracy in different populations, and so their performance must be evaluated in specific populations before its use.[57]

Antibiotics of the penicillin group are considered the basis of treatment, but their efficacy remains unproven.[58] A study exploring the role of corticosteroid and desmopressin in severe leptospirosis patients with pulmonary involvement did not demonstrate any benefit on survival.[59] Current treatment recommendations include a high KRT dose, conservative fluid intake, and approaches to minimize lung injury, including extracorporeal membrane oxygenation support when indicated.[60]

HEMORRHAGIC FEVERS

Viral hemorrhagic fevers (VHFs) are caused by RNA viruses of four different families (Flaviridiae, Arenaviridae, Bunyaviridae, Filoviridae). Dengue, Rift Valley fever, yellow fever, and Crimean-Congo virus can be acquired by bites from infected arthropods, by inhalation of infected rodent excreta particles (Lassa, Junin, Machupo, Hantaan virus), or through contact with contaminated material (Ebola virus). The clinical picture includes fever, malaise, increased vascular permeability, and coagulation abnormalities that may lead to bleeding. Dengue and yellow fever are the most prevalent forms of VHF in the tropics.[1,61,62]

Dengue Fever

Dengue, which is currently the most important urban arboviral disease, is an acute febrile disease caused by an arbovirus transmitted primarily by mosquitoes, mainly the female *Aedes aegypti* mosquito. The number of yearly infections is estimated at 390 million.[62,63]

Several factors account for the rising incidence and widespread occurrence of dengue, such as climate changes (global warming, intensity and duration of rain season, hurricanes), ecosystem modifications, demographic increases, uncontrolled urbanization, and human migration. There are four serotypes of antigenically related dengue *flavivirus* (DEN 1 to DEN4), but immunity to one does not confer enduring immunity to another. The introduction of a new serotype in a determinate area accounts for the occurrence of epidemics and the hemorrhagic fever dengue form, which is a more severe and potentially lethal form of the disease.[63]

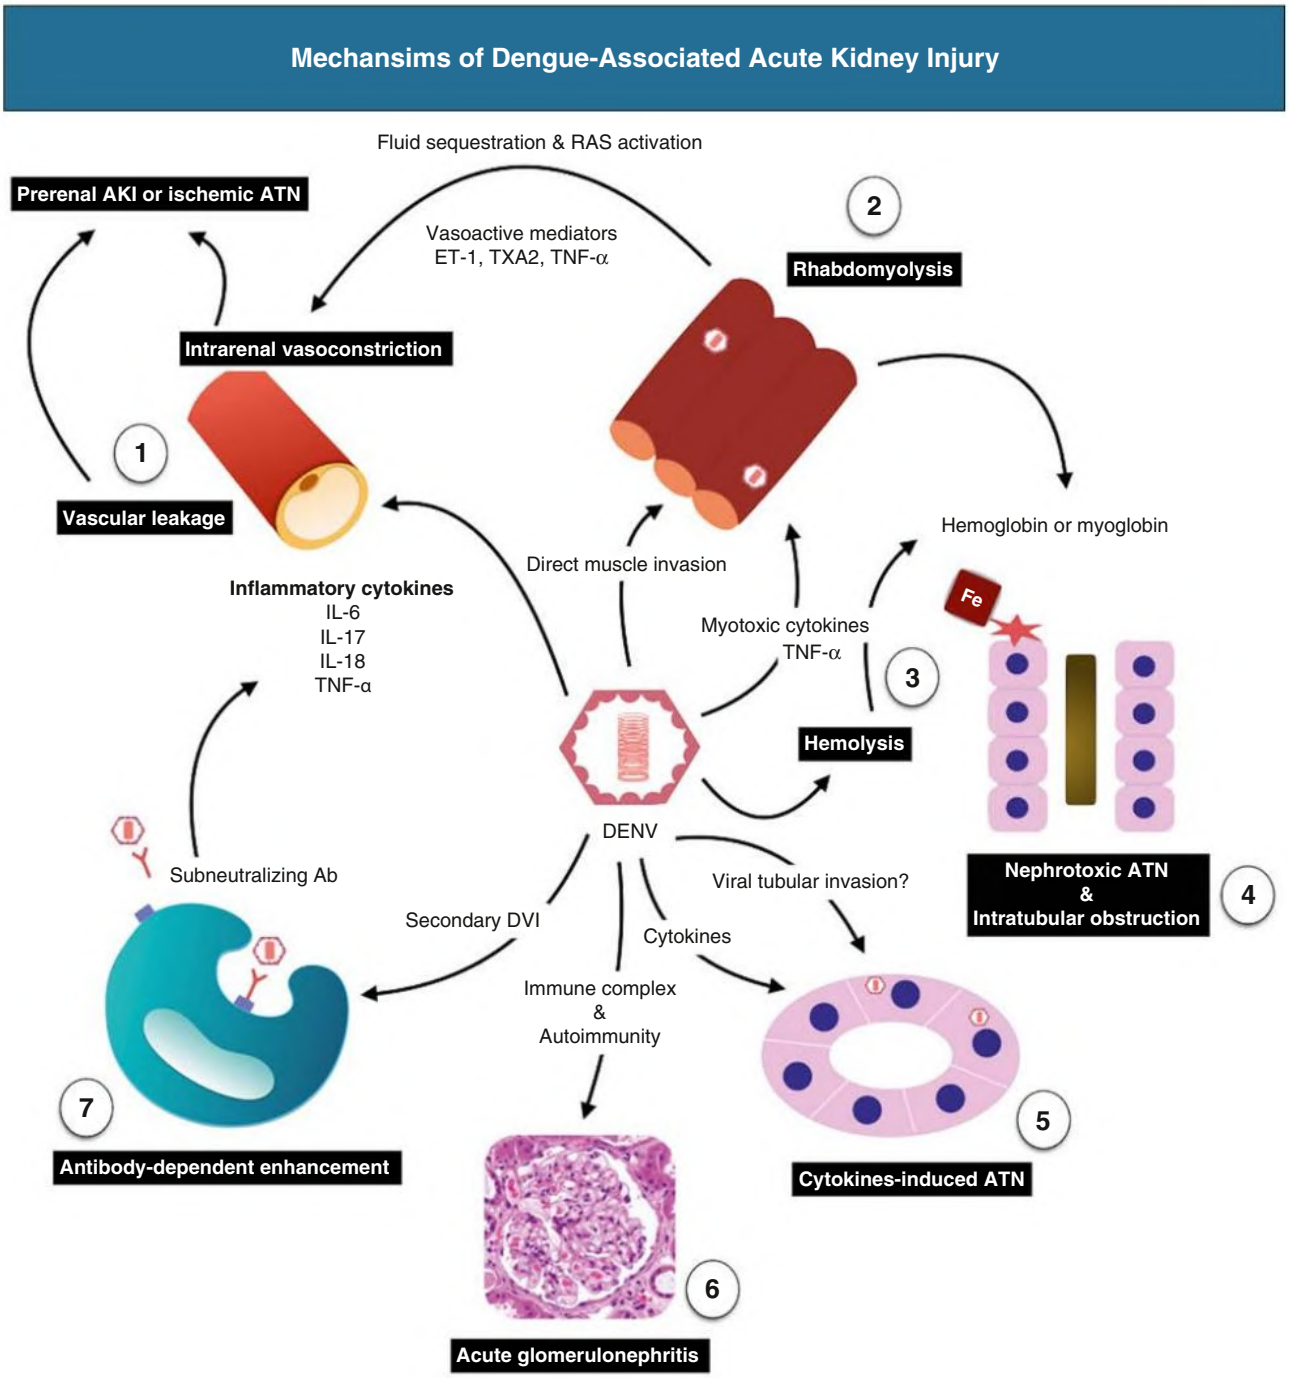

Fig. 71.11 Summary of Mechanisms of Dengue-Associated Acute Kidney Injury (AKI). (1) Dengue virus triggers cascades of inflammatory response, which lead to endothelial injury and vascular leakage. Reduced kidney perfusion occurs as a result. (2) Rhabdomyolysis in dengue virus is proposed to result from direct viral invasion and myotoxic inflammatory cytokines. (3) Intravascular hemolysis can be found, particularly in patients with glucose-6-phosphate dehydrogenase deficiency. (4) Myoglobin and hemoglobin are freely filtered into urine and directly injure kidney tubular cells. In some instances, they can, together with tubular proteins, form casts in the tubular lumens. (5) Acute tubular damage can be accounted for by inflammatory cytokines or by direct viral invasion suggested by the presence of viral antigen in tubular cells of dengue patients with AKI. (6) Evidence of dengue-associated acute glomerulonephritis with glomerular immune complex deposits has been reported, as well as development of autoantibodies to glomerular basement membrane (GBM) resulting in anti-GBM disease. The latter process is thought to be mediated by molecular mimicry of viral antigens. (7) Key immunopathogenesis of severe dengue virus infection (DVI) is based on antibody-dependent enhancement, where subneutralizing antibodies acquired from past infection promote dengue virus (DENV) entry into cells and suppress the antiviral response. *Ab,* Antibody; *ATN,* acute tubular necrosis; *ET-1,* endothelin-1; *IL,* interleukin; *RAS,* renin-angiotensin system; *TNF-α,* tumor necrosis factor-α; *TXA2,* thromboxane A2.

Dengue infection may manifest as undifferentiated fever, dengue fever, dengue hemorrhagic fever (DHF), or dengue shock syndrome (DSS). Common clinical manifestations of dengue fever are high fever, myalgia, arthralgia, retroocular pain, headache, anorexia, nausea, vomiting, and a cutaneous rash. DHF and DSS are severe forms of the disease, characterized by fever, hemorrhage, thrombocytopenia, and evidence of plasma leakage (increased hematocrit, pleural effusion, ascites, and hypoalbuminemia), mental disorientation, shortness of breath, tachycardia, shock, and death.[62,64]

Kidney involvement in dengue includes AKI, proteinuria (sometimes nephrotic), GN (see Chapter 57), hemolytic uremic syndrome, and electrolyte abnormalities.[62,64,65] The frequency of dengue-associated AKI varies from 1% to 30%, and its development and severity are related to poor prognosis.[62,64,66,67]

Dengue-induced AKI is usually associated with shock, hemolysis, and/or rhabdomyolysis but may occur without any of these triggers and is described in all forms of dengue.[62,64] Risk factors for AKI comprise increased hepatic enzymes, hypoalbuminemia, reduced serum bicarbonate, other simultaneous viral or bacterial infection, multiple organ dysfunction, use of inotropic or nephrotoxic drugs, increased age, obesity, dengue severity, rhabdomyolysis, presence of diabetes mellitus, and delayed hospitalization.[62,64]

The pathogenesis of dengue-associated AKI has been attributed to hemodynamic instability, rhabdomyolysis, hemolysis, direct viral invasion, and immune response. Patients with severe dengue infection, mostly reinfected by another viral strain, may develop plasma leakage syndrome, which eventually results in hypotension, causing kidney hypoperfusion and AKI. Inflammatory cytokines produced by dengue-infected monocytes and mast cells probably are linked to this phenomenon.[68] Rhabdomyolysis may occur rarely in dengue, and viral muscle invasion and inflammatory cytokines myotoxicity have been considered as possible agents causing muscles injury.[69] Data from autopsies and from studies in rodents demonstrated the presence of dengue virus in kidney tissue, suggesting direct kidney cytopathic effects. Host immune response may be involved in the pathogenesis of dengue-associated AKI. The concept of secondary infection as the key pathogenic factor for developing DHF/DSS has been well established for decades and is explained by antibody-dependent enhancement. Previous infection by one serotype of dengue virus results in development of subneutralizing antibodies. These antibodies possess high viral attachment efficiency enhancing internalization of virus into cells. Reports of DHF and AKI associated with proteinuria, hematuria, and reduced serum C3 level without presence of hypotension, rhabdomyolysis, hemolysis, or use of nephrotoxic agents support the role of possible immunopathogenic mechanism causing glomerular and tubular damage either by immune complex–mediated mechanism or cytokine-mediated tubular injury. Autoimmunity induced by molecular mimicry is another possible mechanism for dengue-associated kidney disease (Fig. 71.11).[62,64]

There is no specific treatment for dengue fever. Therapy is mostly supportive, avoiding the use of aspirin and nonsteroidal antiinflammatory drugs.

Yellow Fever

Yellow fever is a noncontagious infectious disease that is endemic in tropical Africa, South America, and Panama. The yellow fever virus is part of the *Flavivirus* genus (Flaviviridae family).[61] It is transmitted to humans by blood-eating insect bites, especially by the *Aedes* and *Haemagogus* genera. There are two cycles, termed *sylvatic* and *urban.* The sylvatic cycle affects sporadic individuals who come in contact with the vectors when performing economic or recreational activities in infested forests. The urban cycle is characterized by virus transmission through *A. aegypti* to individuals living in urban areas. The urban cycle was eliminated in the Americas from the 1940s to 1950s, but its resurgence was recently documented in Bolivia. The movement of viremic individuals to cities with high vector populations can potentially generate explosive urban epidemics affecting thousands of nonvaccinated people.[61] There is no evidence of yellow fever in Asia, despite an extensive presence of vectors.[70] It is possible that the hyperendemicity of dengue in Southwest Asia has afforded protection because of cross-reactive antibodies.

Yellow fever infection might be asymptomatic, cause moderate febrile disease, or be severe, causing hemorrhagic fever, liver failure, AKI, and death. Most patients (85%) fully recover after 3 to 4 days and become permanently immunized against the disease. About 20% develop the severe form, with mortality of up to 50%.[61] After 3 to 6 days of incubation, the clinical picture starts abruptly with high fever, chills, anorexia, myalgia, headache, vomiting, and bradycardia. Hemorrhagic manifestations may occur. There is then a remission period with symptom improvement, and mild cases do not have any further manifestation. In the severe forms, fever recurs followed by vomiting, epigastric pain, and jaundice—the so-called intoxication phase. There are large increases in transaminases and bilirubin, and leukopenia and ST segment abnormalities may develop. Hemorrhagic events associated with hepatic damage and consumptive coagulopathy can occur, such as hematemesis, melena, petechiae, bruises, mucosal bleeding, and metrorrhagia in women. Microcirculatory thrombosis, disseminated intravascular coagulation, tissue anoxia, oliguria, and shock may follow.[61]

Yellow fever–associated AKI occurs usually after 5 days of disease in the severe forms and may evolve to anuria and acute tubular necrosis, with increased mortality. In Africa, AKI is observed earlier, without jaundice or liver abnormalities, with higher mortality. AKI mechanisms are poorly understood. Kidney ischemia, intravascular coagulation, shock, bilirubin-induced kidney tubule cell toxicity, virus direct effect on kidney tissue, and intense inflammatory cytokine discharge are likely mechanisms of AKI.[71-73] In 2017 and 2018, outbreaks of yellow fever in Brazil AKI and increased kidney echogenicity were identified as independent factors associated to higher patient mortality.[74-75]

SELF-ASSESSMENT QUESTIONS

1. Bites from what families of snakes may lead to acute kidney injury?
   A. Viperidae and Elapidae
   B. Only Elapidae
   C. Only Tropidophiidae
   D. Colubridae and Aniliidae
   E. Only Aniliidae
2. A 25-year-old farmer from northeast Thailand, without underlying diseases, presented with high fever and history of back pain for the last 3 days. His vital sign revealed heart rate 120 beats/min, blood pressure 80/40 mm Hg, body temperature 38.8°C, and respiratory rate 30 breaths/min. Initial laboratory examination showed leukocytosis with neutrophil predominate. Urinalysis showed white blood cells numbering 10 to 30/high power field (HPF) and red blood cells 5 to 10/HPF.

   On the second day after admission, he was still febrile and had worsening of kidney function. Blood pressure was 120/70 mm Hg. His serum creatinine increased from 1.0 mg/dL to 4.2 mg/dL. A leptospirosis rapid test was negative. Indirect immunofluorescence assay for scrub typhus was pending. Dengue NS1 Ag was negative. Malaria thick and thin films were negative. Hemoculture was negative.

What is the most likely diagnosis?

A. Melioidosis
B. Scrub typhus
C. Dengue infection
D. Leptospirosis
E. Malaria

3. What is the correct sequence (from higher to lower frequency) of *Plasmodium* species associated with AKI development?

A. First *vivax,* then *falciparum,* less common *malariae, ovale,* and *knowlesi*
B. First *falciparum,* then *vivax,* less common *malariae, ovale,* and *knowlesi*
C. First *falciparum* and *vivax* similarly, then *malariae, ovale,* and *knowlesi*
D. *Falciparum, vivax, malariae, ovale,* and *knowlesi* similarly
E. First *malariae, ovale,* and *knowlesi* similarly, then *falciparum* and *vivax*

4. What kind of viral hemorrhagic fevers are more commonly associated with development of acute kidney injury?

A. Crimean-Congo hemorrhagic fever and Ebola
B. Chikungunya fever and Rift Valley fever
C. Dengue, yellow fever, and Hantavirus hemorrhagic fever
D. Malaria and leptospirosis
E. Tick-borne encephalitis and Brazilian hemorrhagic fever

Diagnosis and Clinical Evaluation of Acute Kidney Injury

Eric Judd, Paul W. Sanders, Anupam Agarwal

The term *acute renal failure* (ARF) describes the clinical syndrome in which an abrupt (hours to days) decrease in kidney function leads to the accumulation of nitrogenous waste products and, commonly, a reduction in urine output. *Acute kidney injury* (AKI) has become the consensus term for ARF.[1-3] This change in terminology served to standardize a definition for the syndrome, as well as to incorporate knowledge that increases in serum creatinine as small as 0.3 mg/dL (27 μmol/L) are associated with increased morbidity and mortality.[4]

In 2012 the Kidney Disease: Improving Global Outcomes (KDIGO) guideline unified the definition of AKI and included stages of severity (Table 72.1). AKI has since been defined as an increase in serum creatinine of 0.3 mg/dL or greater within 48 hours of observation or 1.5 or more times baseline, which is known or presumed to have occurred within 7 days, or a reduction in urine volume below 0.5 mL/kg/h for 6 hours.[1] Subclassification of AKI based on disease severity as indicated by the level of increase in serum creatinine and reduction in urine output has been adopted as a three-stage classification by KDIGO. Increasing severity of AKI based on creatinine and urine output associates with increased risk for death.[1]

There are many different causes of AKI, and most are identified through clinical investigation. Globally, hypotension and volume contraction or dehydration accounted for 40% of AKI cases in both the hospital and nonhospital setting.[5] In higher-income countries, hypotension and shock were the most common causes of AKI, whereas volume contraction or dehydration predominated in lower-income countries. Nephrotoxic agents were implicated in up to a quarter of AKI events across all countries.[5] However, nephrotoxin administration may account for a larger proportion of hospital-acquired AKIs in older patients.[6,7] Kidney biopsy is rarely performed to establish the cause of AKI. In an observational study of 745 patients with AKI in the intensive care unit (ICU), only 3% (22 patients) underwent kidney biopsy and, as expected, glomerulonephritis (GN) and acute interstitial nephritis (AIN) were each diagnosed in about a third of the biopsy specimens, and about 23% showed only acute tubular necrosis (ATN).[8]

EARLY DETECTION OF ACUTE KIDNEY INJURY

The definition of AKI is based on increases in serum creatinine, yet when used as a marker of kidney function, serum creatinine concentrations have multiple limitations. In addition to a steady-state balance of creatinine production and excretion being required for appropriate estimation of glomerular filtration rate (GFR), serum creatinine concentrations may not rise for subtle declines in GFR and are slow to rise for rapid falls in GFR. Furthermore, the generation of creatinine from muscle is reduced in sepsis-induced AKI, and serum creatinine concentrations may not increase proportionally to GFR decline.[9] Kidney injury will initially remain undetected until serum creatinine concentrations rise (8–48 hours) (Fig. 72.1).[10] Serum and urine biomarkers with potential as early indicators of AKI include tissue inhibitor of metalloproteinase 2 (TIMP-2), insulin-like growth factor–binding protein 7 (IGFBP7), hepcidin, kidney injury molecule 1 (KIM-1), neutrophil gelatinase–associated lipocalin (NGAL), cystatin C, interleukin-18 (IL-18), proenkephalin A, and others. These biomarkers also may allow for improved prognostication and insight into the specific cause of AKI.[11]

Signifying the integration of nontraditional biomarkers in the diagnosis of AKI, the definition of AKI has been expanded to include biomarker status, including a subclinical stage (1S) where biomarkers are positive without significant changes in serum creatinine or urine output.[11] Biomarkers are categorized by predictive type. The strongest predictor of AKI severity and outcome involves a combination of biomarker types and clinical judgment. For example, the combination of biomarkers reflecting kidney function (cystatin C) and kidney damage (NGAL) was superior to serum creatinine in predicting AKI severity in children undergoing cardiopulmonary bypass.[12]

Serum cystatin C is a 13-kDa cysteine protease inhibitor that is freely filtered at the glomerulus and normally reabsorbed by proximal tubule cells and may be more sensitive than serum creatinine concentrations for detecting small reductions in GFR,[13] and thus may have advantages for diagnosing AKI and predicting AKI severity.[11,14]

The combination of urinary levels or IGFBP7 and TIMP outperforms all other biomarkers in the early detection of AKI in critically ill patients.[15] Both proteins are expressed in tubular cells and have autocrine and paracrine effects that lead to G1 cell cycle arrest for short periods. In AKI, preventing or delaying tubular cell division may be a protective response to injury. The risk for stage 2 or 3 AKI correlated well with logarithmic values of [IGFBP7]*[TIMP-2] measured from a urine sample obtained within 12 hours of the diagnosis of AKI,[15] and their combined urinary levels correlated to clinician-adjudicated AKI better than KDIGO criteria.[16] The release of TGFBP7 and TIMP-2 during cell cycle arrest make their urinary levels potentially useful for predicting the development of AKI.[11,17]

Assessing kidney function with a loop diuretic challenge (furosemide stress test) improves prediction of kidney outcomes compared with biomarker measurement. In patients with early AKI in the ICU, urinary responses to intravenous furosemide predicted the need for dialysis better than biomarker measurement alone.[18] Failure to produce more than 200 mL of urine within 2 hours of intravenous furosemide dosed at 1 to 1.5 mg/kg strongly predicted both the need for dialysis and progression to AKI stage 3.[18]

KIM-1, a cell membrane glycoprotein upregulated in injured proximal tubular cells, can act as a nonmyeloid phosphatidylserine receptor that transforms epithelial cells into semiprofessional phagocytes.[19] The ectodomain of this membrane-associated molecule is shed into the urine of injured but not healthy kidneys. KIM-1 messenger ribonucleic acid

TABLE 72.1 Kidney Disease: Improving Global Outcomes Composite Staging of Acute Kidney Injury

Stage	Serum Creatinine	Urine Output
1	1.5–1.9 × baseline *or* ≥0.3 mg/dL (≥29 μmol/L) increase	<0.5 mL/kg/h for 6–12 h
2	2.0–2.9 × baseline	<0.5 mL/kg/h for ≥12 h
3	3.0 × baseline *or* Increase in serum creatinine to ≥4.0 mg/dL (≥352 μmol/L) *or* Initiation of kidney replacement therapy *or* In patients younger than 18 yr, decrease in estimated glomerular filtration rate <35 mL/min/1.73 m^2	<0.3 mL/kg/h for ≥24 h *or* Anuria for ≥12 h

From the Kidney Disease Improving Global Outcomes (KDIGO) Working Group. KDIGO clinical practice guideline for acute kidney injury. *Kidney Int Suppl.* 2012;2(1):1–138.

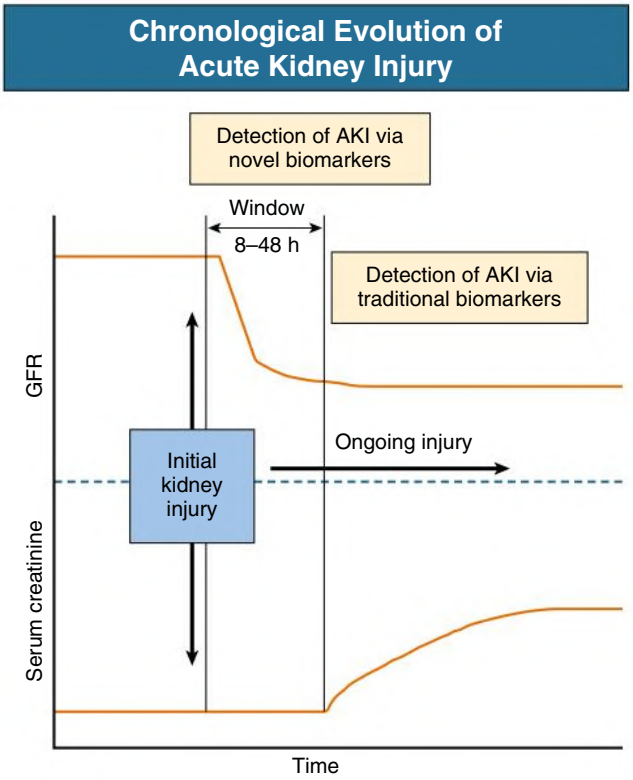

Fig. 72.1 Chronologic evolution of acute kidney injury (AKI). *GFR,* Glomerular filtration rate. (Modified from Ravn B, Rimes-Stigare C, Bell M, et al. Creatinine versus cystatin C based glomerular filtration rate in critically ill patients. *J Crit Care.* 2019;52:136–140.)

(mRNA) levels may rise more than any other gene after kidney injury, and urinary levels are increased specifically with AKI resulting from ischemia or toxin exposure.[20,21] Urine KIM-1 is categorized as a damage biomarker.[11]

NGAL, a protein produced by neutrophils, binds and traffics free iron.[20] It also mediates the tubular response to epidermal growth factor and is thereby involved in the progression of kidney disease.[22] Urinary NGAL levels are increased in the setting of tubular stress or injury, but not in prerenal disease.[23] A large number of studies correlated urinary NGAL levels to early detection of AKI.[10] Plasma and urine levels of NGAL are categorized as a damage biomarker that may be used to diagnose and predict the severity of AKI.[11]

IL-18 is an inflammatory cytokine found in macrophages, monocytes, and proximal tubule cells. Urinary levels are upregulated in kidney ischemic injury in multiple clinical settings.[10] Urinary IL-18 levels are used as a damage biomarker.[11]

Biomarkers have the potential for detecting AKI early, identifying minor kidney injuries that do not raise serum creatinine concentrations (subclinical AKI), monitoring therapeutic benefits of novel treatment interventions, and specifying the cause of AKI. However, AKI frequently occurs unobserved in the community or is present at the time of recognition. Approximately 50% of patients admitted from the emergency department with septic shock have AKI on arrival to the ICU.[24] Even when computer models successfully predict hospital-acquired AKI, early interventions have had little effect on outcomes. The composite outcome of maximum change in serum creatinine level, need for dialysis, or death at 7 days did not change when primary providers were notified of AKI by an electronic alert system.[25] Multicenter implementation of an AKI alert system along with an AKI care bundle and education of health care workers resulted in increased AKI recognition and more frequent assessment of patient fluid status, but the risks of 30-day mortality after AKI (24.5%) and progressive AKI were unchanged.[26] Nevertheless, biomarkers remain an exciting potential tool for diagnosing, identifying a cause of, and predicting outcomes of AKI.

DIAGNOSTIC APPROACH TO ACUTE KIDNEY INJURY

The basic diagnostic approach to patients with AKI is to determine the cause (see Chapter 70). This process should start by excluding or correcting both prerenal and postrenal causes (Fig. 72.2). In hospitalized patients, making a diagnosis often involves selecting the most probable cause among many choices.[27] Assessing daily urine volume can narrow the differential diagnosis, dividing AKI into oliguric (<500 mL/d) and nonoliguric causes. Acute tubular necrosis, the most common cause of hospital-acquired AKI, is oliguric, whereas AIN and glomerular-related AKI are typically nonoliguric. A careful history and physical examination and basic laboratory tests often suffice for diagnosis (Table 72.2).[27]

Acute Kidney Injury Versus Chronic Kidney Disease

It can be difficult to determine whether a patient with kidney failure has AKI or AKI superimposed on chronic kidney disease (CKD). Knowledge of prior serum creatinine concentrations is required to determine the degree of potentially reversible AKI. Ultrasound evidence of small, scarred kidneys is consistent with CKD, but even advanced diabetic nephropathy, amyloidosis, human immunodeficiency virus (HIV) infection–related nephropathy, or polycystic kidney disease can present with normal or increased kidney size. Normocytic anemia, hyperparathyroidism, peripheral neuropathy, and broad waxy casts in the urinary sediment suggest CKD. Patients with CKD are at high risk for developing AKI.[28]

CLINICAL ASSESSMENT

The evaluation of a hospitalized patient with AKI should begin with a complete medical history and review of the hospital records. Once the prior serum creatinine concentration or other evidence of underlying kidney disease is established, the history should be directed toward the events preceding the AKI (see Fig. 72.2). These events

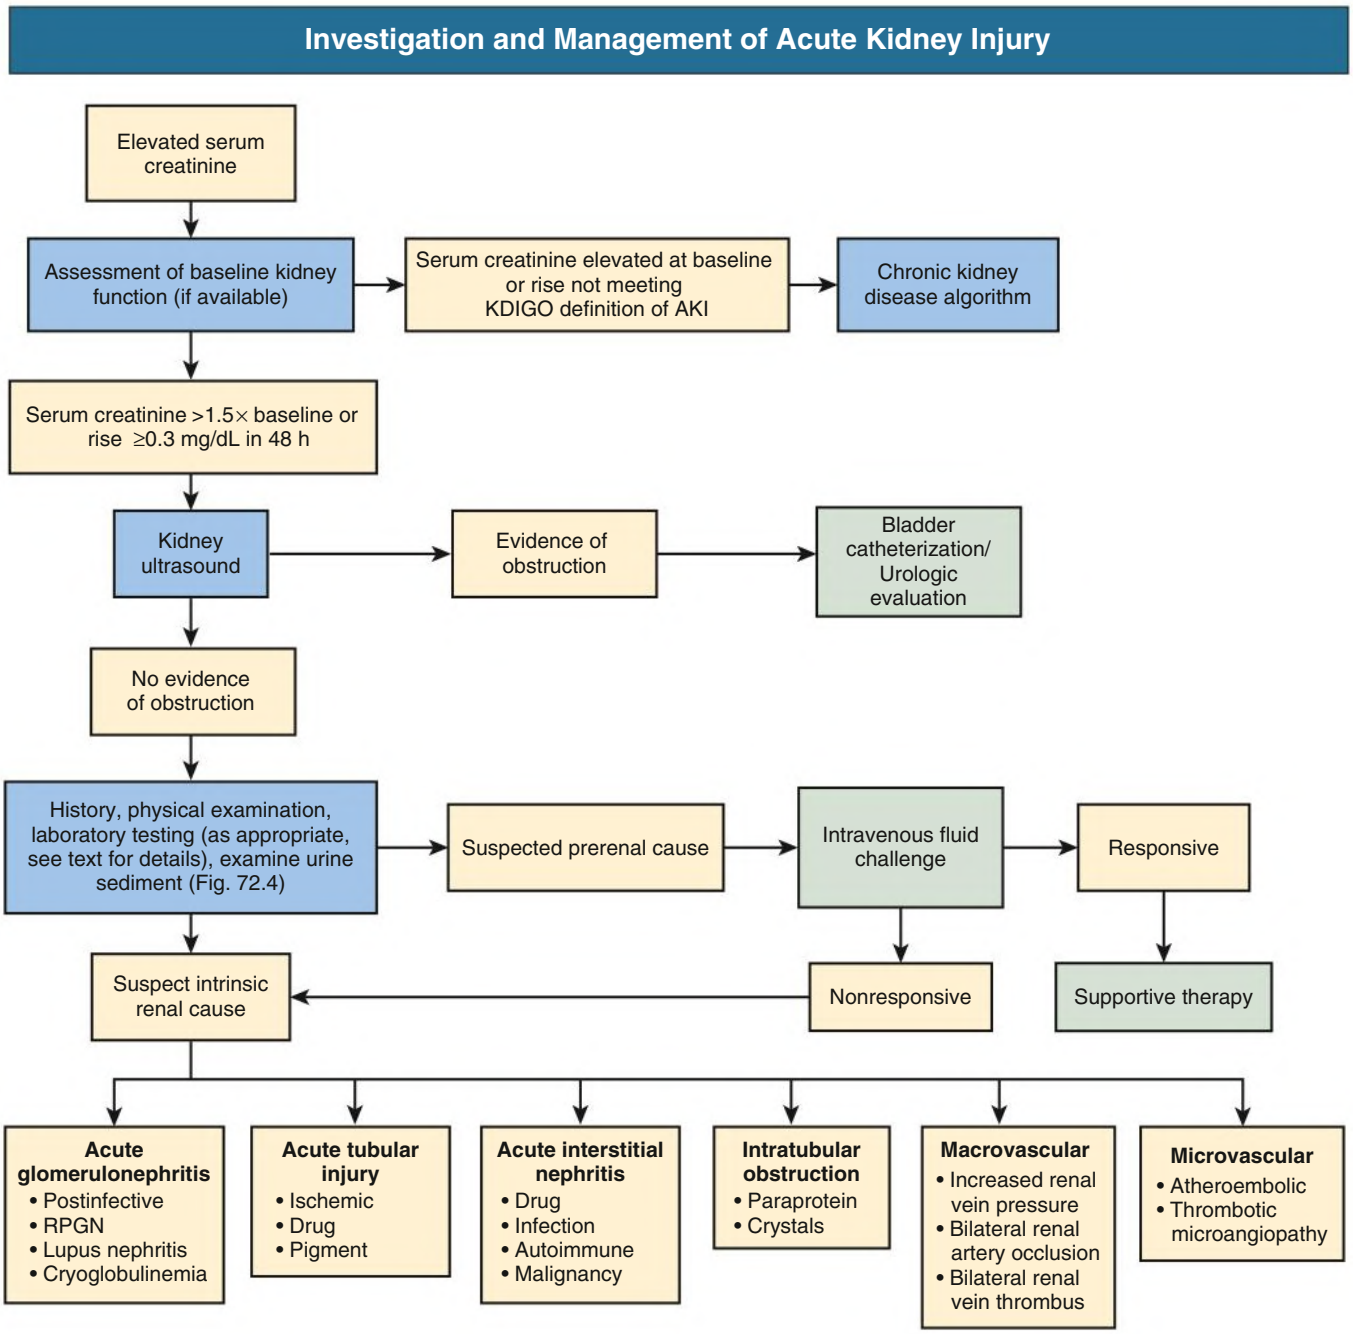

Fig. 72.2 Investigation and Management of Suspected Acute Kidney Injury (AKI). The majority of AKI causes can be identified by reviewing the events that preceded the AKI. Evaluating for urinary obstruction early prevents the delay of urologic therapy, if needed; however, not all patients require a kidney ultrasound. If prerenal and postrenal causes have been excluded, the kidneys are normal size, and the diagnosis remains unclear, a kidney biopsy may be indicated. *KDIGO,* Kidney Disease: Improving Global Outcomes; *RPGN,* rapidly progressive glomerulonephritis.

may be part of a systemic disease process (e.g., sepsis, rhabdomyolysis), an inpatient event (e.g., surgery, nephrotoxic agent exposure), or an outpatient event (e.g., medication or drugs, volume contraction from diarrhea or vomiting). Particular attention should be paid to the medication record, looking for use of nonsteroidal antiinflammatory drugs (NSAIDs), renin-angiotensin-aldosterone antagonists, diuretics, antibiotics, proton pump inhibitors, chemotherapy agents (e.g., platin-based therapies and immune check point inhibitors), herbs that might contain aristolochic acid (see Chapter 65), or a synthetic cannabinoid.[29] In Africa and India the ingestion of hair dyes containing paraphenylenediamine may result in AKI. Clues to a postrenal cause (e.g., urinary hesitancy, frequent nocturia, pelvic or flank pain, overflow urinary incontinence, metastatic cancer) should be assessed early.

Physical examination may reveal reduced body weight, marked orthostatic decrease in blood pressure, an increase in pulse rate, and lack of jugular venous distention, all suggesting a reduction in extracellular fluid volume. Patients with prerenal AKI can appear volume overloaded in heart failure, cirrhosis, and nephrotic syndrome when effective arterial blood volume is reduced. In critically ill patients,

TABLE 72.2 Differential Diagnosis by Pathophysiologic Classification of AKI

Cause	Comments
Prerenal	**30%–60% of AKI**
Volume depletion	Renal losses, GI losses, hemorrhage
Decreased cardiac output	Right- or left-sided heart failure, cardiac tamponade
Systemic vasodilation	Sepsis, anaphylaxis, anesthetics
Afferent arteriolar vasoconstriction	NSAIDs, calcineurin inhibitors, radiocontrast, hepatorenal syndrome, hypercalcemia
Efferent arteriolar vasodilation	ACE inhibitors, ARBs
Intrinsic	**~40% of AKI**
Acute tubular injury	
Ischemic	
Nephrotoxic (drug)	Aminoglycosides, lithium, amphotericin, pentamidine, cisplatin, ifosfamide, radiocontrast
Nephrotoxic (pigment)	Rhabdomyolysis, intravascular hemolysis
Acute interstitial nephritis	
Drug induced	Penicillins, cephalosporins, NSAIDs, PPIs, allopurinol, rifampin, sulfonamides, immune checkpoint inhibitors
Infection related	Pyelonephritis, viral nephritides
Autoimmune diseases	Sjögren syndrome, sarcoidosis, SLE
Malignancy	Lymphoma, leukemia
Intratubular obstruction	
Paraprotein	Immunoglobulin light chains
Crystals	Acute phosphate nephropathy, tumor lysis syndrome, ethylene glycol, acyclovir, indinavir, methotrexate
Acute glomerulonephritis	Postinfectious, cryoglobulinemia, RPGN, SLE
Macrovascular	Increased renal vein pressure from increased intraabdominal pressure, bilateral renal vein thrombosis, bilateral renal artery emboli
Microvascular	Atheroembolic disease, HUS, TTP, scleroderma renal crisis, malignant hypertension
Postrenal (Obstruction)	**Approximately 10% of AKI**
Intrinsic	Bilateral ureteral stones, bladder outlet obstruction (prostatic enlargement or blood clot), neurogenic bladder
Extrinsic	Retroperitoneal fibrosis, metastatic cancer

ACE, Angiotensin-converting enzyme; *AKI,* acute kidney injury; *ARBs,* angiotensin receptor blockers; *GI,* gastrointestinal; *HUS,* hemolytic uremic syndrome; *NSAIDs,* nonsteroidal antiinflammatory drugs; *PPIs,* proton pump inhibitors; *RPGN,* rapidly progressive glomerulonephritis; *SLE,* systemic lupus erythematosus; *TTP,* thrombotic thrombocytopenic purpura.

hemodynamic measurement by right heart catheterization may be necessary to differentiate volume overload from noncardiogenic pulmonary infiltrates. Trends in daily intake and output volumes also assist in determining the extracellular fluid volume of the critically ill patient. Monitoring urine output in the ICU is associated with improved detection of AKI, as well as reduced 30-day mortality in patients with AKI.[30]

Examination of the abdomen may reveal a tender, distended bladder in a lower urinary tract obstruction, and, when this is present, sterile postvoid bladder catheterization should be performed. A distended, tense abdominal wall may represent ascites, aggressive intravenous fluid resuscitation, or recent abdominal surgery. Intraabdominal pressure can be measured in the ICU to distinguish AKI from abdominal compartment syndrome, defined as intraabdominal pressure exceeding 20 mm Hg.[31]

Fever, skin rash, and arthralgias may be signs of systemic lupus erythematosus, vasculitis, endocarditis, or drug allergy with AIN. A history of recent aortic catheterization (e.g., cardiac catheterization) and the findings of livedo reticularis or a discolored toe are diagnostic clues for cholesterol or atheromatous emboli. Painless hematuria suggests acute GN or genitourinary malignancy, whereas painful hematuria is more consistent with obstruction.[27]

DIAGNOSTIC EVALUATION

Differentiating the two most common causes of AKI in hospitalized patients, prerenal AKI and ATN, may be difficult when both the effective arterial blood volume and the time course of the kidney injury are unknown.[32] Here the term *acute tubular injury* may more accurately describe the pathology involved in intrinsic AKI from ischemic or toxic insults.[33] Evaluation of urine volume, urinary sediment, and urinary indices (the last is useful only in patients with oliguria) is helpful in making the correct diagnosis (Table 72.3 and Fig. 72.2). Initial laboratory tests include a urinalysis, blood urea nitrogen (BUN), serum sodium, potassium, bicarbonate, and creatinine levels not only for the diagnosis but also for assessment of complications of AKI.[27] The dipstick urinalysis, a low-cost test that provides rapid information about urinary protein and cellular content, is commonly underutilized. Among 3 tertiary care hospitals, a urinalysis was obtained less than half the time in patients diagnosed with AKI.[34]

Results from initial laboratory testing may prompt further evaluation. For example, in the absence of treatment with a sodium-glucose cotransporter-2 inhibitor, glycosuria occurring with a normal plasma glucose level offers evidence for proximal tubular dysfunction. The presence of amino acids and bicarbonate in the urine and/or elevated urinary fractional excretion of phosphate and uric acid can be used to confirm Fanconi syndrome (see Chapter 50).

Ratio of Blood Urea Nitrogen to Creatinine

The ratio of BUN to creatinine in healthy individuals is 10:1 to 15:1 (when both are expressed in mg/dL, or 40:1 to 60:1 when expressed in mmol/L). In prerenal AKI the ratio may exceed 20:1 because of a disproportionate increase in urea reabsorption resulting from elevated serum vasopressin levels. However, BUN-to-creatinine ratio has limited value in differentiating the type of AKI. Upper gastrointestinal tract bleeding, impaired protein anabolism (e.g., systemic corticosteroid administration), increased catabolism (e.g., sepsis), and increased

TABLE 72.3 Clinical and Laboratory Variables in the Differential Diagnosis Between Prerenal and Intrarenal Acute Kidney Injury

	Prerenal	Intrarenal
History	Volume loss from GI, urinary, skin, or blood or reduced EABV (e.g., heart failure, pancreatitis)	Drugs or toxin exposure, hemodynamic change
Clinical presentation	Hypotension or volume depletion	No specific symptoms or signs
Laboratory studies		
BUN/S_{Cr}	>20	<20
Sediment	Normal to few hyaline casts	Muddy brown casts
U_{osm} (mmol/kg)	>500	<350
Proteinuria	None to trace	Mild to moderate
U_{Na} (mmol/L)	<20	>40
FE_{Na} (%)	<1	>1
FE_{Urea} (%)	<35	>35
Novel biomarkers	None	IGFBP7*TIMP-2, KIM-1, cystatin C, NGAL, CYR61, others

BUN, Blood urea nitrogen; *CYR61,* cysteine-rich protein 61; *EABV,* effective arterial blood volume; FE_{Na}, fractional excretion of sodium; FE_{Urea}, fractional excretion of urea; *GI,* gastrointestinal; IGFBP7*TIMP-2, insulin-like growth factor-binding protein 7 and tissue inhibitor of metalloproteinase 2; *KIM-1,* kidney injury molecule 1; *NGAL,* neutrophil gelatinase–associated lipocalin; S_{Cr}, serum creatinine; U_{Na}, urinary sodium; U_{osm}, urinary osmolality.

protein intake all raise BUN levels. Furthermore, diminished urea production from decreased protein intake or underlying liver disease are associated with lower BUN levels. Also, elevations in serum creatinine levels may exceed BUN levels in patients with creatinine release from muscle breakdown, as in rhabdomyolysis.

Urine Volume

In AKI, urine volume directly correlates with residual GFR.[35] Urine volume can indicate the severity of AKI and also provide important diagnostic information. Oliguric AKI (<500 mL/d) is typically associated with worse outcomes than AKI with preserved urine volume, especially with a positive fluid balance in the critical care setting.[36-39] Oliguria commonly occurs in AKI caused by ATN, although it can be seen in early prerenal AKI or AIN. Wide variations in daily urine output suggest obstruction. Anuria (urine output <100 mL/d) suggests obstruction or a bilateral acute vascular catastrophe (renal vein or renal artery occlusion), shock, rarely kidney cortical necrosis, hemolytic uremic syndrome, or anti–glomerular basement membrane (GBM) antibody disease.[27]

Urinalysis and Urine Microscopy

In the setting of AKI, a dipstick urinalysis may reveal microhematuria or proteinuria but must be interpreted in conjunction with more specific tests such as a ratio of spot urinary protein or albumin to creatinine and urine microscopy. Dipstick urinalysis may not detect immunoglobulin free light chains (FLCs) or may be falsely positive for protein in the setting of radiographic contrast or alkaline urine. In conjunction with urine microscopy, the presence of urinary hemoglobin or myoglobin by dipstick can be further differentiated. Urine microscopy has been validated as a diagnostic and prognostic tool in hospitalized patients with AKI.[32] A fresh urine sample is centrifuged, and the sediment is examined for the presence of cells, casts, and crystals (Figs. 72.3 and 72.4) (see also Chapter 4). Urine microscopy in early prerenal AKI is typically normal with occasional hyaline casts. "Muddy brown" granular casts and renal tubular epithelial cells in the urine support ATN-related AKI. In hospitalized patients with AKI, the presence of more than 10 granular casts per low-power field had a positive predictive value of 100% for a final diagnosis of ATN, and a urine sediment score based on granular casts and renal tubular epithelial cells was directly associated with worsening AKI. Thus, urine microscopy is useful for distinguishing ATN-related AKI from prerenal AKI and predicting the severity of AKI.[32]

Findings on urinalysis and urine microscopy (see Chapter 4) may suggest CKD (broad, waxy casts), but, more important, they may be diagnostic clues to a rare cause of AKI. Proliferative GN may be characterized by considerable microhematuria and proteinuria by dipstick and an active urinary sediment consisting of red blood cells (RBCs) and RBC casts. In this setting the history and physical examination findings should be supported by serologic testing and a kidney biopsy, if the kidneys are normal in size. The presence of white blood cells (WBCs) in clumps and casts, in the absence of bacteria, suggests AIN.[27] Renal tubular epithelial cells, granular casts, RBCs and, rarely, even RBC casts can occur in patients with AIN, whereas urinary eosinophils are no longer considered helpful in diagnosing AIN (see Chapter 64).[40] A urine sediment with abundant uric acid crystals accompanying high serum phosphorus levels in a patient undergoing chemotherapy may indicate tumor lysis syndrome (TLS).

Fractional Excretion of Sodium and Urea

The urine-serum concentrations of sodium in relation to the urine-serum concentrations of creatinine (fractional excretion of sodium [FE_{Na}]) have been used to approximate kidney tubular function:

$$FE_{Na} = \frac{[U/S]_{Na}}{[U/S]_{Cr}} \times 100\%$$

where *U* is urine, *S* is serum, *Na* is s odium, and *Cr* is creatinine.

The basic premise is that renal tubular cells will reabsorb sodium in the prerenal setting, whereas tubules damaged by ATN will not.[41] FE_{Na} less than 1% is consistent with prerenal AKI, and FE_{Na} greater than 3% is typical of ATN. However, FE_{Na} may be less than 1% despite ATN in the setting of sepsis, hemoglobinuria or myoglobinuria, radiocontrast exposure, nonoliguria, heart failure, and advanced cirrhosis. Underlying CKD, diuretic use, recent intravenous fluid administration, glycosuria, bicarbonaturia, and salt-wasting disorders may be associated with elevated FE_{Na} despite the presence of prerenal AKI.[41] Therefore, FE_{Na} has significant limitations in the setting of hospital-acquired AKI, yet may be helpful in differentiating prerenal AKI from ATN in specific patient populations with oliguria.

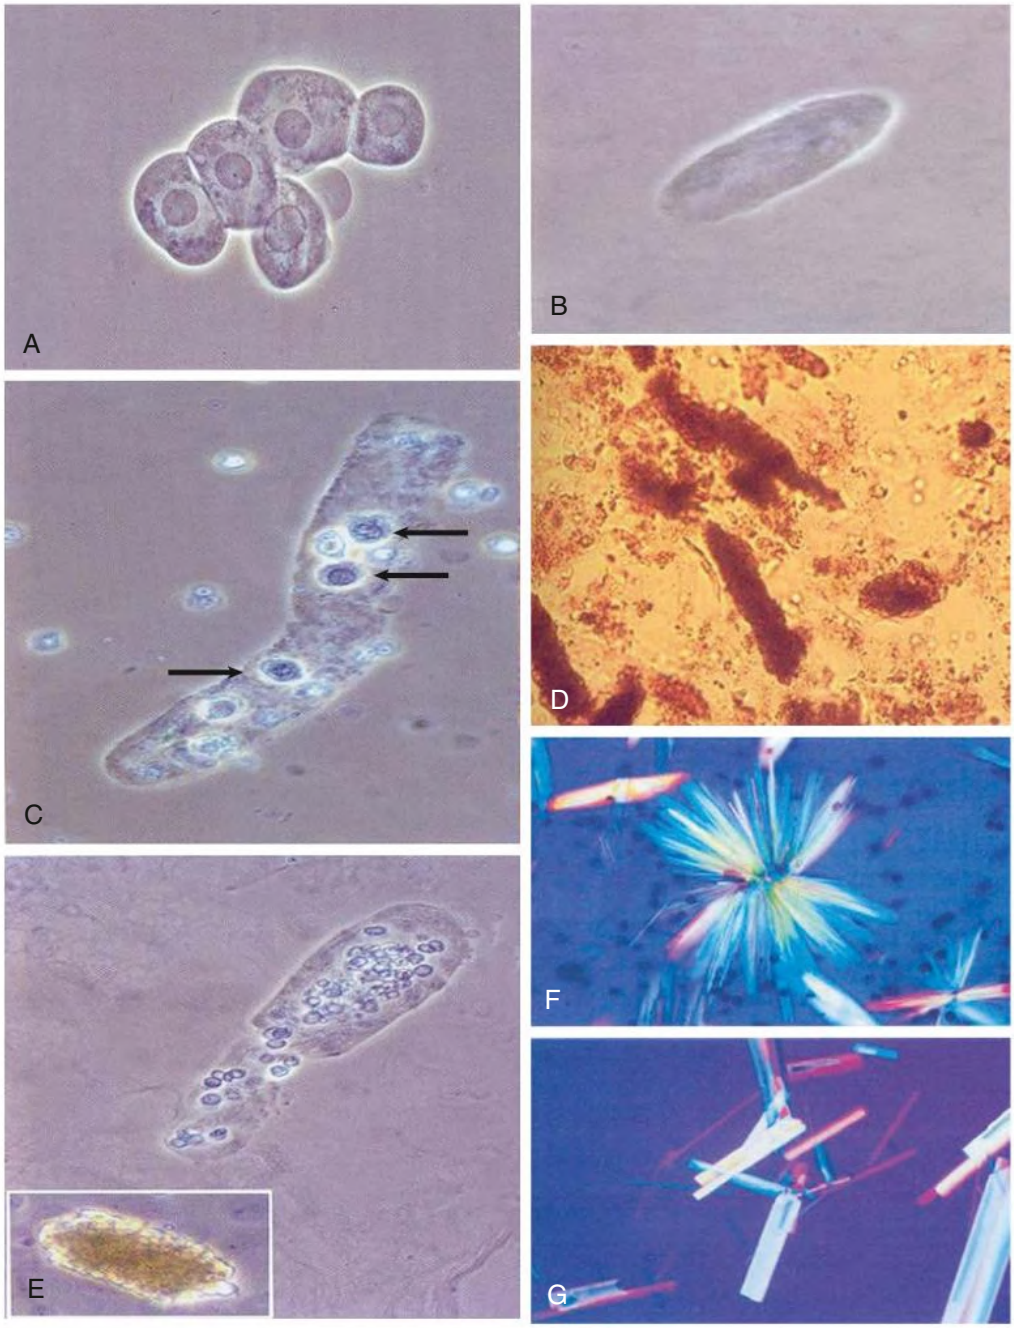

Fig. 72.3 Examples of Urinary Sediments Seen in Acute Kidney Injury (AKI). (A) Epithelial cell aggregate. (B) Hyaline cast as can be seen in prerenal AKI. (C) Epithelial cast as can be seen in early acute tubular necrosis (ATN; *arrows* indicate epithelial cells). (D) Muddy brown cast, typical of established ATN. (E) Erythrocyte cast as seen in glomerulonephritis and vasculitis. *Inset:* Hemoglobin cast. (F–G) Two forms of indinavir crystals.

Urea reabsorption, primarily occurring in proximal tubules, is less affected by loop and thiazide diuretics, and the fractional excretion of urea (FE_{Urea}) may be an alternative to FE_{Na} in patients receiving diuretics. The calculation of FE_{Urea} is identical to that of FE_{Na}, and values less than 35% favor prerenal AKI over ATN.

Laboratory Evaluation of Acute Kidney Injury in Systemic Illnesses

In the presence of systemic illness, additional laboratory evaluation may narrow the differential diagnosis of AKI. Serum complement levels of C3 and C4 are useful in differentiating causes of GN, particularly when a kidney biopsy is not feasible. Postinfectious GN, infective endocarditis, lupus nephritis, mixed cryoglobulinemia, and membranoproliferative GN are typically associated with low levels of serum C3 and/or C4 (see Chapter 22), whereas serum complement levels are normal in antineutrophil cytoplasmic antibody (ANCA)-associated vasculitis, anti–glomerular basement antibody disease, and immunoglobulin A (IgA) vasculitis (Henoch-Schönlein purpura). Despite activation of the complement system in thrombotic microangiopathy (see Chapter 30), serum C3 and C4 can be maintained at normal levels through increased hepatic production.[42] Alternatively, when liver synthesis is impaired, low

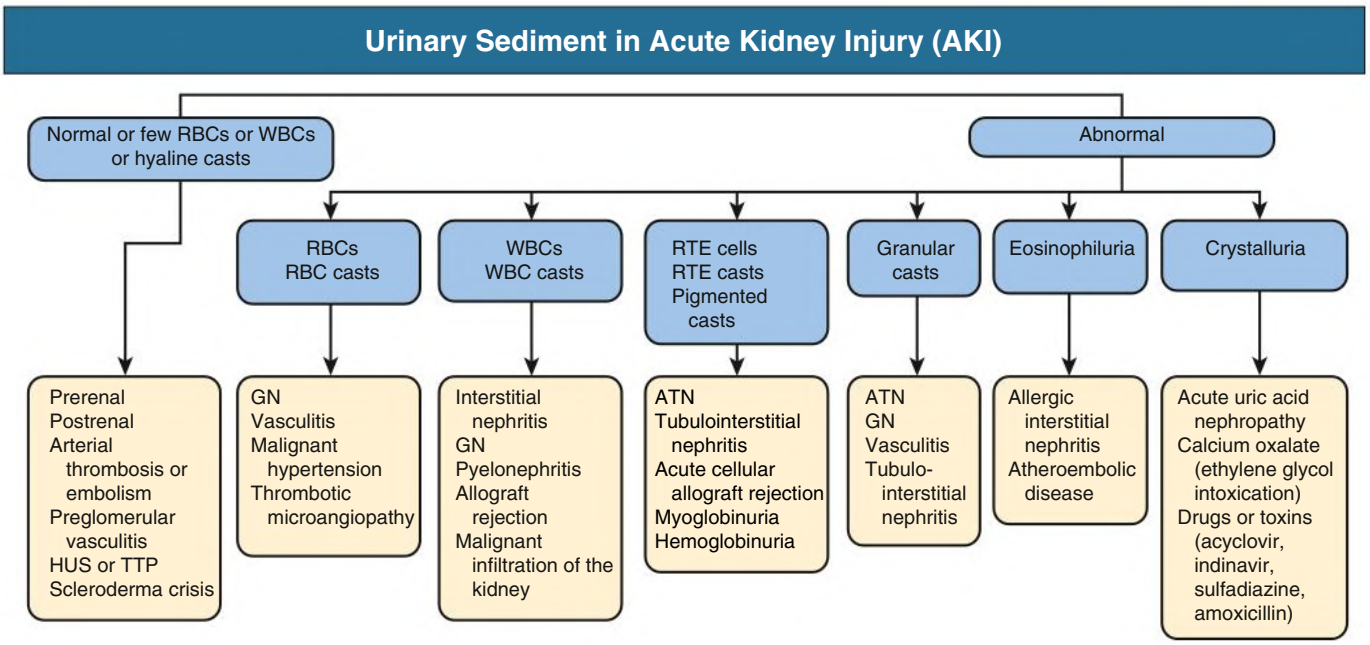

Fig. 72.4 Urinary sediment in acute kidney injury (AKI). *ATN,* Acute tubular necrosis; *GN,* glomerulonephritis; *HUS,* hemolytic uremic syndrome; *RBC,* red blood cell; *RTE,* renal tubular epithelial; *TTP,* thrombotic thrombocytopenic purpura; *WBC,* white blood cell.

serum levels of C3 and/or C4 are less reliable in differentiating the type of acute GN.

In the right clinical setting, laboratory studies may support a specific cause of AKI. For example, AKI with thrombocytopenia, schistocytes on peripheral blood smear, and an elevated blood lactate dehydrogenase level would be consistent with thrombotic microangiopathy from atypical hemolytic uremic syndrome or thrombotic thrombocytopenic purpura. However, these laboratory findings may also be present in sepsis with disseminated intravascular coagulation (DIC). AKI in sepsis with DIC typically results from ATN or antibiotic-related AIN and not thrombotic microangiopathy.

In the appropriate clinical setting, the following laboratory tests can help identify a cause: complete blood count with differential/platelet count, serum albumin, creatine kinase, uric acid, phosphorus, urine myoglobin, HIV antibody, hepatitis C antibody, cryoglobulins, rheumatoid factor, hepatitis B virus studies, antinuclear antibody, anti–double-stranded DNA antibody, ANCA, anti-GBM antibody, and serum FLC with ratio.

Imaging Studies

Kidney imaging may not be necessary if the explanation for AKI is apparent (e.g., prerenal AKI or ATN). However, when the diagnosis is uncertain, and especially if urinary obstruction or renal vascular occlusion are suspected, imaging is indicated.[27] Risk factors associated with hydronephrosis include history of prior hydronephrosis, current urinary tract infection, abdominal or pelvic cancer, and neurogenic bladder.[43] Point-of-care ultrasound is an emerging tool for assessing volume responsiveness in critically ill and ventilated patients, but it may also be a rapid and relatively low-cost option for excluding urinary obstruction in AKI (see Chapter 5).[44] A dedicated kidney ultrasound can identify urinary obstruction, polycystic kidney disease, and the size and number of kidneys. When Doppler flow is used, renal arteries and veins can be assessed. High-resolution, noncontrast computed tomographic imaging is the preferred test for the detection of urinary tract calculi. Radionuclide renography using radiolabeled mercaptoacetyltriglycine (MAG3) may be used to estimate the kidney plasma flow in a transplanted kidney with AKI but is increasingly replaced by Doppler ultrasound. Other radionuclide methods are less useful in AKI (e.g., tagged WBC scan for AIN). Magnetic resonance imaging without contrast is now recommended to evaluate renal arterial or venous thrombosis.[27]

Kidney Biopsy

Kidney biopsy is reserved for patients in whom prerenal and postrenal AKI have been excluded and the cause of intrinsic AKI remains unclear (see Fig. 72.2). Kidney biopsy is particularly useful when clinical assessment and laboratory investigations suggest diagnoses other than ischemic or nephrotoxic injury that may respond to disease-specific therapy (e.g., vasculitis, systemic lupus erythematosus, and AIN).

Electronic Health Record to Predict Acute Kidney Injury

Computer-based models have been used to develop AKI electronic alerts.[45,46] In one study, real-time alert of worsening of AKI by an AKI "sniffer" increased the timeliness of early therapeutic intervention.[47] However, in a large randomized controlled study, an electronic alert system for AKI in hospitalized patients did not demonstrate any improvements in clinical outcomes and rather increased the use of health care resources.[25] Further studies are needed to further define the utility of such AKI alerts.

ACUTE KIDNEY INJURY IN SPECIFIC SETTINGS

Acute Tubular Necrosis

ATN is a clinical syndrome of abrupt and sustained decline in GFR that is triggered by an acute ischemic or nephrotoxic event and develops within minutes to days after the insult.[27] Apart from kidney biopsy, no definitive test can diagnose ATN. The diagnosis is suggested by a history of recent hypotension, volume depletion, sepsis, or nephrotoxic exposure. Muddy brown, coarse, granular casts are present on urine microscopy in the majority of patients

with ATN, particularly those who are oliguric.[27] Other laboratory findings consistent with the diagnosis of ATN are shown in Table 72.3.

The pathophysiology of ATN involves multiple pathways (see Chapter 70). Obstruction of flow within the tubule by cellular debris, disruptions of tubular cell polarity and cytoskeleton, loss of the lining epithelium with resulting backleak of glomerular filtrate into the kidney interstitium, and afferent arteriolar constriction all may play pathophysiologic roles in ATN. ATN has been described as a (mal)adaptive response of the kidney—"trading away" GFR for the preservation of medullary oxygenation and tubular integrity.[33]

ATN after ischemia/reperfusion injury is usually most severe within the outer medulla of the kidney (see Chapter 70).[48] The typical histologic features of human proximal tubular injury include vacuolation, loss of brush border, disruption of the epithelial cells lining the tubule, and presence of intratubular casts. Necrosis of tubular cells is typically focal and may be missed in a biopsy specimen because most biopsies contain cortex and the outer medulla is not sampled adequately. Apoptosis of tubular cells is present in kidney biopsy specimens from humans with ATN, and evidence of cellular regeneration is often seen, most commonly in areas of greatest tubular cell loss. Regenerative changes and fresh epithelial injury are often observed in the same biopsy specimen, suggesting that recurrent episodes of tubular ischemia continue to occur during the maintenance phase of ATN. The morphologic appearance of the common forms of nephrotoxin-induced ATN is similar to that of ischemic ATN, with loss of microvasculature and immune cell infiltration. Correlations of morphologic findings to functional endpoints have been difficult.

Acute Interstitial Nephritis

AIN is characterized by the presence of inflammatory infiltrates and edema within the interstitium, with an acute deterioration in GFR (see Chapter 64).[49] It is a relatively common cause of AKI, accounting for 15% to 27% of kidney biopsies performed because of AKI, yet AIN may be overlooked as a cause of AKI in settings in which ATN is common (e.g., sepsis). Drug use, in particular antimicrobials, proton pump inhibitors, and NSAIDs, is the most common cause of AIN (see Table 72.2).[49]

The diagnosis of AIN generally requires kidney biopsy. The clinical presentation of drug-induced AIN is variable, with a mean delay between drug exposure and the appearance of kidney manifestations of 10 days, although the latent period can be as short as 1 day with some antibiotics or as long as several months with NSAIDs.[49] In AIN the reported frequency of symptoms included arthralgias (45%), fever (36%), and skin rash (22%). In the same analysis, urinary findings included nonnephrotic proteinuria (93%), leukocyturia (82%), and microscopic hematuria (67%).[49] The classic clinical presentation of maculopapular rash, peripheral eosinophilia, and arthralgias may not be present in drug-induced AIN and is uncommon in infection-related or idiopathic AIN (see Table 72.2). Although the presence of urine eosinophils is not sensitive or specific for AIN, urinary levels of tumor necrosis factor α and interleukin-9 show promise as biomarkers of AIN.[50]

Acute Kidney Injury From Intratubular Obstruction

Several endogenous and exogenous molecules can precipitate in the tubular lumen to produce AKI, including uric acid, calcium phosphate, calcium oxalate, immunoglobulin FLCs, myoglobin, and medications (e.g., acyclovir, indinavir, methotrexate, sodium phosphate–containing cathartics, and sulfadiazine).[27] Medication-induced crystal nephropathy occurs more commonly when high doses of medication are combined with low tubular flow rates from volume contraction or underlying CKD.

Ethylene glycol ingestion from solvents and antifreeze may result in AKI from calcium oxalate crystal deposition. Patients with ethylene glycol poisoning typically have high anion gap metabolic acidosis because the ethylene glycol is metabolized into glycolic acid. The glycolic acid is converted to oxalic acid, which binds free calcium to form calcium oxalate crystals. Crystal deposition resulting in AKI typically manifests 48 to 72 hours after ingestion; oxalate crystals can be readily identified in the urine soon after exposure.

Intratubular obstruction from calcium phosphate and urate crystals contribute to AKI in TLS, which is characterized by a constellation of metabolic derangements caused by massive and abrupt release of intracellular components in the blood after rapid lysis of malignant cells. It is typically seen after initiation of cytotoxic therapy for hematologic malignancies with large tumor burden or cell counts.[51] Clinical features of TLS result from the effects of the metabolic derangements. Nucleic acids released during cell lysis are metabolized to hypoxanthine and then xanthine, which is converted by xanthine oxidase to uric acid. With significant tumor lysis, severe hyperuricemia and intratubular obstruction from urate crystals may result. Hyperkalemia may induce cardiac arrhythmias, weakness ("spaghetti legs"), and paresthesias. Hyperphosphatemia initially produces muscle cramps and lethargy but also can promote nausea, vomiting, diarrhea, and seizure. Hypocalcemia, primarily caused by phosphorus binding, causes similar symptoms with muscle cramps, tetany, cardiac arrhythmias, and seizures.[51] Hyperkalemia and hypocalcemia associated with AKI in a patient receiving cytotoxic chemotherapy may be the only initial clues to the syndrome because blood uric acid and phosphate levels are not routinely monitored. Urine microscopy can assist in the diagnosis by revealing the presence of many urate crystals.

Rhabdomyolysis

Rhabdomyolysis is characterized by the leakage of muscle-cell contents, including myoglobin, electrolytes, creatine kinase, aldolase, lactate dehydrogenase, nucleic acids, and aspartate aminotransferase into the circulation.[52] AKI, occurring primarily in severe rhabdomyolysis, results from renal vasoconstriction, proximal tubular cell injury from oxidant stress, and intranephronal obstruction. Both myoglobin, a heme pigment protein that contains iron in the ferrous (Fe^{2+}) state, and uric acid have less nephrotoxicity in alkaline urine. Intravascular volume contraction and acidic urine promote distal tubule obstruction from myoglobin and uric acid precipitation. A recent study showed that macrophages activated by platelets are able to form macrophage extracellular traps that are pathogenic in rhabdomyolysis-induced kidney injury.[53] See Table 72.4 for common causes of rhabdomyolysis.[52]

Patients with acute rhabdomyolysis often present with muscle pain and reddish-brown urine. The presence of pigmented granular casts and the lack of RBCs on urine microscopy coupled with a blood-positive urinary dipstick are important diagnostic clues for rhabdomyolysis-related AKI. However, the diagnosis must be confirmed by elevated serum creatine kinase levels and the presence of urinary myoglobin.[27] A weak correlation exists between creatine kinase values and the incidence of AKI. The risk for AKI is lower when creatine kinase levels are less than 20,000 U/L. Rhabdomyolysis may contribute to AKI with creatinine kinase levels as low as 5000 U/L when coexisting conditions such as sepsis, intravascular volume contraction, and acidosis are present.[52]

TABLE 72.4 Causes of Rhabdomyolysis[52]

Trauma[a]	Increased Exertion	Genetic Defects	Infections	Body Temperature Changes	Drug or Toxin Exposure	Metabolic and Electrolyte Disorders
Crush injury	Seizure	Disorders of glycolysis or gluconeogenesis	Influenza A and B	Heat stroke	Lipid-lowering drugs	Hypokalemia
Prolonged immobilization	Alcohol withdrawal	Disorders of lipid metabolism	Coxsackievirus	Neuroleptic malignant syndrome	Alcohol[a]	Hypophosphatemia
Limb compression from loss of consciousness	Strenuous exercise	Mitochondrial disorders	Epstein-Barr virus	Hypothermia	Quetiapine	Hypocalcemia
			Streptococcus pyogenes	Malignant hyperthermia	Cocaine[a]	Nonketotic hyperosmotic conditions
			Pyomyositis *(Staphylococcus aureus) Clostridioides*		Heroin[a]	Diabetic ketoacidosis

[a]Most commonly associated with acute kidney injury.

Acute Kidney Injury in Myeloma

Monoclonal immunoglobulin FLCs are responsible for the majority of severe AKI in patients with myeloma. In such patients, monoclonal FLCs are overproduced, often with circulating levels hundreds of times higher than normal.[54] Unlike most endogenously produced proteins, monoclonal FLCs have a strong propensity to cause tubular damage (see Chapter 28).[54] Some κ monoclonal FLCs are cytotoxic and promote proximal tubular cell injury, with one mechanism resulting in a defect in sodium-coupled cotransport processes producing type II renal tubular acidosis, aminoaciduria, phosphaturia, and glycosuria (i.e., Fanconi syndrome).[55] A separate mechanism of FLC-mediated AKI is intratubular obstruction from precipitation of monoclonal FLCs in the distal nephron, that is, cast nephropathy.[27] Cast formation occurs under specific conditions mediated by the ionic composition of tubule fluid, tubule fluid flow rates, the concentration of Tamm-Horsfall glycoprotein and FLCs, the strength of the binding interaction between Tamm-Horsfall glycoprotein and FLC, and the presence of furosemide.[54] AKI attributed to cast nephropathy occurs in approximately one-third of patients with multiple myeloma and AKI. Other causes of AKI include extrarenal obstruction (e.g., nephrolithiasis, amyloid deposition in the ureters), hypercalcemia, hyperviscosity syndrome, and non–myeloma-related causes (e.g., AIN or contrast-associated AKI).[27,56]

Cast nephropathy should be considered, particularly in older patients with unexplained AKI. Predisposing conditions may include hypercalcemia, intravascular volume contraction, furosemide use, exposure to radiocontrast, and/or NSAID use. AKI may be the presenting event in patients with an undiagnosed plasma cell dyscrasia. Because FLC may not be detected on dipstick analysis, urinalysis in cast nephropathy will often show no or trace protein and the urinary sediment is typically bland. Assay of serum FLC levels is critical in assisting in the differential diagnosis of unexplained AKI (Chapter 68), but kidney biopsy may be needed to diagnose cast nephropathy. A low urinary albumin excretion (<10%) assessed with 24-hour urine electrophoresis was found useful in distinguishing cast nephropathy from ATN and less acute causes of kidney injury in multiple myeloma (e.g., amyloid light-chain [AL] amyloidosis and monoclonal immunoglobulin deposition disease).[57]

Contrast-Associated AKI

Historically, AKI occurring shortly after exposure to intravenous radiocontrast was termed *contrast-induced nephropathy*. However, iodinated contrast exposure may be one of multiple causes of AKI following a radiographic study or procedure. In a retrospective analysis with statistical adjustment, incidence rates of AKI were similar between contrast and noncontrast groups (5.5% vs. 5.6%, respectively).[58] The broader term, contrast-associated AKI, has gained favor in describing the pathophysiology of an AKI after contrast exposure.[56] The incidence of contrast-associated AKI is low (<1%) in patients with normal kidney function and no other risk factors for AKI.[27] Risk factors for contrast-associated AKI include CKD, diabetic nephropathy, advanced heart failure, states of reduced kidney perfusion, high total dose of contrast, and concomitant exposure to other nephrotoxins. Data from animal models suggest that both renal vasoconstriction from direct effects of the contrast media and toxic injury of tubular cells (likely from activation of osmolality-sensitive aldose reductase in the proximal tubule) are the main factors in the pathophysiology of contrast-associated AKI.[59] Emerging data suggest a role for contrast-induced uricosuria in the pathogenesis of contrast-associated AKI.[60] The kidney injury likely occurs within minutes of contrast exposure; however, the detection of AKI is typically delayed by 24 to 48 hours after contrast exposure. The timing of AKI in relation to contrast exposure and the exclusion of other causes of AKI generally suffice for diagnosis. Urinalysis and urine sediment findings are typically consistent with ATN. Kidney biopsy is generally not helpful in the setting of contrast-associated AKI because the expected findings of ATN are nonspecific, no specific treatment exists, and the kidney injury is typically short lived.

SELF-ASSESSMENT QUESTIONS

A 20-year-old man with Marfan syndrome is admitted to the hospital for elective aortic valve replacement and endovascular repair of a distal (type B) thoracic aortic dissection. On postoperative day 4, his urine output decreases to 420 mL over a 24-hour period and the urine appears dark in his Foley catheter collection bag. He requires mechanical ventilation and pressor support, with a mean arterial blood pressure of 70 mm Hg. There is no rash visible on examination. Available laboratory data are as follows.

Preoperation Blood

Sodium	140 mEq/L
Potassium	4.0 mEq/L
Chloride	108 mEq/L
Bicarbonate	24 mEq/L
BUN	12 mg/dL
Creatinine	0.6 mg/dL
Glucose	100 mg/dL

Postoperation Day 4 Blood

Sodium	141 mEq/L
Potassium	6.1 mEq/L
Chloride	106 mEq/L
Bicarbonate	14 mEq/L
BUN	24 mg/dL
Creatinine	4.4 mg/dL
Glucose	98 mg/dL
Calcium	5 mg/dL
Phosphate	10.2 mg/dL
Albumin	3.8 g/dL
Osmolality	294 mOsm/kg
Lactate	Normal

Postoperation Day 4 Blood

Arterial Blood Gas	
pH	7.27
P_{CO_2}	31 mm Hg
P_{O_2}	97 mm Hg
HCO_3^-	14 mEq/L
Urinalysis	
Specific gravity	1.028
pH	6.0
Protein	Negative
Blood	Positive
Ketones	Negative
Red blood cells	None

1. What is the most appropriate next diagnostic test?
   A. Serum creatine kinase level
   B. Kidney ultrasound with Doppler
   C. Kidney biopsy
   D. Serum antineutrophil cytoplasmic antibody
   E. Fractional excretion of urea
2. Which test result is most consistent with preserved kidney tubular function in a person who is volume contracted and has healthy kidneys?
   A. Urine osmolality of 300 mOsm/kg
   B. Fractional excretion of urea of 45%
   C. BUN of 34 mg/dL
   D. Spot urine sodium of 40 mEq/L
   E. None of the above
3. A 78-year-old man is brought to the emergency department by his family because of worsening confusion throughout the day. One week ago the patient fell and fractured his distal radius, necessitating splinting and pain medication. His medical history was pertinent with chronic kidney disease stage 3 (baseline serum creatinine 1.4 mg/dL), longstanding hypertension, chronic obstructive pulmonary disease, osteopenia, and benign prostatic hypertrophy. Current medications included lisinopril 20 mg/d, amlodipine 5 mg/d, hydrochlorothiazide 25 mg/d, doxazosin 4 mg nightly, oxycodone 5 mg every 8 hours as needed for arm pain, vitamin D 2000 U/d, and ipratropium bromide–albuterol inhaled 4 times per day. Arrival vital signs include blood pressure 176/92 mm Hg, pulse 114/min, respirations 18/min, weight 55 kg, and temperature 98.5°F. Physical examination revealed an agitated older man with flat neck veins, reduced air movement on chest auscultation, a large and tender abdomen, a right forearm cast, and trace lower extremity edema. No skin lesions were seen or palpated. Initial laboratory test results were as follows: sodium 138 mEq/L, potassium 5.2 mEq/L, chloride 110 mEq/L, bicarbonate 20 mEq/L, BUN 54 mg/dL, serum creatinine 2.6 mg/dL, leukocyte count 7500 cells/mL, hemoglobin 11.2 g/dL, platelet count 150,000 cells/μmol, alanine aminotransferase 28 U/L (normal 15–58 U/L), aspartate aminotransferase 36 U/L (normal 15–40 U/L), and prothrombin time 14 seconds. Urinalysis with microscopy: specific gravity 1.010, no blood or protein, and a bland sediment with no casts and few cells. What is the most appropriate next diagnostic test?
   A. Kidney ultrasound with Doppler
   B. Peripheral blood smear
   C. Kidney biopsy
   D. Postvoid bladder catheterization
   E. None of the above

Epidemiology and Prognostic Impact of Acute Kidney Injury and Acute Kidney Disease

Neesh Pannu, Marcello Tonelli

INCIDENCE OF ACUTE KIDNEY INJURY

Epidemiologic studies have primarily identified acute kidney injury (AKI) through administrative data or changes in serum creatinine without specifying etiology. These studies have primarily focused on acute tubular necrosis in hospitalized populations and may not be generalizable to other forms of AKI. The incidence of AKI in unselected hospitalized patients is between 0.4% and 18%, depending on the definition used, and accounts for 1% to 4% of all hospital admissions.[1] Large studies using administrative data suggest that the incidence of AKI in hospitalized patients has increased by approximately 13% per year over the last 3 decades.[2] In these studies, incidence was identified by diagnostic codes that are highly specific for AKI (97%) but are relatively insensitive (35% sensitivity).[3] The findings of such studies may be influenced by increasing clinical recognition of less severe AKI, leading to increased coding of AKI without a change in true incidence. In addition, there may be financial incentives to code patients as having AKI to increase reimbursement. However, similar increases have been observed in the incidence of AKI requiring kidney replacement therapy (KRT): in general, populations of hospitalized patients, as well as in specific settings including surgery, sepsis, stroke, cardiovascular events, and liver disease.[4] Although more objective and clinically relevant than diagnostic codes, dialysis utilization may also be influenced by increased availability of KRT or changing trends in medical practice rather than true changes in the burden of disease.

The incidence of AKI can be estimated using consensus definitions based on serum creatinine and urine output (Table 73.1) and has been best characterized in critically ill populations. Despite using standardized definitions for AKI, multicenter studies of critically ill patients have reported the incidence of AKI to be between 10% and 67%, likely reflecting differences in case mix between health care systems and countries.[5]

Less is known about AKI in the community; there is significant etiologic and geographic variation in the reported incidence and risk factors for AKI in outpatient settings, where serum creatinine is infrequently measured. The concept of acute kidney disease (AKD) was proposed in the 2012 Kidney Disease: Improving Global Outcomes guidelines in recognition that subacute kidney injury may not meet criteria for AKI or chronic kidney disease (CKD) despite being clinically relevant (Fig. 73.1). AKI is recognized as a subset of AKD; the relationships between AKI, AKD, CKD, and the absence of kidney disease are shown in Fig. 73.2. A population-based study in Alberta, Canada ($n = 921{,}116$) compared the incidence and prognosis of AKD compared with AKI and CKD. AKD was 2.7-fold more prevalent than AKI, affecting 4.4% of the cohort, and was primarily identified in outpatients (77%).[6]

RISK FACTORS FOR AKI

Risk factors for AKI have been determined in a variety of clinical settings including cardiac surgery, contrast-induced AKI, and critically ill populations. However, risk prediction models that accurately predict the occurrence of AKI have been elusive. Nonmodifiable risk factors common to all populations are presented in Box 73.1.

Age

Multiple studies show that AKI is more common in older individuals, and many have shown an independent association between AKI and older age.[7] In a community-based prospective study, patients aged 80 to 89 years were 55 times more likely to develop AKI than adults younger than 50 years.[8] Possible explanations for this association include (1) structural and functional changes associated with age that lead to diminished nephron reserve and reduced capacity for kidney autoregulation, (2) accumulation of comorbidity that increases susceptibility to AKI (vascular disease, diabetes, hypertension, CKD), and (3) increased exposure among older persons to medications and procedures that predispose to AKI.[7]

Reduced Estimated Glomerular Filtration Rate

Preexisting reduction in estimated glomerular filtration rate (eGFR) is a potent risk factor for AKI after exposure to radiocontrast,[9] major surgery, and medical illness,[10] although the pathophysiology underlying this association is poorly understood. It has been reported that the odds of developing dialysis requiring AKI are increased at lower baseline eGFR; the excess risk compared with normal eGFR was approximately twofold in patients with baseline eGFR 45 to 60 mL/min/1.73 m^2, but more than 40-fold for patients with baseline eGFR less than 15 mL/min/1.73 m^2.[11] These associations were confirmed in several systematic reviews that demonstrate strong independent associations between risk for AKI and lower baseline eGFR[12-14] (see Fig. 73.3). Although these analyses support a causal association between CKD and in-hospital AKI, little is known about how this association may be modified by the presence of one or more comorbidities, such as heart failure, or whether all causes of CKD confer similar risk for AKI.

Albuminuria

Albuminuria is also strongly associated with AKI risk. A case-control study of over 600,000 patients identified proteinuria as an independent predictor for AKI,[11] which was replicated in multiple settings, including after cardiac surgery in Taiwan and in general population studies from the United States and Canada[15-17] (Fig. 73.4).

Hyperuricemia

Two prospective randomized trials[18,19] also found allopurinol plus hydration to be superior to hydration alone in preventing AKI following radiocontrast administration. Nevertheless, uric acid can also be a biomarker for other risk factors (e.g., mild CKD, cancer), and although the two studies are interesting, more data is needed before this intervention is recommended. A recent systematic review and meta-analysis

TABLE 73.1 Recent Consensus Definitions of Acute Kidney Injury

Definitions	Serum Creatinine Criteria	Urine Output Criteria
RIFLE (2003)	Increase in serum creatinine × 1.5 or decrease in GFR by 25% within 48 hr	Urine volume <0.5 mL/kg/hr for 6 hr
AKIN (2007)	Increase in serum creatinine × 1.5 or by ≥0.3 mg/dL (≥26.5 μmol/L) within 48 hr	Urine volume <0.5 mL/kg/hr for 6 hr
KDIGO (2012)	Increase in serum creatinine by ≥0.3 mg/dL (≥26.5 μmol/L) within 48 hr Increase in serum creatinine to ≥1.5 times baseline, which is known or presumed to have occurred within the prior 7 days Severity staging after initial criteria met	Urine volume <0.5 mL/kg/hr for 6 hr

GFR, Glomerular filtration rate.

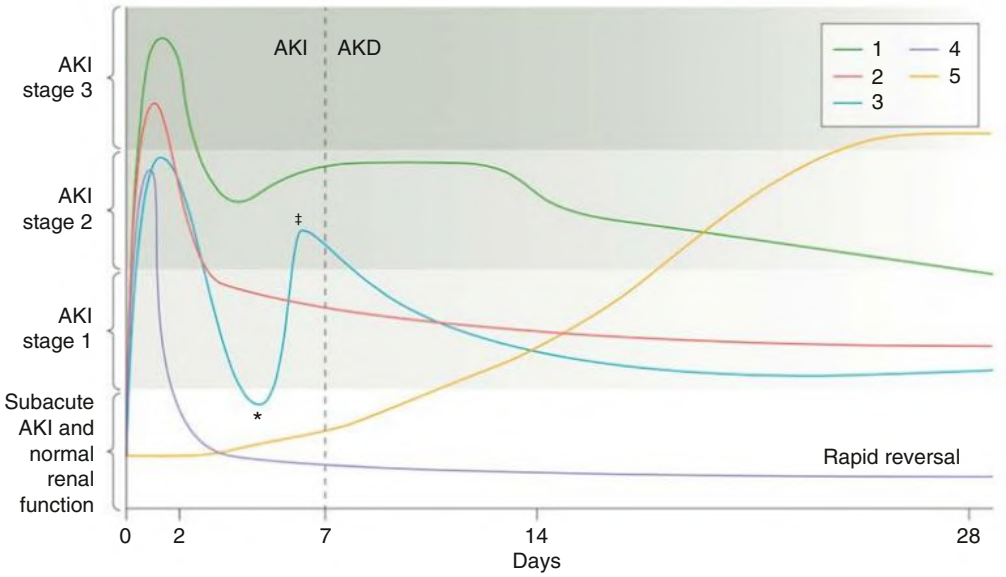

Fig. 73.1 Hypothetical Trajectories of Acute Kidney Disease (AKD). AKD follows on from acute kidney injury (AKI) in those patients who do not fully recover within 7 days. The trajectory of AKD can take many forms, largely depending on the severity of the initial AKI episode. Here, a series of hypothetical scenarios representing typical trajectories of the AKI-AKD continuum are depicted. Stage 3 AKI might slowly improve to stage 2 AKI and then progress to AKD *(1)*. Stage 1 AKI might progress to stage 3 AKI, then improve rapidly to stage 1 AKI before progressing to stage 1 AKD *(2)*. An episode of persistent AKI (>48 hr) might be followed by a period of sustained reversal, then a second episode of AKI leading to AKD *(3)*. Stage 2 AKI might rapidly reverse *(4)*. Subacute AKD might occur wherein the first 7 days are marked with slowly worsening kidney function that does not technically meet the criteria for AKI, and progress to stage 3 AKD *(5)*. This trajectory can be seen in patients treated with chronic nephrotoxic medications (e.g., aminoglycosides). (From Chawla LS et al. Acute kidney disease and renal recovery: consensus report of the Acute Disease Quality Initiative [ADQI] 16 Workgroup. *Nat Rev Nephrology.* 2017;13[4]:241–257.)

(n = 13,084) of 18 studies also found that that the presence of hyperuricemia was independently associated with increased risk of contrast-related AKI (adjusted odds ratio [OR], 1.68; 95% confidence interval [CI], 1.38–2.04).[20,21]

ASSOCIATION BETWEEN AKI AND ADVERSE OUTCOMES

AKI is associated with high costs and adverse clinical outcomes, including excess mortality, increased length of hospital stay, development and/or progression of CKD, and requirement for chronic dialysis in survivors (Box 73.2). However, not all transient changes in serum creatinine are associated with kidney injury or poor outcomes. Randomized trials of diuretics and renin-angiotensin-aldosterone system inhibitors in decompensated heart failure and hypertension have shown that medication-associated increases in serum creatinine are associated with *decreased* mortality.[22] These findings speak to the need for more precise definitions for AKI.

Mortality

Multiple observational studies demonstrate increased mortality among patients who develop AKI in hospital. In its most severe form (requirement for acute dialysis), AKI is associated with mortality ranging from 15% (AKI only) to 80% (AKI in critically ill patients).[23] However, comparing patients with AKI to those without AKI does not distinguish between the increased risk for death caused by kidney disease per se and the increased risk associated with the underlying illness that was sufficiently severe to result in

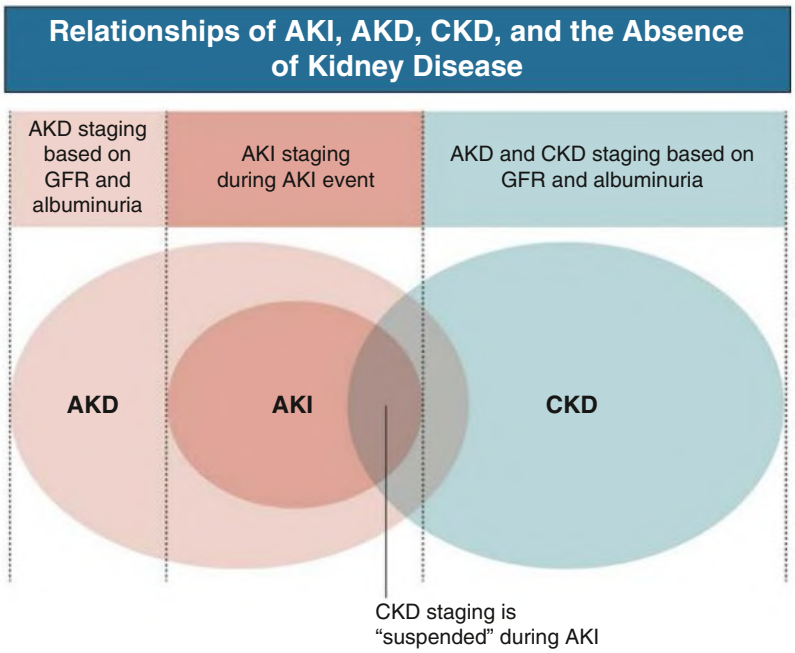

Fig. 73.2 Relationships of AKI, AKD, CKD, and the absence of kidney disease according to KDIGO definitions. *AKD,* Acute kidney disease; *AKI,* acute kidney injury; *CKD,* chronic kidney disease; *GFR,* glomerular filtration rate; *KDIGO,* Kidney Disease: Improving Global Outcomes; *NKD,* no kidney disease; *SCr,* serum creatinine. AKI. Therefore, there is uncertainty about whether the association between AKI and mortality is truly independent. Nonetheless, the development of AKI signifies a poor prognosis in individual patients.

Small changes in serum creatinine of as little as 25% above baseline are a significant predictor of all-cause short-term mortality.[24] A meta-analysis of eight studies of hospitalized patients (most of whom were critically ill or had heart failure) confirmed a graded relationship between increasing severity of AKI and short-term mortality.[25] Most importantly, it confirmed that even mild forms of AKI are clinically relevant; an increase in serum creatinine of 0.3 mg/dL (26 μmol/L) was associated with a 2.3-fold increase in the relative risk for death. After adjustment for comorbidities, the ORs or hazard ratios (HRs) for death associated with AKI ranged from 1.7 to 1.92. Similar findings were reported in several population-based studies of unselected hospitalized patients.[26]

The association between AKI and mortality is likely influenced by several factors, including the presence of underlying CKD, the duration and severity of AKI, and the degree of recovery of kidney function. A population-based study of hospitalized AKI patients in Canada found that the relation between AKI and in-hospital mortality was strongest in those with severe AKI and baseline eGFR greater than 60 mL/min/1.73 m^2, for whom the adjusted HR suggested a more than tenfold increase in the risk of death compared with those without AKI.[26,27] The presence of CKD modifies this association; by comparison, in patients with a baseline eGFR less than 30 mL/min/1.73 m^2, the adjusted HR of in-hospital mortality was increased fivefold compared with those without CKD or AKI. An analysis of postoperative AKI comparing kidney and survival outcomes in those with and without preexisting CKD (eGFR <45 mL/min/1.73 m^2) found a lower attributable mortality rate because of AKI (HR 1.26, 95% CI 1.09–1.78) when subjects with prior CKD but no AKI were used as the reference.[28]

Although the incidence of AKI continues to climb, there has been a corresponding improvement in survival. A recent analysis reported a 19% decrease in mortality between 2000 and 2009 in patients who required acute dialysis. Whether this represents a trend toward earlier use of dialysis (rather than a true improvement in survival) requires further investigation.

Chronic Kidney Disease

Until recently, it was accepted that AKI survivors generally recovered kidney function and remained independent from dialysis. This assumption was supported by the findings of small cohort studies of predominantly critically ill patients. One recent study described long-term outcomes of 226 critically ill patients with previously normal eGFR who required acute dialysis for AKI and reported that 86% of survivors had "normal" kidney function at 5 years.[29]

However, an increasing number of recent studies have linked AKI survivorship to the development of CKD or end-stage kidney disease (ESKD). For example, in one study AKI (defined using ICD-9 codes)

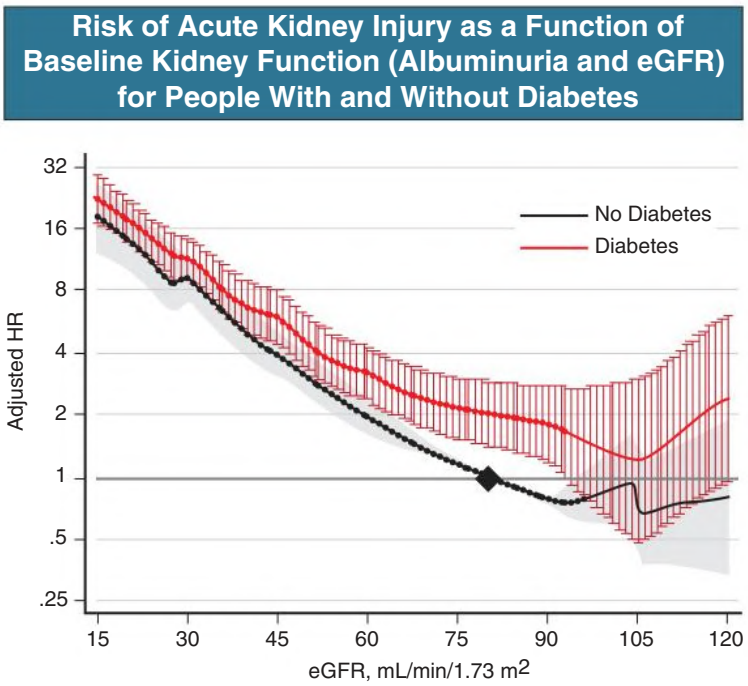

Fig. 73.3 Hazard ratio (HR) of acute kidney injury for people with and without diabetes according to baseline estimated glomerular filtration rate. *eGFR,* Estimated glomerular filtration rate.

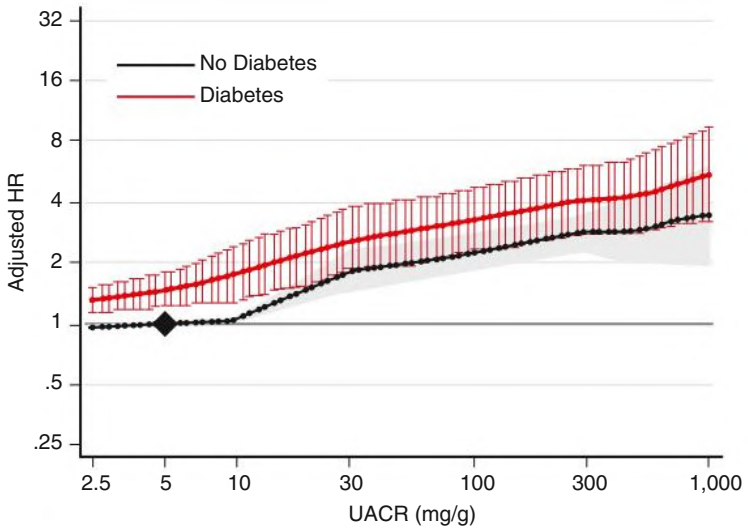

Fig. 73.4 Hazard ratio (HR) of acute kidney injury for people with and without diabetes according to the ratio of urine albumin to creatinine. *UACR,* Urine albumin/creatinine ratio.

was associated with an eightfold increase in the risk for ESKD compared with subjects without AKI or CKD.[30] A second cohort study evaluated the risk for progressive CKD after AKI in subjects with baseline eGFR greater than 45 mL/min/1.73 m^2, finding that survivors of dialysis-dependent AKI had a 28-fold increased risk for developing stage 4 CKD (eGFR <30 mL/min/1.73 m^2) or greater, compared with those without AKI.[31]

Since then, multiple studies have demonstrated an association between AKI and initiation or progression of CKD and/or ESKD in a variety of clinical settings, including cardiac surgery, cardiac catheterization, and in unselected hospitalized patients. A meta-analysis of 13 cohort studies reported that the HRs for CKD and ESKD were 8.8 (95% CI 3.1–25.5) and 3.1 (95% CI 1.9–5.0), respectively, compared with subjects without AKI. Kidney recovery after AKI appears to be an important determinant of future kidney function;[32] a Canadian population-based study showed that AKI that failed to return to within 25% of baseline kidney function was associated with a fourfold risk of CKD/ESKD.[33] National kidney registry data from the United States shows that approximately 2% to 3% of patients with AKI requiring dialysis will fail to recover kidney function and/or progress to ESKD within 1 year.[34] Recurrent episodes of AKI further increase the risk for progressive CKD; each additional AKI event after the first episode appears to double the risk for progression to stage 4 CKD.

It is possible that the apparent association between AKI and CKD is confounded by age, frailty, and unmeasured comorbidity. Also, it is sometimes difficult to distinguish AKI from progressive CKD, and there is the possibility that the observed associations are due to misclassification. However, AKI also has been linked to the development

BOX 73.2 Risk Factors for Chronic Kidney Disease After Acute Kidney Injury

- Age
- Baseline eGFR
- Congestive heart failure
- Hypertension
- Recurrent AKI
- Serum albumin during hospitalization
- Severity of AKI (AKI stage, requirement for dialysis)
- eGFR at hospital discharge

AKI, Acute kidney injury; *eGFR,* estimated glomerular filtration rate.

of CKD in children, in whom these potential confounders are less likely.[35] A prospective single-center study of 126 critically ill pediatric AKI survivors who fully recovered kidney function reported that 10% of patients developed CKD (albumin-to-creatinine ratio ≥30 mg/g or eGFR <60 mL/min/1.73 m^2) over 3 years of follow-up.[36] Importantly, 38% of the cohort had mildly decreased eGFR (60–90 mL/min/1.73 m^2), 3.2% had hypertension, and 8.7% had hyperfiltration—all risk factors for future CKD. Given that the median age of these patients at the time of the AKI episode was 0.5 years, these numbers likely underestimate the long-term risk for CKD for these children. Similar findings were reported in a meta-analysis of outcomes after pediatric hemolytic uremic syndrome.[37]

Cardiovascular Risk

Contrast-induced nephropathy after cardiac catheterization is known to be associated with excess risk for subsequent cardiovascular events; however, there are conflicting data about whether AKI is associated with an increased risk for cardiovascular events in patients without preexisting cardiovascular disease. Several large retrospective cohort studies of patients undergoing both vascular and nonvascular major surgery have recently confirmed an association between postoperative AKI and cardiovascular mortality.[38,39] Further, a recent systematic review analyzed data from 25 cohort studies of patients (n = 254,408) with and without AKI and reported that AKI is associated with an 86% increased risk for cardiovascular mortality, a 38% increased risk for major adverse cardiovascular events, and a 40% increased risk for heart failure.[40] The pathophysiology of this association remains unclear.

In summary, the development of AKI during hospitalization identifies a cohort of patients at high risk for adverse outcomes. Recognition of AKI therefore presents an opportunity to mitigate future risk through appropriate monitoring and implementation of evidence-based care for CKD. However, US data suggest that only 5% of AKI survivors saw a nephrologist after hospital discharge,[34] and AKI survivors with CKD and proteinuria often do not receive treatment with angiotensin-converting enzyme inhibitors or angiotensin receptor blockers after discharge from hospital.[41] This treatment gap is undoubtedly larger in patients with AKI from lower-income countries.

Health Care Costs

A single-center study of AKI in hospitalized patients demonstrated a direct relationship between severity of AKI and associated hospital length of stay and hospital costs.[24] When defined as a 0.3 mg/dL (26 μmol/L) increase in serum creatinine, AKI was associated with an incremental hospitalization cost of $4886; a doubling of serum creatinine was associated with an incremental cost of $9000. Studies of specific populations of hospitalized patients support these findings; a recent study of the cost of AKI after cardiac surgery suggests that the average difference in postoperative costs ranges between $9000 and $14,000 depending on AKI severity. Postoperative AKI in noncardiac surgery is associated with an $11,308 increase in the median cost compared with patients who do not experience postoperative AKI.[42] In multivariable analysis, AKI was the most costly postoperative complication for these patients and resulted in the largest proportion of resource use compared with all other complications. Another study of 5875 surgical patients found severe AKI requiring KRT to be the second most costly postoperative complication, with an estimated mean increase in hospital expenditures of $28,359 compared with an uncomplicated postoperative course, and resulted in almost twice the excess cost compared with cardiac arrest.[43] However, none of these studies accounted for the impact of CKD on AKI and attendant costs, which is likely to be significant.

AKI AS A PUBLIC HEALTH ISSUE

Conservative population-based estimates of AKI incidence in hospitalized adults are in the range of 3000 per 100,000 person-years;[44] the majority of these patients will survive to hospital discharge. The incidence of stage 4 CKD or greater in AKI survivors is approximately 120 per 100,000 person-years,[45] and the number of adults developing new CKD after AKI may be as high as 100,000 per year in the United States alone. Extrapolated to a global scale, AKI is likely responsible for hundreds of thousands of new CKD cases each year. Given this tremendous burden of morbidity and mortality, strategies that mitigate the progression of CKD after AKI should be a public health priority.

SELF-ASSESSMENT QUESTIONS

1. All of the following are risk factors for AKI except:
   A. age.
   B. CKD.
   C. congestive heart failure.
   D. thyroid disorders.
   E. diabetes.
2. The incidence of AKI in hospitalized patients has:
   A. decreased by more than 10% annually over the past decade.
   B. decreased by 1% over the past decade.
   C. increased by more than 10% annually over the past decade.
   D. increased by 1% annually over the past decade.
   E. stayed the same.
3. AKI is associated with:
   A. higher health care costs.
   B. increased risk for CKD.
   C. increased risk for chronic dialysis.
   D. all the above.
4. The incidence of stage 4 CKD (eGFR < 30 mL/min/1.73 m^2) or greater in AKI survivors is approximately:
   A. 1200 per 100,000 person-years.
   B. 120 per 100,000 person-years.
   C. 12 per 100,000 person-years.
   D. 1.2 per 100,000 person-years.

Prevention and Nondialytic Management of Acute Kidney Injury

Josée Bouchard, Etienne Macedo

Acute kidney injury (AKI) often results from a combination of insults. The most commonly associated causes are failure of kidney autoregulation, direct nephrotoxicity, ischemia/reperfusion, and inflammatory states. AKI severity predicts adverse outcomes, including requirement for kidney replacement therapy (KRT), length of hospital stay, and mortality. Studies using the Risk, Injury, Failure, Loss of Kidney Function, and End-Stage Kidney Disease (RIFLE); Acute Kidney Injury Network (AKIN); and Kidney Disease Improving Outcomes (KDIGO) classification systems (see Chapter 72) have shown that even small changes in creatinine levels are associated with short-term and long-term mortality.[1,2] Furthermore, the distant effects of AKI contribute to dysfunction of other organs, such as the heart, lungs, brain, and liver.[3] Consequently, primary prevention and early diagnosis of AKI are of primary importance. Once AKI has been detected, efforts to attenuate the effects of injury and treatment of its consequences are necessary.

RISK ASSESSMENT

Considering the conceptual model of AKI illustrated in Fig. 74.1, the first step in preventing AKI is an adequate risk assessment. The initial care of patients at risk should focus on identification and, if possible, reversal of the risk factors. Several factors are associated with AKI (Box 74.1). Risk scores are also available to help predict AKI development; most of them focus on specific situations (see Box 74.2). However, in most clinical settings, there are scarce data to evaluate the potential impact of modifiable risk factors on AKI development and progression.

The most common identifiable risk factor is chronic kidney disease (CKD), and thus adequate determination of baseline kidney function is fundamental. Because 40% to 50% of patients do not have a baseline kidney function available, and the first creatinine measured in the hospital may be affected by the disease process occurring before hospital admission, CKD status is sometimes difficult to determine. In addition to the damage biomarkers, markers of kidney stress such as TIMP-2*IGFBP7 have been shown to be helpful in identifying ongoing injury and enabling early assessment. For a further discussion of risk factors and scoring systems, see Chapters 72 and 73.

PRIMARY PREVENTIVE MEASURES

Optimizing Volume and Hemodynamic Status

To prevent AKI, ensuring adequate kidney perfusion is essential. Prompt resuscitation of patients with hypoperfusion was shown to improve outcomes twenty years ago. Means of optimizing perfusion pressure include administration of fluid and the improvement of hemodynamic status and cardiac output. Common reasons for fluid administration and/or use of vasopressors to prevent AKI include hypovolemia, hypotension, and sepsis. However, assessment of volume status can be challenging, particularly in patients in the intensive care unit (ICU). In addition, studies in ICU patients or patients undergoing surgery have shown that only about half of hemodynamically unstable patients respond to fluid administration. There are no guidelines for optimizing hemodynamic and fluid status for kidney function preservation. Too often, the effect of fluid expansion on hemodynamic status and kidney function is retrospective and evaluated by trial and error. However, dynamic measures such as the passive leg raising maneuver and the fluid bolus test coupled with real-time stroke volume monitoring can determine fluid responsiveness accurately.[4,5] Unfortunately, these are rarely performed even in ICUs. On the ward, volume status assessment and response to fluid administration most often relies on blood pressure, heart rate, oxygen saturation, central venous pressure, and urine output. These parameters are not specific or sensitive, and thus better simple tools are urgently needed to assess volume status and fluid responsiveness outside ICUs. In emergency settings, point-of-care ultrasound can be useful. For example, a collapsing inferior vena cava at the end of expiration is suggestive of hypovolemia.

Four phases of fluid therapy have been conceptualized, including rescue, optimization, stabilization, and deescalation.[6] *Rescue* implies the "administration of fluid for immediate management of life-threatening conditions associated with impaired tissue perfusion." *Optimization* refers to the "adjustment of fluid type, rate, and amount based upon context to achieve optimization of tissue perfusion." Fluid boluses are used during the rescue phase, whereas fluid challenges are administered during the optimization phase. Fluid bolus in an adult typically includes the infusion of 500 mL of isotonic fluids over 15 minutes or less without close monitoring. Fluid challenge involves the administration of 250 mL or 3 mL/kg of isotonic fluids over 5 to 10 minutes with stroke volume (SV) reassessment. Some studies have defined fluid responders as an increase of 10% to 15% of SV or cardiac output after fluid challenge. These two phases are essential in preventing AKI secondary to hypoperfusion. *Stabilization* aims for achieving a neutral or slightly negative fluid balance to favor organ support, and *de-escalation* is defined by the "minimization of fluid administration, mobilization of extra fluid to optimize fluid balance." In the stabilization and de-escalation phases, clinicians should target a neutral and then a negative fluid balance if fluid overload is present. To obtain a neutral or negative fluid balance, fluid administration should be minimized and oral or intravenous (IV) diuretics or even ultrafiltration may be required depending on the clinical scenario and underlying kidney and cardiac function. Adverse outcomes associated with fluid overload include cardiopulmonary complications, delayed wound healing and kidney function recovery, and increased mortality.[7,8] A meta-analysis has confirmed an association between elevated central venous pressure most often measured within 24 hours of ICU admission and AKI, suggesting a role of venous congestion in the development of AKI.[9]

BOX 74.1 Major Risk Factors for Acute Kidney Injury

Patient Factors
- Older age (>75 years)
- Diabetes
- Liver failure
- Chronic kidney disease
- Atherosclerosis
- Kidney artery stenosis
- Hypertension
- Hypotension
- Hypercalcemia
- Hyperuricemia
- Sepsis
- Perioperative cardiac dysfunction
- Rhabdomyolysis
- Tumor lysis syndrome

Medications and Agents
- Nonsteroidal antiinflammatory drugs
- Cyclooxygenase-2 inhibitors
- Cyclosporine or tacrolimus
- Angiotensin-converting enzyme inhibitors
- Angiotensin receptor blockers
- Iodinated radiocontrast agent
- Hydroxyethyl starch
- Aminoglycosides
- Amphotericin

Procedures
- Cardiopulmonary bypass procedures
- Surgery involving aortic clamp
- Increased intra-abdominal pressure
- Large arterial catheter placement with risk for atheroembolization
- Liver transplantation
- Kidney transplantation

There is controversy about the optimal fluid to use for resuscitation. The 2012 KDIGO AKI guideline suggests that isotonic crystalloids should be used instead of synthetic (hydroxyethyl starch [HES]) and nonsynthetic (albumin) colloids for intracellular volume expansion in patients at risk or presenting with AKI, in the absence of hemorrhagic shock.[10] Large studies have clearly demonstrated that HES solutions increase the risk for AKI. A randomized controlled trial (RCT) in 7000 ICU patients has shown that even solutions with lower molecular weight such as 6% HES 130/0.4 increased the need for KRT compared with 0.9% sodium chloride (normal saline).[11] Another large RCT including 804 patients with severe sepsis has shown that 6% HES 130/0.4 is detrimental to kidney function and also survival compared with Ringer acetate.[12] The mechanism of HES-induced AKI may be because of proximal kidney epithelial cell uptake of HES causing an acquired lysosomal storage disease. Therefore, HES should be avoided in patients at risk for and with AKI.

For albumin, the Saline Versus Albumin Fluid Evaluation (SAFE) trial of 6997 critically ill patients found that fluid resuscitation with saline or albumin resulted in similar relative risks for death.[13] In addition, no significant differences were found in new single-organ and multiple-organ failure or days on KRT. Two subgroup analyses from this study showed that use of albumin may be deleterious in patients with traumatic brain injury and potentially beneficial in sepsis. Albumin can be considered when substantial amounts of crystalloids (e.g., 2 L) are required to maintain adequate mean arterial pressure (MAP), especially in septic patients. However, its effect must be balanced against its potential risks; that is, it is possibly deleterious in patients with trauma and has low potential for transmission of infectious diseases.

The type of crystalloids used can also influence kidney outcomes. When comparing kidney artery flow velocity and cortical tissue perfusion, there was a significant reduction in artery flow and cortical tissue perfusion with isotonic saline but not with the use of chloride-restrictive fluids. Indeed, greater chloride delivery to the macula densa may activate tubuloglomerular feedback, triggering kidney vasoconstriction and reduced glomerular filtration rate (GFR). Two large single-center RCTs have shown beneficial effects of chloride-restrictive

BOX 74.2 Specific Risk Factors for the Development of Acute Kidney Injury in Common Clinical Situations

Cardiac Surgery
Female sex
COPD
Proteinuria
Preoperative S_{Cr} >2.1 mg/dL
Anemia
Insulin-dependent diabetes
ACE inhibitor therapy
Heart failure
LV ejection fraction < 35%
Preoperative IABP
Hyperglycemia
Hyperuricemia
Emergency surgery
Valve Surgery only
Previous cardiac surgery
Other cardiac surgery
Combination of CABG + valve surgery
Blood transfusion

Critically Ill
High A–a gradient
Low serum albumin
Proteinuria
Hyperglycemia
High intra-abdominal pressure
Active cancer
Age
SCr >1.3 mg/dL
Serum bilirubin > 1.5 mg/dL
Elevated CVP > 8 cm
Hemodynamic instability
Sespsis

Gastrointestinal and Endocrine
Cirrhosis/biliary surgery
Obstructive jaundice
Diabetes mellitus
Hyperglycemia

Hemodynamic
Congestive heart failure
Aortic cross-clamping
Cardiac instability
Major vascular surgery
Infection/sepsis
Multiorgan failure

Iodinated Contrast Administration
Age > 75 yr
Heart failure
Diabetes mellitus
SCr > 1.5 mg/dL or eGFR < 60 mL/min/1.73 m^2
History of pulmonary edema
Anemia/blood loss (Hct < 395 for men, < 36% for women)
Hyperuricemia
Volume of contrast > 100 mL
Intra-arterial injection
Systolic BP < 80 mm Hg for > 1 hour and need for inotropic support or IABP 24 hours after procedure
Use of IABP

Nephrotoxic Antibodies
Volume depletion
Older age
Chronic kidney disease
Amphotericin
Aminoglycosides
Duration of therapy > 7 days
Volume depletion
Divided dose regimens
Liver disease

Miscellaneous
Age
Proteinuria
Hypertension
Massive blood transfusion

[a]A–a gradient is the alveolar-arterial oxygen gradient calculated with the sea level standard formula (713 × Fio_2) – (Pco_2/0.8) – Pao_2, where Fio_2 is fractional inspired oxygen concentration, Pao_2 is arterial partial oxygen pressure, and Pco_2 is partial carbon dioxide pressure.
ACE, Angiotensin-converting enzyme; *BP,* blood pressure; *CABG,* coronary arterial bypass graft; *COPD;* chronic obstructive pulmonary disease; *CVP,* central venous pressure; *Hct,* hematocrit; *IABP:* intra-aortic balloon pump; *LV,* left ventricular; S_{Cr}, serum creatinine.

fluids.[14,15] In critically ill adults, chloride-restrictive fluids (lactated Ringer's solution or Plasma-Lyte) compared with isotonic saline decreased major kidney events (MAKE), defined as the composite outcome of death from any cause, new kidney replacement therapy, or persistent kidney dysfunction (14.3% vs. 15.4%; odds ratio [OR], 0.91; 95% confidence interval [CI], 0.84–0.99; $P = .04$).[14] In noncritically ill adults, chloride-restrictive fluids (lactated Ringer's solution or Plasma-Lyte) also decreased the incidence of MAKE compared with isotonic saline (4.7% vs. 5.6%; OR, 0.82; 95% CI, 0.70–0.95; $P = .01$).[15] A meta-analysis in critically ill patients has found that resuscitation with chloride-restrictive fluids decreased 30-day mortality and need for KRT compared with isotonic saline.[16] Other RCTs are underway to confirm these findings (PLUS and BASICS trials). The choice of chloride-rich (isotonic saline) versus low-chloride solutions (lactated Ringer's solution or Plasma-Lyte) should be based on the patient's clinical condition, including electrolyte and acid-base balance. Physicians must also remember that the sodium content of isotonic saline is 154 mEq/L, whereas it is 130 mEq/L for lactated Ringer's and 140 130 mEq/L for Plasma-Lyte. Of note, normal saline should be used in head-injured patients and patients with severe liver disease or other conditions imposing risk of worsening cerebral edema.

There is no consensus on how to use vasopressors to prevent AKI or avoid further deterioration of kidney function. According to international guidelines for sepsis management, after initial fluid resuscitation with 30 mL/kg of crystalloids and addition of albumin in patients requiring substantial amounts of crystalloids to maintain adequate MAP, vasopressors should be initiated targeting a MAP above 65 mm Hg.[17] In sepsis, norepinephrine is the first-choice

vasopressor. In addition, angiotensin II and vasopressin are noncatecholamine options that may improve glomerular flow through several mechanisms. With regard to the kidney, one RCT showed that vasopressin is equivalent or may be better than norepinephrine to improve kidney outcomes in patients with septic shock.[18] KRT was required in 25% of patients in the vasopressin group and in 35% of the norepinephrine group; however, rates of KRT were comparable among survivors from each group, and the overall mortality rate was also similar between groups.

Inotropic agents such as dobutamine should be administered if myocardial dysfunction or ongoing signs of hypoperfusion are present. The optimal MAP values to prevent AKI need to be better delineated. One study has found that in hypertensive patients with septic shock, targeting MAP between 80 to 85 mm Hg instead of 65 to 70 mm Hg reduced the risk for AKI and KRT, whereas the risk for atrial fibrillation seemed to be heightened.[19] Therefore, target MAP values may need to be individualized depending on age, hypertension status, and degree of peripheral artery and renovascular disease and are likely to be between 60 and 80 mm Hg.

Prevention of Contrast-Induced Acute Kidney Injury

The concept of contrast-induced AKI (CI-AKI) has been recently questioned. However, physicians are less likely to prescribe contrast to patients with lower estimated GFR (eGFR) and more likely to prescribe IV fluids when contrast is administered, which may affect results from observational studies.

According to the KDIGO guideline, measures to reduce the risk of AKI should be implemented in patients with a baseline eGFR below 45 mL/min/1.73 m^2 for IV iodinated contrast administration. For prevention of CI-AKI, patients at risk should receive IV hydration (Fig. 74.2). Hydration with isotonic saline is superior to half-isotonic (0.45%) saline. When comparing the effectiveness of sodium bicarbonate with isotonic sodium chloride and oral *N*-acetylcysteine (NAC) with placebo in 8680 high-risk patients scheduled to undergo coronary or noncoronary angiography, the PRESERVE trial showed no difference in terms of AKI or mortality between the use of sodium bicarbonate and isotonic sodium chloride.[20] Therefore, because of the risks of compounding errors with sodium bicarbonate, isotonic sodium chloride should be used. The use of NAC is discussed later in this chapter. Ringer's lactate is another option because it contains less chloride than isotonic sodium chloride, possible decreasing kidney vasoconstriction and causing less hyperchloremic acidosis. In addition, it causes alkalization of renal tubular fluid, which is a suggested mechanism to decrease the damages caused by free radicals. Studies are needed to determine whether the use of balanced solutions compared with normal saline would lower AKI incidence.

Iodinated contrast can be categorized according to osmolality into high-osmolar contrast medium (approximately 2000 mOsm/kg), low-osmolar contrast medium (600–800 mOsm/kg), and iso-osmolar contrast medium (290 mOsm/kg). The KDIGO AKI guidelines recommend either iso-osmolar (preferred) or low-osmolar iodinated contrast for patients at risk for CI-AKI because the risk for nephrotoxicity is higher with increasing osmolarity.

The volume of contrast administered is also an independent predictor of CI-AKI and should be reduced as much as possible. Based on the volume (V) of contrast given (in mL) and the creatinine clearance (CrCl; mL/min), a V:CrCl ratio above 3.7 independently predicts CI-AKI. Administration of iodinated contrast more than once over 48 to 72 hours should be avoided. The drugs used for CI-AKI prevention are included in the section on pharmacologic approaches.

Prevention of Drug-Induced and Nephrotoxin-Induced Acute Kidney Injury

Drug-induced nephrotoxicity often can be predicted because it is more common in certain patient populations and clinical situations. Prevention involves the knowledge of mechanisms of kidney injury, patient-related risk factors, and drug-related risk factors. The most important patient-related factors are older age (60 years or older), CKD, diabetes, heart failure, volume depletion, and sepsis. Preventive

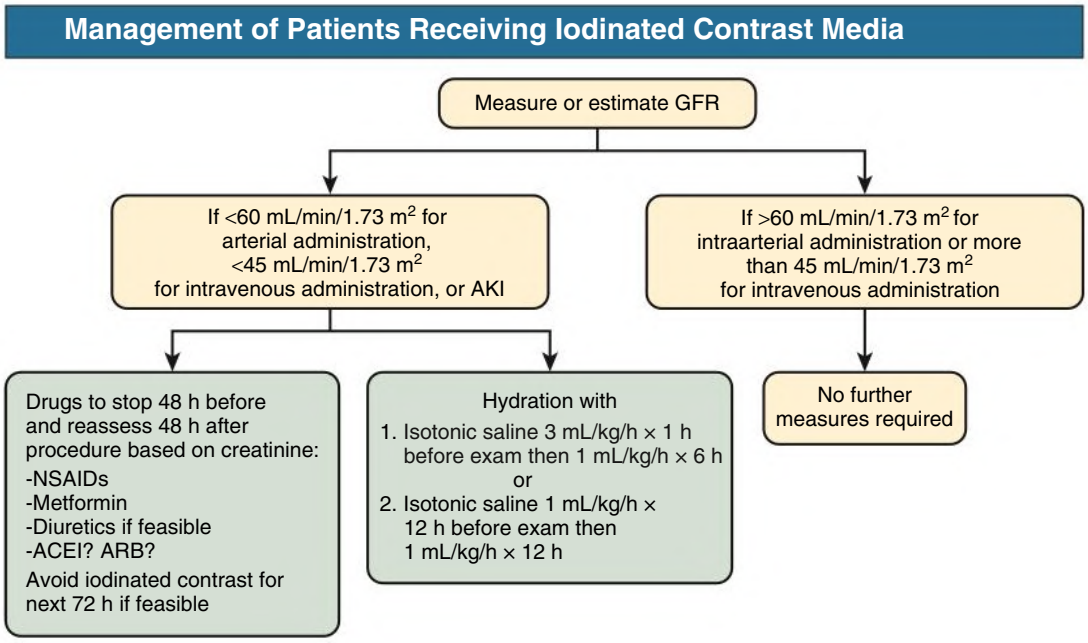

Fig. 74.2 Management of patients receiving iodinated contrast media. *ACEI,* Angiotensin-converting enzyme inhibitor; *AKI,* acute kidney injury; *ARB,* angiotensin receptor blocker; *CKD-EPI,* Chronic Kidney Disease Epidemiology Collaboration; *GFR,* glomerular filtration rate; *MDRD,* Modification of Diet in Renal Disease; *NSAIDs,* nonsteroidal antiinflammatory drugs.

measures include correctly estimating the GFR before initiating therapy, adjusting the dosage, monitoring kidney function and drug dosage during therapy, and administering administration IV saline before exposure if possible. Alternative nonnephrotoxic drugs should be used, and nephrotoxic drug combinations should be avoided whenever feasible.

Amphotericin

Amphotericin-associated nephrotoxicity can occur in as many as one-third of treated patients, and the risk for AKI increases with higher cumulative doses. Lipid formulations cause less nephrotoxicity compared with the standard formulation, and therefore liposomal amphotericin is preferred over conventional amphotericin; however, it is significantly more expensive. Recently, alternative antifungal agents such as itraconazole, voriconazole, and caspofungin have been more commonly used in patients at high risk for AKI because of their absence of nephrotoxicity and should be used rather than conventional amphotericin when appropriate antifungal coverage is provided.

Angiotensin-Converting Enzyme Inhibitors and Angiotensin Receptor Blockers

Angiotensin-converting enzyme (ACE) inhibitors and angiotensin receptor blockers (ARBs) cause vasodilation of the efferent glomerular arteriole, further reducing intraglomerular pressure already compromised by the blood pressure–lowering effect of these agents. After the initiation of an ACE inhibitor or ARB, if creatinine increases by more than 30%, bilateral kidney artery stenosis, stenosis of the kidney artery in a solitary kidney, diffuse intrakidney small-vessel disease, or generalized volume depletion should be suspected, and these drugs should be discontinued. It remains unclear whether withdrawing an ACE inhibitor or ARB before iodinated contrast administration is beneficial.

Nonsteroidal AntiInflammatory Drugs

Nonsteroidal antiinflammatory drugs (NSAIDs) should be avoided if possible in CKD and intravascular volume depletion because they inhibit cyclooxygenase, which blocks prostaglandin-induced vasodilation of the afferent arteriole, potentially reducing GFR and kidney blood flow. The risk of NSAIDs must be balanced against their benefit, and patients should be instructed about increased risk situations and advised on when to hold these drugs during sick days. Clinicians may also decide to temporarily stop ACE inhibitors or ARBs in patients with high-normal potassium or more severe CKD. In critically ill patients, kidney hypoperfusion caused by decreased effective circulating volume is relatively common and inhibition of prostaglandin-induced vasodilation may further compromise kidney blood flow and exacerbate ischemic injury.

Aminoglycosides

AKI caused by aminoglycoside nephrotoxicity (AG-AKI) usually occurs 5 to 10 days after initiation of the treatment. AG-AKI is typically nonoliguric and associated with decreased urine concentrating ability and urinary magnesium wasting. Aminoglycoside toxicity can also result in vestibular toxicity that can lead to tinnitus or difficulty ambulating. A large population-based study in adults undergoing surgery receiving antibiotic prophylaxis found an association between one dose of gentamicin (4 mg/kg) and AKI that challenges the notion that AG-AKI only occurs after a few days of treatment.[21] The KDIGO guideline recommends against using aminoglycosides in patients with or at risk for AKI unless no other alternative is available. With multiple daily administration schedules, elevated aminoglycoside peak levels appear to correlate with nephrotoxicity. Because aminoglycoside uptake by proximal tubular cells is saturable, once-daily administration can decrease tubular cell toxicity. In the general population, extended intervals between doses maintains the target dose while decreasing the risk for nephrotoxicity compared with multiple daily doses; therefore, in patients with normal eGFR who are not at risk for AKI, aminoglycosides should be administered daily if possible, with serum concentrations measured as recommended.

Tumor Lysis Syndrome

Tumor lysis syndrome (TLS) is caused by uric acid and calcium-phosphate precipitation in the tubules. Identification of patients at high risk is fundamental to prevent AKI in this setting. The most common hematologic malignancies associated with TLS are aggressive lymphomas and acute lymphoblastic leukemia. Rare cases of a TLS-type of AKI have also been reported in other catabolic states, such as after heart surgery. The risk factors for TLS are related to patient (age, baseline kidney function) and tumor characteristics (cell turnover rate, growth rate, extensive bone marrow involvement, tumor bulk, and chemosensitivity).[22] Baseline uric acid higher than 7.5 mg/dL, lactate dehydrogenase levels higher than 1500 U/L, and white blood cells greater than 25×10^9/L are also risk factors. The diagnosis is based on two simultaneous laboratory abnormalities occurring within 3 days before or 7 days after chemotherapy: uric acid greater than 8 mg/dL, potassium greater than 6 mEq/L, phosphate greater than 4.5 mg/dL, calcium less than 7 mg/dL, and at least one clinical complication among AKI defined as an increase in baseline creatinine by 1.5 times or greater, cardiac arrhythmia, or seizure.

In patients at low risk for developing TLS as defined in an expert consensus, management includes hydration and close monitoring of volume status and kidney function.[22] The use of urine alkalinization to promote elimination of urate is not recommended because it can induce calcium phosphate deposition and therefore aggravate TLS. In patients at intermediate and high risk, aggressive hydration with isotonic saline 2 to 3 L/m^2 per day aiming for urine output between 80 and 100 mL/m^2/hr should be initiated. Hydration should be continued until there is no significant evidence of tumor lysis, as shown by uric acid and phosphorus levels. If urine output decreases despite adequate fluid administration, a loop diuretic should be added, and KRT will be required if oliguria persists. In patients at intermediate risk with uric acid levels up to 8 mg/dL, a xanthine oxidase inhibitor such as allopurinol also should be started 2 days before chemotherapy, whereas rasburicase should be used in patients with uric acid levels greater than 8 mg/dL or with concomitant cardiac or kidney diseases limiting hydration. The risk of severe cutaneous adverse events associated with allopurinol appears higher in some Asian populations. Rasburicase should not be used in patients with glucose-6-phosphate dehydrogenase (G6PD) deficiency. For high-risk patients, a single dose of rasburicase (up to 0.2 mg/kg, although a lower dose such as 3 mg is usually prescribed) is recommended, followed by close monitoring of uric acid levels. If uric acid normalizes, allopurinol treatment can be started.

Secondary Prevention

After the kidney insult has occurred, secondary preventive measures should be directed to avoid further injury, facilitate repair and recovery, and prevent complications. The timeliness of interventions is crucial to their effectiveness. Various approaches have been applied but are best appreciated in the context of specific clinical scenarios.

Traumatic and Nontraumatic Rhabdomyolysis

The main step in preventing AKI after traumatic rhabdomyolysis and crush syndrome is early and aggressive fluid therapy.[23] IV isotonic saline should be initiated even before the crushed limb is

relieved to prevent precipitation of the pigment in the tubular lumen. Nontraumatic rhabdomyolysis can be caused by ischemia, bacterial or viral infections, severe heat, prescribed medications (statins), drugs of abuse (cocaine or heroin), inflammatory or metabolic myopathies, and electrolyte disorders (hypokalemia or hypophosphatemia). Plasma creatine kinase (CK) levels greater than 5000 U/L have been associated with AKI. In patients with CK levels above 10,000 U/L or with severe crush injury, aggressive IV fluid administration should be considered to correct hypovolemia and target urine output of 200 to 300 mL/h to reduce kidney injury. In patients with less severe rhabdomyolysis with no rapid increase in CK levels (i.e., peak 5000–10,000 U/L) and in those with underlying CKD or heart failure, less aggressive fluid infusion can be targeted. Fluid composition is controversial because no direct comparative trials have been performed. Recommendations to use sodium bicarbonate intend to maintain alkaline urine and decrease precipitation of myoglobin and arteriolar vasoconstriction. However, sodium bicarbonate also can precipitate calcium phosphate deposition and worsen hypocalcemia and should be avoided in severe hypocalcemia or metabolic alkalosis. On the other hand, large volumes of normal saline can cause hyperchloremic metabolic acidosis. Some experts use both normal saline and sodium bicarbonate. For example, if urine pH is less than 6.5, each liter of normal saline can be alternated with 850 mL of 5% dextrose plus 150 mmol of sodium bicarbonate. Bicarbonate should not be administered if there is concomitant hypocalcemia or metabolic alkalosis. Mannitol has been suggested to be beneficial because of its diuretic, antioxidant, and vasodilatory properties. Mannitol could prevent kidney tubular cast deposition, expand extracellular volume, and reduce intracompartmental pressure, muscle edema, and pain. However, mannitol may exacerbate heart failure and nephrotoxicity, requires close monitoring, and is contraindicated in oliguria, hypervolemia, hypertension, and heart failure. Mannitol may be considered in patients with CK levels greater than 30,000 U/L who have a urine flow greater than 20 mL/hr at a rate of 5 g/hr added to each liter of infusate not to exceed 1 to 2 g/kg/day.

Muscle damage induces stretch-activated ion channels, allowing for influx of calcium into cells after reperfusion. The resulting hypocalcemia is usually asymptomatic but can lead to cardiac dysrhythmias. Hence, care must be taken to avoid sodium bicarbonate–induced hypocalcemia, which can trigger tetany, seizures, and cardiotoxicity and worsen muscle damage. During AKI recovery, hypercalcemia is frequent, mainly in patients who received calcium infusion, as a result of the mobilization of previously precipitated calcium. Thus, hypocalcemia should be treated only if symptomatic.

In treating patients with rhabdomyolysis, it is important to consider when to stop fluid resuscitation. A general recommendation is to stop when CK levels decrease to less than 5000 U/L and myoglobinuria disappears, as shown by a negative urine dipstick for blood. However, the risk for fluid accumulation and compartmental expansion always should be evaluated. Frequent assessment of serum creatinine and CK also help the clinician determine the appropriate volume expansion. KRT should be considered in resistant hyperkalemia or metabolic acidosis, rapidly rising serum potassium, oliguria, anuria, or volume overload.

Hyperglycemia

It remains uncertain whether strict control of blood glucose reduces AKI incidence and mortality. In a large RCT in ICU patients, intensive glucose control (glucose of 81–108 mg/dL [4.5–6.0 mmol/L]) increased the risk for death at 90 days compared with conventional glucose control (<180 mg/dL [<10 mmol/L]). Intensive glucose control also increased the risk for severe hypoglycemia. There was no change in the incidence of AKI or use of KRT. Other studies have not found an increase in mortality with intensive glucose control. In summary, intensive glucose control in ICU patients increased the incidence of severe hypoglycemia and either increased or had no effect on mortality compared with blood glucose ranges of 140 to 180 mg/dL (7.8–10 mmol/L) and 180 to 200 mg/dL (10–11 mmol/L). We recommend maintaining glucose concentration in the range of 110 to 149 mg/dL (6.1–8.3 mmol/L).

Remote Ischemic Preconditioning

Remote ischemic preconditioning (RIPC) is performed by applying inflation of a blood pressure cuff for four or five short cycles in the upper or lower limb. RIPC aims to create brief ischemia and reperfusion in the arm or leg to provide protection in distant organs, such as heart, kidney, lung, and brain. The underlying mechanisms include activation of humoral factors, including adenosine, bradykinin, and cannabinoids, in addition to subcellular modulators, nuclear factor-κB (NF-κB), and nitric oxide (NO). A meta-analysis including 28 studies, which randomized a total of 6851 patients, concluded that RIPC does not confer a benefit over sham conditioning (placebo) to prevent AKI or reduce mortality in cardiac or vascular surgery.[24]

Pharmacologic Approaches

Because of the multiple different causes of AKI, various pathways have been targeted in studies to prevent or alter the course of AKI. These pathways include inflammation, oxidative and mitochondrial stress, cellular metabolism and repair, apoptosis, and hemodynamics. Most of these preventive strategies were successful in animal models but did not translate into beneficial effects in patients. Only a few have shown benefits (Table 74.1).

N-Acetylcysteine

N-Acetylcysteine (NAC) is a tripeptide analogous to glutathione and is able to cross cellular membranes. NAC may reduce vasoconstriction and oxygen free radical generation after the administration of contrast material. Because an increased production of free radicals by the kidneys is partly responsible for their cellular damage in postischemic and nephrotoxic AKI, several clinical studies have attempted to use NAC to prevent AKI, mainly in CI-AKI and during cardiac surgery.

In the initial study, NAC at a dose of 600 mg orally twice daily the day before and the day of the procedure prevented AKI after iodinated contrast administration. The multicenter PRESERVE trial has shown that the use of NAC does not provide any benefit to prevent CI-AKI.[20] Therefore, NAC is no longer recommended to prevent CI-AKI.

Allopurinol

Hyperuricemia has been associated with the development of AKI. There are retrospective observational studies showing a reduced incidence of AKI in patients treated with allopurinol compared with those who were not. Animal models of heat stress and rhabdomyolysis with hyperuricemia have also demonstrated that allopurinol administration could prevent AKI. Allopurinol may also help in reducing AKI after iodinated contrast administration. Additional studies are required.

Loop Diuretics and Natriuretics

Diuretics are often used to manage fluid in patients who develop AKI. Although nonoliguric AKI has been associated with better outcomes than oliguric AKI, diuretics have been shown to be ineffective in the prevention of AKI or for improving outcomes once AKI occurs. In addition, diuretics should be avoided when AKI is attributed to prerenal causes. Meta-analyses have confirmed that the use of diuretics to prevent AKI did not reduce in-hospital mortality or need for KRT.[25]

TABLE 74.1 Drugs Used in Prevention of Acute Kidney Injury

Drug	Level of Evidence	Results	Comments
Dopamine	RCTs	No effect on kidney function	
Fenoldopam	Small RCTs One meta-analysis	No effect on kidney function Beneficial effect on kidney function	Further studies required
Norepinephrine vs. vasopressin	RCT in septic shock	Tendency toward less kidney replacement therapy with vasopressin	Further studies required
Loop diuretics	RCTs and meta-analysis	No effect on kidney function	
Nesiritide	RCTs in cardiac surgery	Decreased incidence of AKI Controversial effect on kidney replacement therapy requirement	Further studies required
N-Acetylcysteine	RCTs and meta-analysis	No effect in CI-AKI	
Allopurinol	Observational studies and small pilot studies	Possible beneficial effect on kidney function	Further studies required
Statins	RCTs in perioperative period (cardiac surgery) RCTs in CI-AKI	No effect on kidney function Possible beneficial effect on kidney function	Patients not receiving statins who need this drug for other indications may receive statins before their angiography
Insulin	Meta-analyses	Controversial effect	KDIGO recommends targeting blood glucose 110–149 mg/dL (6.1–8.3 mmol/L)
Calcium channel blockers	RCT in peritransplant period	No effect on kidney function	Further studies required
Levosimendan	RCT in cardiac surgery	No effect on need for kidney replacement therapy	
Adenosine antagonists	RCTs	Controversial effect on kidney function	Further studies required
Alpha-melanocyte-stimulating hormone analog (ABT-719)	Phase IIb study in cardiac surgery	No effect on kidney function	
Alpha-2 adrenergic agonist (dexmedetomidine)	Meta-analysis in cardiac surgery Small RCT in aortic surgery	Might decrease AKI Decreased incidence of AKI	
Antioxidative enzyme heme oxygenase-1	Small phase III trial	Trend toward lower levels of the urinary AKI biomarkers	Ongoing phase III in kidney transplantation (NCT03646344)
Propofol	RCTs	Controversial results on kidney function	Current RCTs in kidney transplantation (NCT02727296), after nephrectomy (NCT04474600), orthopedic surgery (NCT03336801)
Small interfering RNA targeting p53	Phase II RCT in cardiac surgery	Beneficial effect on kidney function	Phase III trial ongoing in cardiac surgery (NCT03510897)
Peroxisome proliferator-activated receptor	Phase I clinical trials		Phase II RCT in cardiac surgery (NCT03941483)
Nicotinamide riboside and pterostilbene	Phase I clinical trials		Phase II RCT in complex aortic surgery (NCT04342975)
Hepatocyte growth factor (HGF)-like peptide (ANG-3777)			Phase II RCT in cardiac surgery (NCT02771509)
THR-184[a]	Phase II RCT	No effect on kidney function	
Mesenchymal stem cells	Phase I clinical trial	Decreased incidence of AKI	Further studies required

[a]A bone morphogenetic protein-7 agonist.
AKI, Acute kidney injury; *CI-AKI,* contrast-induced acute kidney injury; *KDIGO,* Kidney Disease: Improving Global Outcomes; *RCT,* randomized controlled trial; *RNA,* ribonucleic acid.

An RCT including 94 patients undergoing high-risk cardiac surgery showed that prophylactic nesiritide (β-type natriuretic peptide) did not reduce the KRT requirement or lengths of stay, although AKI rates were lower with nesiritide. Conversely, a Japanese RCT including 303 patients with CKD who underwent coronary artery bypass graft (CABG) surgery showed that human atrial natriuretic peptide (hANP, carperitide) decreased postoperative serum creatinine and need for dialysis,[26] although other studies using the same medication have shown increased mortality in patients with acute heart failure. Further studies are required.

Vasoactive Agents: Vasopressors, Inotropes, and Vasodilators

Kidney-dose dopamine 0.5 to 3 μg/kg/min given as a kidney vasodilator increases urine output, but several studies have confirmed that this drug does not affect AKI outcome or mortality.[27] Dopexamine, a synthetic dopamine analog, is a dopamine type-1 and less potent dopamine type-2 receptor agonist. Small studies performed in patients undergoing liver transplant surgery have not found a beneficial effect of dopexamine in preventing AKI.

Fenoldopam is a pure dopamine type-1 receptor agonist with hemodynamic kidney effects similar to those of low-dose dopamine,

without systemic α- or β-adrenergic stimulation. In meta-analyses, fenoldopam was shown to reduce the risk for AKI in postoperative or critically ill patients (OR, 0.43–0.46).[28,29] Intrakidney administration of fenoldopam allows the use of a substantial dose of fenoldopam mesylate while avoiding systemic adverse effects, such as hypotension. Data from experimental models suggest that fenoldopam may have additional anti-inflammatory effects. We do not recommend use of fenoldopam to prevent AKI because no high-quality data support use of this agent.

A meta-analysis on the use of levosimendan, a calcium-sensitizing agent with inotropic and vasodilatory effects, has demonstrated reduced AKI after cardiac surgery, KRT requirement, and mortality. However, a large RCT showed that levosimendan did not reduce mortality or need for KRT.[30]

Calcium channel blockers (CCBs) have been shown to reverse the afferent arteriolar vasoconstriction induced by a variety of stimuli and also have an independent natriuretic effect. These drugs have been evaluated in the prevention of delayed graft function (DGF). A large multicenter RCT did not find any benefit on the incidence and severity of DGF. A systematic review did not find strong evidence that CCBs reduce the incidence of DGF after transplantation.

Theophylline, a nonselective adenosine receptor antagonist, prevents adenosine-mediated vasoconstriction of the afferent arteriole. Adenosine is released in response to increased luminal chloride concentrations in the distal tubules as part of the tubuloglomerular feedback. Meta-analyses have found a significant reduction in CI-AKI with theophylline.[31] However, there is insufficient evidence to recommend theophylline monotherapy, and the KDIGO AKI guideline does not suggest using theophylline to prevent CI-AKI.

Selective adenosine blocking agents, such as rolofylline, have been used in trials for prevention and treatment of cardiorenal syndrome. In a small double-blind RCT in decompensated heart failure with AKI, the coadministration of adenosine A_1 antagonist with furosemide increased diuresis and prevented further decrease in GFR.

Statins

Although the pathogenesis of CI-AKI is not completely known, multiple mechanisms may be involved. Statins induce downregulation of angiotensin receptors, decrease endothelin synthesis, decrease inflammation, improve endothelial function by inhibiting NF-κB, decrease expression of endothelial adhesion molecules, increase NO bioavailability, attenuate production of reactive oxygen species, and protect against complement-mediated injury. Those mechanisms may be involved in CI-AKI. A number of observational studies and some but not all RCTs support the potential for kidney protection with statin before an intra-arterial administration of iodinated contrast. The statins most commonly studied in this setting were rosuvastatin and atorvastatin. Therapy should continue in patients who are already receiving a statin, and those who need statins for another indication such as myocardial infarction may receive statins before their angiography. It is currently unclear whether statins should be specifically initiated to prevent CI-AKI. A recent meta-analysis suggested that CKD patients may benefit more from statins in this setting.[32] Regardless, according to the KDIGO lipid guideline, CKD patients aged 50 or older with eGFR less than 60 mL/min/1.73 m^2 should be treated with a statin. A large recent retrospective study failed to show any benefit of statins for preventing AKI related to administration of IV iodinated contrast.[33]

Statins were associated with lower risk of AKI after elective surgery in observational studies. However, RCTs did not confirm these findings. In the largest RCT, the incidence of AKI after cardiac surgery was similar between atorvastatin and placebo groups among all participants (20.8% vs. 19.5%; risk ratio [RR], 1.06; 95% CI, 0.78–1.46; $P = .75$).[34] Similar results were observed when stratifying for statin-naïve patients or statin users.

Antiinflammatory Agents

An alpha-melanocyte-stimulating hormone analog, ABT-719, inhibits inflammatory, cytotoxic, and apoptotic pathways. In a phase IIb study, patients with CKD who underwent cardiac surgery did not have a lower incidence of AKI compared with placebo.

Dexmedetomidine, an alpha-2 adrenergic agonist used for its sedative properties, also has hemodynamic and antiinflammatory effects. A recent meta-analysis in cardiac surgery found that dexmedetomidine might reduce the incidence of AKI.[35] A small RCT after aortic surgery has also shown a decreased incidence of AKI.[36]

Antioxidants

The endogenous antioxidative enzyme heme oxygenase-1 (HO-1) is a stress-inducible enzyme and has important antiapoptotic and anti-inflammatory functions. Preliminary data suggest that the induction of HO-1 may be protective in several forms of injury, including AKI. A phase III RCT including 600 patients is currently determining whether this drug reduces the incidence of DGF after kidney transplantation (HOT 2 Trial, NCT03646344).

Propofol, which has antioxidant and anti-inflammatory properties, can also increase levels of bone morphogenetic protein-7 (BMP-7), a potential tubular repair agent.[37] Propofol has previously shown conflicting results on kidney function. There are ongoing RCTs assessing the effect of propofol on kidney function, including one in kidney transplantation (VAPOR-2 Trial, NCT02727296), one after nephrectomy (NCT04474600), and another one in orthopedic surgery patients (NCT03336801).

Apoptosis p53 Inhibitor

In a phase II trial, patients treated with small interfering ribonucleic acid targeting p53 had a reduced AKI rate compared with those treated with placebo. Because p53 has, among other activities, a tumor suppression function, one of the major drawbacks to the use of an inhibitor of p53 is its potential carcinogenic effect. A phase III trial is underway to assess the efficacy of teprasiran to prevent AKI in cardiac surgery (NCT03510897).

Targeting Mitochondrial Stress and Cell Metabolism

ASP1128, a peroxisome proliferator-activated receptor (PPAR) delta modulator, is currently studied in a phase II trial in patients undergoing cardiac surgery (NCT03941483). A phase II trial is ongoing targeting metabolic pathways related to cellular protection using NAD^+ supplementation with nicotinamide riboside and pterostilbene to prevent AKI in patients undergoing complex aortic surgery (NCT04342975).

Tubular Repair Agents

In a recent phase II RCT in patients at risk for AKI undergoing cardiac surgery, THR-184, a peptide that activates the bone morphogenetic protein pathway, did not reduce AKI over the postoperative week.[38] ANG-3777, a hepatocyte growth factor (HGF)-like peptide, is evaluated in a phase II trial in patients having cardiac surgery.

Mesenchymal stem cells (MSCs) were shown to prevent ischemia/reperfusion–induced AKI in rats. A phase I clinical trial evaluated the feasibility and safety of suprakidney aorta infusion of allogeneic MSCs in patients undergoing on-pump cardiac surgery.[39] No adverse events were associated with the MSC infusion, and lengths of hospital stay and readmission rates were decreased by 40% compared with matched historical controls. Postoperative kidney function remained at baseline

levels and no patients in the treatment group required hemodialysis (HD), whereas 20% of controls developed AKI. In addition, kidney function in the treatment group was stable for up to 16 months in patients with CKD, whereas matched controls showed progressive deterioration in kidney function.[39] The long-term safety of MSC is unknown.

Sodium-Glucose Transporter Inhibitors

Sodium-glucose transporter (SGLT2) inhibitors have shown beneficial cardiovascular and kidney effects in patients with diabetic nephropathy. However, after approval, there were several reports of severe AKI. In recent RCTs and meta-analysis, SGLT2 inhibitors reduced the incidence of AKI by 25%, without heterogeneity across studies. These findings were replicated in real-world analyses. The reasons why these drugs may reduce AKI remain to be determined, and there is no current recommendation to use them to reduce the risk of AKI. Importantly, patients should be instructed to temporarily withhold these agents during sick days.

Summary

To prevent AKI, hypovolemia, hypotension, and sepsis should be quickly addressed. Isotonic fluids and vasopressors can be administered depending on the clinical scenario. Preference should be given to balanced solutions, especially if high volumes will be given in patients at high risk for AKI. HES and other nephrotoxins should definitively be avoided. For prevention of CI-AKI (see Fig. 74.2), patients with eGFR less than 45 mL/min/1.73 m^2 receiving IV contrast or those with eGFR less than 60 mL/min/1.73 m^2 receiving intra-arterial contrast should receive IV hydration with crystalloid solution. The benefit of statins and RIPC is controversial. To prevent TLS, patients at intermediate and high risk should receive aggressive hydration with crystalloid solutions. A xanthine oxidase inhibitor or rasburicase should be administered depending on the underlying risk and uric acid levels. For rhabdomyolysis, normal saline is preferable. Additional studies are required to assess whether fenoldopam, certain vasopressors, nesiritide, and statins are beneficial to prevent AKI.

TREATMENT OF ACUTE KIDNEY INJURY

Once measures to prevent AKI have failed, a key question is whether AKI can be managed with nondialytic therapy alone or if KRT is necessary (see Chapter 75). Management of AKI in liver failure is discussed in Chapter 76.

General Management

Appropriate management requires timely diagnosis of the clinical condition. Considerable effort and investment have been directed in the search for a more sensitive and specific biomarker to diagnose AKI. Initial management of AKI includes assessment of the cause and volume status. Adequate hemodynamic status should be maintained to ensure kidney perfusion and avoid further kidney injury. In the injured kidney, autoregulation of blood flow, the mechanism responsible for maintaining a constant flow during fluctuations in BP, is lost. This loss increases the susceptibility to develop AKI after episodes of hypotension. Therefore, fluid and vasoactive drug management is needed in both patients at risk for AKI and with AKI. In patients with AKI attributed to dehydration only, it is expected that the serum creatinine decreases after the administration of 1 to 3 L of isotonic fluid over 24 to 48 hours, depending on the severity of the underlying condition. The optimal MAP is unknown and probably needs to be individualized according to age, hypertension status, and degree of peripheral artery and renovascular disease. Any potentially nephrotoxic agents should be avoided, including intravascular iodinated contrast. Gadolinium-based contrast agents are associated with the risk of developing nephrogenic systemic fibrosis (NSF) in patients with eGFR lower than 30 mL/min. The risk of NSF is higher with group I (linear) agents and lower with newer group II (cyclic) agents, such as gadobenate dimeglumine, gadobutrol, gadoteridol, and gadoterate meglumine. The risk with group III agents remains unknown. If gadolinium-based contrast agents need to be used in AKI, patients should be informed about the risk for nephrogenic systemic fibrosis, and group II agents should be preferred. The lowest dosage possible should be administered and repeated exposures avoided. Antimicrobial agents such as aminoglycosides, amphotericin, acyclovir, and pentamidine should be avoided whenever possible, or their dose should be adjusted to prevent further insult. Any medications associated with AKI also should be avoided if possible.

Fluid and Electrolyte Management

Although early and vigorous resuscitation with crystalloid solutions and aggressive infection control can reduce the incidence of AKI (see earlier discussion), the role of fluid resuscitation in established AKI not attributed to dehydration is less clear. Volume status is one of the most difficult parameters to assess, and fluid resuscitation should target a predefined preload, SV, or cardiac output rather than a set MAP. Nevertheless, many clinical studies have emphasized the limitations of static measures such as central venous pressure, right atrial pressure, and pulmonary artery occlusion pressure in predicting volume expansion efficacy. Other bedside indicators of preload, such as the right ventricular end-diastolic volume (evaluated by thermodilution) and the left ventricular end-diastolic area (measured by echocardiography), are ineffective in differentiating volume responder from nonresponder patients. As previously discussed, two techniques have an acceptable degree of clinical accuracy to determine fluid responsiveness: the passive leg raising maneuver and the fluid bolus test both coupled with real-time SV monitoring. In ICU patients receiving mechanical ventilation, respiratory changes in left ventricular SV also can predict fluid responsiveness. In hypovolemic patients, positive-pressure ventilation may induce a fall in the venous return and consequently in cardiac output. Based on the positive relationship between ventricular end-diastolic volume and SV, the expected hemodynamic response to volume expansion is an increase in right ventricular end-diastolic volume, left ventricular end-diastolic volume, SV, and cardiac output.

Volume expansion in ICU patients can frequently result in a relative increase in body weight of 10% to 15% or more, sometimes doubling the total body water in a short time. As previously highlighted, studies have demonstrated an association between fluid accumulation and mortality in AKI. A prospective multicenter observational study found that fluid overload at AKI diagnosis (defined as an increase in body weight of ≥10% relative to baseline) was independently associated with increased mortality.[7] The risk for death was proportional to the magnitude and duration of fluid accumulation. However, the effect of fluid overload on kidney recovery was inconsistent. A second analysis from the Fluids and Catheters Treatment Trial (FACTT) in AKI patients confirmed that in early AKI, positive fluid balance is strongly associated with mortality. The study showed a protective effect of furosemide on mortality, which disappeared after adjustment for fluid balance. Other studies have shown a deleterious effect of fluid overload on kidney function. In summary, results from observational studies suggest that a conservative fluid approach may be beneficial in terms of mortality and kidney recovery in patients with severe AKI. Fluid resuscitation should be performed rapidly if there is hypoperfusion and then ideally should be guided based on the aforementioned dynamic measures. After the initial resuscitation period, treatment should focus

on preventing further fluid overload, monitoring signs of fluid overload, and ensuring early removal of excess volume. However, RCTs are required to confirm these findings before any formal recommendation can be made. Of note, in the STARRT-AKI RCT comparing standard versus accelerated strategies for KRT initiation, even in the subgroup where fluid overload was more common in the standard compared with the accelerated group (6.7% of body weight vs. 3.1%), 90-day mortality was similar between groups.

Drugs to Promote Recovery From Acute Kidney Injury

See Table 74.2 for a summary of drugs used in treatment of AKI.

Loop Diuretics

Although loop diuretics are often prescribed in established AKI, a meta-analysis confirmed that they are not associated with reduced mortality or improved kidney recovery.[40] Other meta-analyses have shown that loop diuretics do not affect mortality, need for dialysis, or the number of dialysis sessions. Concomitant prescription of aminoglycosides and diuretics should be avoided because of an increased risk of ototoxicity. We suggest using diuretics to manage fluid overload as needed but not in attempts to speed recovery from AKI per se.

Natriuretics

Atrial natriuretic peptide (ANP) has been studied as a treatment for AKI in four RCTs. ANP was initially shown to reduce need for dialysis but not mortality. In the largest study published, ANP improved dialysis-free survival in the subgroup of oliguric patients only. Unfortunately, a subsequent trial including 222 oliguric patients did not confirm that ANP reduces mortality or dialysis-free survival.[41] A smaller, more recent study showed that ANP decreased the probability of dialysis and improved dialysis-free survival. Therefore, larger studies are required to confirm the benefits of ANP in AKI. Nesiritide, a β-type natriuretic peptide, has been studied to treat heart failure. Nesiritide induces vasodilation and an indirect increase in cardiac output but has no inotropic effects and neutral effect on heart rate. In addition, it inhibits adverse neurohormonal activation and can result in natriuresis and diuresis in some individuals. However, in a large RCT in patients with acute heart failure, this drug did not decrease mortality or rehospitalization rates and had a nonsignificant effect on dyspnea.[42] Nesiritide did not adversely affect kidney function, but it increased hypotension. Nesiritide also has been assessed in high-risk cardiovascular surgery, in which it reduced AKI rates in the immediate postoperative period but did not improve long-term survival. The KDIGO guideline does not support the use of ANP or nesiritide to treat AKI.

Vasoactive Agents: Vasopressors, Inotropes, and Vasodilators

Dopamine use to treat AKI is not recommended (see earlier discussion). Vasopressors often have been considered detrimental for organ perfusion. In septic shock, a small prospective study showed that norepinephrine improved serum creatinine and creatinine clearance when MAP was raised above 70 mm Hg. However, in another small RCT, increasing MAP from 65 to 85 mm Hg with norepinephrine did not

TABLE 74.2 Drugs Used in Treatment of Acute Kidney Injury

Drug	Level of Evidence	Results	Comments
Dopamine	RCTs	No effect on mortality or kidney function	
Fenoldopam	Small RCTs One meta-analysis	No effect on mortality or kidney function Beneficial effect on mortality and need for dialysis	Further studies required
Norepinephrine	Prospective observational studies	Possible beneficial effect on kidney function	Further studies required
Angiotensin II	Post hoc analysis from one RCT including patients with vasodilatory shock on dialysis	Decreased dialysis-dependence at 7 days	Further studies required; one RCT in hepatorenal syndrome (NCT04048707)
Loop diuretics	RCTs and meta-analyses	No effect on kidney function	
Atrial natriuretic peptide	RCTs	Possible beneficial effect on survival and kidney function	Further studies required
B-type natriuretic peptide	RCT in acute heart failure	No effect on kidney function	
Levosimendan	Meta-analysis in critically ill patients at risk or with AKI	Decreased need for dialysis	Ongoing phase 4 trial in cardiac surgery (LEVOAKI, NCT02531724)
Mesenchymal stem cells	Animal models and human studies	Beneficial effect on kidney function in animal models but no effect in one human RCT	Ongoing phase II studies (NCT04194671, NCT03015623). Study NCT03015623 showed that mesenchymal stem cells can trigger a phenotypic switch from tissue injury to repair, but the study was not powered for clinical efficacy.
Alkaline phosphatase	Small phase II RCT	No effect on kidney function in sepsis	Further studies required; ongoing phase III trial (NCT04411472)
CD28 receptor antagonist (AB 103 – Reltecimod)	Phase III RCT in necrotizing soft tissue infections	Improved organ dysfunction	Further studies required; ongoing phase II trial in peritonitis or necrotizing soft tissue infections (NCT03403751)
Hepatocyte growth factor (HGF)-like peptide (ANG-3777)			Phase III trial in kidney transplants with delayed graft function (NCT02474667)

AKI, Acute kidney injury; *RCT,* randomized controlled trial.

improve kidney function. No studies have compared the effect of different target MAPs to treat AKI.

A posthoc analysis of the ATHOS-3 data found that septic patients with AKI requiring dialysis who received angiotensin II were more likely to be dialysis-free at 7 days compared with placebo.[43] Confirmation of these results in large prospective studies is needed.

In a meta-analysis, fenoldopam decreased the need for dialysis (7% vs. 10%) and in-hospital mortality (15% vs. 19%) in postoperative or ICU patients.[28] Several limitations were present in this meta-analysis, such as absence of an independent measure of GFR and standardized criteria for initiation of dialysis, heterogeneity of populations, AKI definitions, dosage, and duration of treatments. In addition, fenoldopam has hypotensive properties and may be more dangerous in real-world patients than in selected trial participants. No individual trial has shown that fenoldopam can reduce the need for dialysis. The results of the meta-analysis should be confirmed with an adequately powered trial, and like the KDIGO guideline, we do not suggest using fenoldopam to treat AKI.

One small RCT is currently assessing the effect of levosimendan on kidney outcomes after cardiac surgery in patients with AKI (LEVOAKI, NCT02531724).

Specific therapy for patients with the hepatorenal syndrome includes the use of terlipressin in combination with octreotide (see Chapter 76). In countries such as the United States, where terlipressin is not available, a combination of midodrine, octreotide, and albumin infusions is often used. Norepinephrine also has been used in these settings with good response equivalent to that of terlipressin. One trial will test the efficacy of angiotensin II in hepatorenal syndrome (ANTHEM Trial, NCT04048707).

Tubular Repair Agents

Other agents have been studied for treatment of established AKI. ANG-3777, a hepatocyte growth factor (HGF)-like peptide, is evaluated in a phase III trial in kidney transplants having delayed graft function aiming to activate HGF-related repair pathways. One promising therapy is MSCs. MSCs are multipotent cells with anti-inflammatory and immunomodulatory properties proven to be beneficial in animal models of myocardial ischemia, sepsis, and AKI. In animal models, infusion of MSCs improved recovery of kidney function in cisplatin-induced ischemia/reperfusion injury and glycerol-induced AKI. A dose-escalating phase I clinical trial was conducted to test the safety and preliminary efficacy of MSCs in patients at high risk for AKI.[39] An experimental study using a model of progressive mesangioproliferative nephritis evaluated the long-term effects of intrakidney, syngeneic MSC transplantation. Although rats in the MSC-treated group had lower proteinuria and better kidney function on day 60, 20% of the glomeruli of MSC-treated rats contained single or clusters of large adipocytes with pronounced surrounding fibrosis. Therefore, the MSC benefit of maintaining kidney function in the short term needs to be balanced with a possible long-term effect of partial maldifferentiation of intraglomerular MSC into adipocytes and subsequent glomerular sclerosis. There are ongoing studies on the use of MSC to improve AKI outcomes (NCT04194671, NCT03015623). However, in a phase II trial of patients with cardiac surgery, no benefit from MSCs, administered into the aorta at the time of surgery, could be demonstrated.[43a]

Antiinflammatory Agents

In severe sepsis and septic shock, a small study has shown that the infusion of alkaline phosphatase, an enzyme expressed along the brush border of the proximal tubule, improves kidney function, possibly through reduced kidney inflammation. A phase II study assessing the effect of recombinant alkaline phosphatase in septic patients with AKI failed to show an improvement in 7-day kidney function.[44] However, there were dose-dependent signals of beneficial effects on kidney function and mortality, prompting a phase III RCT (NCT04411472).

In a phase III RCT including critically ill patients with necrotizing soft tissue infections, reltecimod, a CD28 receptor antagonist, improved resolution of organ dysfunction/failure by day 14.[45] This agent was designed to help control the cytokine storm, by modulating rather than inhibiting acute inflammation. A phase II including patients with peritonitis or necrotizing soft tissue infections is currently underway to determine whether this drug can improve kidney recovery (NCT03403751).

Summary

Dehydration, hypotension, and infections should be rapidly treated. Any potentially nephrotoxic agents should be avoided, including intravascular iodinated contrast. Gadolinium-based contrast agents should also be avoided. Fluid overload should be minimized and eventually corrected once the patient's clinical condition permits. No agent has been clearly shown to facilitate kidney recovery. Several studies are ongoing to test the efficacy of new drugs to treat AKI in specific conditions.

TREATMENT OF ACUTE KIDNEY INJURY COMPLICATIONS

Fluid Overload

When fluid overload occurs in AKI, all intakes should be minimized and medical treatment should be attempted before dialysis initiation. In patients with positive fluid balance with large fluid intake and inadequate urine output and in those presenting with symptomatic volume overload, a loop diuretic can be initiated with measures to optimize systemic and kidney perfusion. IV bolus doses of diuretics may be necessary to optimize the response, especially in patients with heart failure and nephrotic syndrome. If there is a response to an IV bolus, continuous infusion can be considered because it is less ototoxic. When starting or increasing the dose of a continuous infusion, a bolus should be administered before. Natriuretic peptides inhibit sodium reabsorption in the nephron, resulting in net sodium excretion. There is currently no evidence to support the use of natriuretic peptides as an adjunctive treatment in AKI.

Morphine and nitrates can be used to alleviate the respiratory symptoms of pulmonary edema in urgent situations. Morphine can be administered intravenously at an initial dose of 2 to 4 mg over a 3-minute period and repeated at 5- to 15-minute intervals as needed. Nitrates are also commonly used. Nitroglycerin reduces left ventricular filling pressure through venodilation; an initial dose of 5 μg of IV nitroglycerin per minute can be used. When fluid overload cannot be rapidly treated with medical management, positive-pressure ventilation may be initiated with or without endotracheal intubation and dialysis, depending on the clinical situation.

Potassium Disorders

Hyperkalemia, covered in detail in Chapter 10, is a frequent complication of AKI that may affect cardiac conduction and lead to bradycardia or even asystole. If electrocardiographic changes are present, IV administration of calcium is urgently needed. Sources of potassium should be removed, including drugs with effect on potassium handling, such as

β-adrenergic antagonists, potassium-sparing diuretics, ACE inhibitors, and ARBs.

The next step is to enhance the shift of potassium to the intracellular space by parenteral glucose and insulin infusions. Sodium bicarbonate also promotes shift of potassium and is most efficient when there is concomitant metabolic acidosis. It can be started if there is no concern regarding fluid overload. β-Adrenergic agonists given as aerosols are effective at very high doses but more likely to produce side effects and therefore are rarely prescribed to treat hyperkalemia.

Potassium excretion should be increased by the administration of saline, loop diuretics, and cation exchange resins such as sodium polystyrene sulfonate or calcium resins. The resins can be administered orally or rectally as a retention enema and are usually not effective after a single dose only. There is concern that coadministration of sorbitol with sodium polystyrene sulfonate may promote intestinal necrosis. Sodium polystyrene sulfonate should be avoided postoperatively until normal bowel function resumes and in patients with bowel obstruction or ileus. Newer agents, such as sodium zirconium cyclosilicate (SZC) and patiromer, have shown reductions in potassium levels within hours of administration. SZC has been effective in normalizing average potassium levels of 5.5 mmol/L (range, 5.1–7.3) in 82% of subjects within 24 hours, and in 96% within 48 hours.[46] If hyperkalemia is unresponsive to conservative measures, emergency HD is the treatment of choice. If HD is unavailable, continuous KRT can be used with higher volumes of replacement solution and/or dialysate and low or no potassium content. Because KRT initiation usually takes a few hours, medical management always should be used pending initiation of dialysis. Monitoring of potassium levels should continue after conservative or dialytic management to prevent and treat rebound hyperkalemia.

Sodium Disorders

Hyponatremia can occur as a result of relative impairment in free water excretion and is more common in AKI associated with heart failure, liver failure, or diuretics. In these settings, water restriction to below the level of output is mandatory. Sodium restriction is usually necessary to treat fluid overload and edema. In patients with true volume depletion and prerenal AKI, isotonic saline needs to be administered to correct both disorders.

In patients with AKI and hypernatremia, treatment of the cause is necessary and water deficit should be estimated. Water should be administered orally or intravenously as dextrose in water to correct serum sodium concentration at a maximum rate of 12 mmol/L/day. Dialysis and continuous KRT may be required to optimally correct sodium disorders in AKI.

Calcium, Phosphorus, and Magnesium Disorders

Hyperphosphatemia and hypocalcemia are common in AKI. Hyperphosphatemia is usually caused by reduced excretion by the kidneys, and continuous release from rhabdomyolysis or TLS also can be contributive (see Chapters 11 and 70). As phosphorus levels increase, calcium levels decrease, resulting in hypocalcemia. Total calcium levels usually drop to 7 to 8 mg/dL (1.75–2.0 mmol/L). Other causes of hypocalcemia in AKI are skeletal resistance to parathyroid hormone (PTH) and low calcitriol production. Hypocalcemia is aggravated when bicarbonate is administered to correct acidosis. A high-calcium, high-phosphorus product could theoretically trigger tissue calcium deposition, which can cause cardiac arrhythmia. No RCT has evaluated the benefits of treating these disorders. However, because hyperphosphatemia caused by oral phosphorus-containing medications and TLS can cause AKI, severe hyperphosphatemia should be avoided to prevent further damage. Calcium-based phosphate binders and other phosphate binders can be used in this setting. If there is symptomatic hypocalcemia or hemodynamic instability, calcium gluconate infusion should be administered.

Hypercalcemia is rare in AKI and is usually seen in the recovery phase of rhabdomyolysis when calcium is released from calcium-containing complexes in muscle (see Chapters 11 and 70). In addition, when production of calcitriol is reestablished by the recovering kidney, an enhanced responsiveness to PTH can be seen. Hypercalcemia in this setting is rarely problematic and can be easily treated with medical management. Mild hypermagnesemia is frequent in AKI and usually does not have clinical consequences.

Acid-Base Disorders

In AKI, normal anion gap metabolic acidosis is the most common acid-base abnormality (see Chapter 13) because of reduced regeneration of bicarbonate and failure to excrete ammonium ions. Accumulation of phosphate and unexcreted unmeasured anions, such as sulfate, urate, hippurate, hydroxypropionate, furanpropionate, and oxalate, is contributory. Hypoalbuminemia can attenuate this acidification process, and it is exacerbated by lactic acidosis. Despite retention of unmeasured anions, the anion gap remains within normal in 50% of patients. Although metabolic acidosis is frequent, triple acid-base disturbances also can occur. The approach to acid-base disturbances in AKI needs to be adjusted according to the underlying causes.

When metabolic acidosis is a complication of AKI, sodium bicarbonate can be administered if the serum bicarbonate concentrations fall below 15 to 18 mmol/L. In stable patients, oral sodium bicarbonate may be given because volume overload can occur after the administration of IV bicarbonate. The administration of bicarbonate in shock with lactic acidosis is controversial, given the possibility of an increase in carbon dioxide generation, worsening of the intracellular acidosis, and volume overload. In addition, bicarbonate therapy may reduce calcium and potassium levels. However, the recent BICAR-ICU trial has shown that in critically ill patients with AKI stage 2 or higher and lactic acidosis with pH less than 7.2, bicarbonate administration may prevent the need for dialysis and improve survival.[47] Alternative forms of base treatment such as tris(hydroxymethyl)aminomethane (THAM) are not recommended in patients with AKI because THAM can cause hyperkalemia. Restriction of protein intake also has been suggested as a method of acidosis control because protein breakdown has been associated with worsening acidosis, as in CKD. However, protein restriction is not recommended in AKI.

Nutrition

Patients with AKI have an increased risk for protein-energy malnutrition because of poor nutrient intake and high catabolic rate. Nutritional assessment is difficult, especially in AKI patients with high metabolic demands. Subjective global assessment evaluates nutritional status, requires no additional laboratory testing, and is highly predictive of outcome.

Patients with AKI should receive a basic intake of 0.8 to 1.0 g of protein/kg/day if not catabolic and a total energy intake of 20 to 30 kcal/kg/day, as recommended in the KDIGO guidelines. In addition, in patients on KRT, 1.0 to 1.5 g of protein/kg/day should be administered up to 1.7 g/kg/day in continuous KRT and hypercatabolic patients. The enteral route should be favored if the gastrointestinal tract is functioning; parenteral nutrition should be prescribed only when the gastrointestinal tract cannot be used or when the enteral route is inadequate to reach nutrient intake goals.

SELF-ASSESSMENT QUESTIONS

1. In a general population of critically ill patients, administering starches has proven to be:
   - **A.** beneficial for kidney function (decrease in need for KRT).
   - **B.** beneficial for hypotension.
   - **C.** detrimental for kidney function (increase in need for KRT).
   - **D.** detrimental for hypotension.
2. Which of the following drugs should be stopped, if feasible, 48 hours before iodinated contrast administration in patients with chronic kidney disease and a glomerular filtration rate below 45 mL/min/1.73 m^2?
   - **A.** Furosemide
   - **B.** Metformin
   - **C.** NSAIDs
   - **D.** Thiazide diuretics
   - **E.** All the above
3. The measures to prevent AKI in patients with traumatic rhabdomyolysis include all of these statements *except:*
   - **A.** Urine output should be maintained around 300 mL/h until CK levels are lower than 1000 U/L.
   - **B.** Urine output should be maintained around 300 mL/h until myoglobinuria disappears.
   - **C.** Mannitol may be beneficial because of diuretic, antioxidant, and vasodilatory properties.
   - **D.** Mannitol can prevent kidney tubular cast deposition, expand extracellular volume, and reduce intracompartmental pressure, muscle edema, and pain.
   - **E.** Monitoring of ionized calcium is important to avoid $NaHCO_3$-induced hypocalcemia (as a result of metabolic alkalosis).
4. Regarding fluid administration for critically ill patients at risk for AKI, all the following statements are true *except:*
   - **A.** Chloride-restrictive fluids (lactated solution, Plasma-Lyte 148, or chloride-poor 20% albumin) seem preferable to chloride-rich intravenous fluids (0.9% saline, 4% succinylated gelatin solution, or 4% albumin solution), although further studies are needed and ongoing.
   - **B.** Volume expansion should be maintained after major vascular surgeries unless patients develop evidence of pulmonary congestion.
   - **C.** Guidelines on sepsis management mention that septic patients should receive initial fluid resuscitation with crystalloids at a minimum of 30 mL/kg.
   - **D.** Intravenous administration of albumin can be considered in patients with sepsis who require substantial amounts of crystalloid to maintain adequate mean arterial pressure.
   - **E.** Fluid expansion should be stopped when patients are no longer fluid responsive.

Extracorporeal Therapies for Acute Kidney Injury and Heart Failure

Mark Marshall, Nithin Karakala, Luis A. Juncos

Acute kidney injury (AKI) is a common complication of critically ill patients and is most commonly caused by sepsis, hypoperfusion, congestive heart failure, liver failure, or nephrotoxins. AKI is associated with increased morbidity, length of stay, health care costs, and adverse clinical outcomes, including death, development/progression of chronic kidney disease (CKD), and end-stage kidney disease (ESKD). Furthermore, AKI affects distant organs (e.g., heart, lungs, brain, and liver), contributing to their dysfunction during critical illness. Therefore, much effort is aimed at preventing its development and progression. Despite this, approximately 5% to 10% of patients will ultimately require kidney replacement therapy (KRT).[1] This chapter reviews best practices for providing KRT in critically ill patients and those with advanced heart failure (Box 75.1).

ESSENTIALS OF ACUTE KIDNEY REPLACEMENT THERAPY

Mechanisms of Water and Solute Transport

There are four mechanisms by which water and solute are removed with extracorporeal blood purification techniques. Fluid transport across semipermeable membranes is driven by ultrafiltration (UF), whereas solute transport occurs via convection, diffusion, and adsorption (Fig. 75.1A). These mechanisms are used by the blood purification techniques described in this chapter (Fig. 75.2). The necessary formulas for calculating essential functions are presented in Table 75.1.

Ultrafiltration and Convection

UF is the process by which plasma water is pushed through a semipermeable membrane, driven by a hydrostatic pressure gradient. Its rate, Q_{UF}, is determined by the transmembrane pressure (TMP) and the filter's UF coefficient (DK_{UF}, the product of the membrane's K_{UF} and its surface area).[2] In KRT, the TMP is the pressure gradient between the blood and effluent compartments; it is generated by the blood pump (causing a positive blood compartment pressure) and the effluent pump, which maintains the desired Q_{UF}. The TMP necessary to maintain a determined Q_{UF} increases over time because the membrane gets coated with macromolecules (creating a secondary membrane), decreasing its permeability. When UF is prescribed as a stand-alone procedure, it is called isolated UF or slow continuous UF (SCUF),[3] depending on the technique. An additional mechanism generating UF is by osmotic gradients, which is a key mechanism of volume removal during peritoneal dialysis (PD), but it is of limited significance in KRT.

UF also results in solute clearance via solvent drag (convection). Because convection drags any solute that fits through the pores across the membrane, it allows for small- and medium-solute transport. The convective flux of a solute depends on the Q_{UF}, the membrane surface area, the solute concentration in plasma, and its sieving coefficient.[2] Solute clearance is limited in isolated UF because progressive volume depletion limits the amount of attainable UF. This complication is avoided by administering replacement fluids at sufficient quantities to allow for the desired Q_{UF}, and consequently solute clearance, a process referred to as *hemofiltration*. The quantity of replacement fluid to be infused equals the total UF volume (UF_{Total}) minus the volume needed to achieve the desired negative balance in the patient, resulting in a net UF (UF_{NET}, or net volume removed from the patient). From a clearance perspective, the fluid is ideally replaced postfilter (postdilution). However, higher Q_{UF} rates lead to hemoconcentration in the filter, which increases the blood viscosity and facilitates premature clotting of the filter. Thus, the filtration fraction should not exceed 30%.[4] This problem is ameliorated by increasing blood flow rate (Q_b) or administering some or all of the replacement fluid prefilter, thus diluting the blood before it reaches the filter (predilution). The disadvantage of predilution is that it lowers the concentration of the uremic solutes in the blood reaching the hemofilter, thus decreasing net clearance.[5,6] The magnitude of the decreased clearance varies depending on the Q_b and replacement fluid rate (Q_r).

Diffusion

Diffusion is the net movement of solutes from a region of higher concentration to one of lower concentration. In KRT, the concentration gradient across the filter membrane is created by running dialysate in the effluent compartment. The diffusive flux follows Fick's law of diffusion[7]; it is proportional to the diffusion coefficient of the solute (as approximated using Stokes-Einstein equation) and inversely proportional to the distance between the compartments (membrane thickness and permeability also add resistance). Because the diffusivity coefficient is inversely proportional to a molecule's radius,[2] this mechanism results in very efficient transport of the fast-moving small solutes, but inefficient transport of the slower-moving larger solutes, even those small enough to fit through the filter pore. Other factors that influence solute clearance include its protein binding and electrical charge. The differences in solute clearance between diffusion and convection are depicted in Fig. 75.1B.

Adsorption

Adsorption is the process that refers to the binding of blood components to the membrane, and is determined by the specific characteristics of each molecule (i.e., dimension, charge, and structure) and each membrane (i.e., porosity, composition, hydrophobicity, surface potential).[2] It was originally thought that adsorption may contribute substantially to overall clearance of certain substances during KRT. However, the rapid saturation of the membrane binding sites limits its effectiveness. Consequently, specialized adsorption cartridges with higher affinity and capacity for targeted substance have been developed. Their clinical effectiveness remains unproven.

Who, When, and How of Acute Kidney Replacement Therapy

Initiating Kidney Replacement Therapy

Classic indications for starting KRT include volume overload, metabolic acidosis, or hyperkalemia refractory to medical management, and overt uremia. However, specific thresholds for these indications are empiric and subject to individual preference. Many have argued for early initiation to prevent, rather than treat these complications. Indeed, KRT is commonly initiated to prior to the development of life-threatening complications. This approach has been supported by early observational studies that found a strong association between the severity of volume overload and mortality.[8-10] However, a causal relationship is not proven, and it remains unknown whether removal of excessive fluid improves outcomes. Any potential benefits of early initiation must be balanced with the potential harmful complications of KRT, including catheter-related infection, hypotension, electrolyte disturbances, suboptimal dosing of antibiotics, nutrition, and so forth.

Recent randomized controlled trials (RCT) have addressed the question of early versus late initiation of KRT (Table 75.2).[11-16] Five used Kidney Diseases Improving Global Outcomes (KDIGO) criteria to determine the severity of AKI.[11-15] Of these, one found that starting very early (within 8 hours of KDIGO stage 2 AKI) was associated with better survival.[11] However, this was a single center study of mainly cardiac surgical patients and had a fragility index of 3 (a measure of the robustness or fragility of the results of a clinical trial), thus limiting its external validity. Three of the remaining five studies were multicenter RCTs and had a more representative mix of AKI[12-14]; they found no difference in outcomes between early and late start. Because of the lack of benefit in starting early, the AKIKI 2 (Artificial Kidney Initiation in Kidney Injury 2) study examined whether there was any benefit in implementing an even more delayed strategy; they compared a delayed versus very delayed initiation strategy.[15] Although crude mortality was not different between groups, a prespecified multivariate analysis indicated a higher 60-day mortality in the very delayed group. It is important to note that 38% to 50% of patients randomized to the late start groups in the 3 multicenter RCTs never required KRT. This not only suggests that many patients in the early start group would not have required KRT, but also that our ability to predict who will ultimately require KRT is suboptimal. This highlights the need to identify markers that better predict who will require KRT and then establish its optimal timing.

The furosemide stress test* trial was a pilot study that examined this question; they only randomized patients nonresponsive to the furosemide stress test, thus enriching the study population with those patients most likely to require KRT.[15] In this study, 75% of the late patients required KRT, but there was no difference in outcomes between early and late initiation of KRT. The overall evidence obtained from these trials suggests that routinely starting KRT early is not beneficial. However, waiting for absolute indications before considering KRT is also not appropriate and creates logistical challenges. Hence, KRT should be initiated if the burden of fluid and solute derangements is increasing and anticipated to result in complications, remembering that patients with certain illnesses, such as heart and lung disease, may have less tolerance to these homeostatic derangements. A systematic approach to initiating KRT, derived from existing guidelines, is presented in Fig. 75.2.[17]

Therapeutic Goals

When preparing the dialysis prescription in acutely ill patients, one should first clearly delineate the goals of therapy and then tailor the prescription to achieve these goals. That is, the prescription should be individualized to the patient. Therapeutic goals for KRT are divided into (1) physiologic targets, (2) dose of KRT delivered, and (3) volume status goals. These goals should be achieved without exacerbating hemodynamic instability, increasing end organ damage, or delaying kidney recovery. *Physiologic targets* refer to the correction of the metabolic abnormalities. In general, ensuring delivery of an adequate dose (see later) is sufficient to normalize most metabolic derangements. However, there are circumstances that may require adjustments of doses and solutions to achieve the desired electrolyte homeostasis (e.g., severe rhabdomyolysis) or clearance of a specific toxin, as may occur during intoxications or severe hyperammonemia (e.g., in infants with inborn errors of urea metabolism, or occasionally postlung transplant patients).† Of note, continuous KRT (CKRT) is not an effective therapy for lactic acidosis (hepatic clearance is 10- to 100-fold greater).[18] The only effective treatment is to address the cause of the lactic acidosis (e.g., improving tissue

*The furosemide stress test consists of giving 1 mg/kg intravenous bolus (1.5 mg/kg in patients who are chronically on a loop diuretic). Urine output is then monitored for 2 hours. A urine output of less than 200 mL is considered nonresponsive and predicts progression to renal replacement therapy with an area under the curve of approximately 0.87.

†The use of kidney replacement therapy for this indication has not been established.

Strategies for the optimal timing to start renal replacement therapy in critically ill patients with acute kidney injury. *Kidney Int.* 2017;91[5]:1022–1032.)

oxygenation, removing dead gut). Finally, standard modalities are not effective at clearing inflammatory cytokines in a sustained manner and have not been shown to improve clinical outcomes.[19,20] Thus, cytokine clearance should not be a therapeutic goal of KRT.

The *dose of KRT delivered* should at minimum meet the available evidence-based targets for each modality. In intermittent kidney replacement therapy (IKRT) and prolonged intermittent kidney replacement therapy (PIKRT), adequacy is measured as small solute clearance. The lower limit for intermittent hemodialysis (IHD) is a delivered single-pool Kt/V (spKt/V) of 1.0 per session, because doses below this were associated with decreased survival in patients with intermediate severity of illness.[21] The VA/NIH ATN study (which permitted switching of KRT modality, depending on the Sequential Organ Failure Assessment [SOFA] cardiovascular score) showed that increasing the delivery of an spKt/V of 1.2 or more, from three to six times weekly, did not provide additional benefit.[22] Subsequently, the minimum delivered spKt/V when using IKRT in patients with AKI was recommended to be 1.3 or more per session thrice weekly.[23] However, because solute clearance is commonly decreased in the acutely ill patient, the spKt/V target is frequently not achieved with standard dialysis prescriptions. Indeed, the ATN study found that delivered spKt/V was approximately 1.1 after the first treatment and the prescribed dialysis time had to be increased to approximately 4 hours. Thus, to avoid underdelivery of IKRT, measurements of the delivered dose should be undertaken and the IKRT prescription adjusted accordingly (Box 75.2). Another way of expressing urea clearance is as continuous small-solute clearance (corrected equivalent renal urea clearance [EKRc]), which kinetically quantifies the "time-averaged KT." It is particularly useful for PIKRT because EKRc is independent of treatment type and schedule. The Hannover Dialysis Outcome Study of PIKRT found that patients treated with PIKRT to achieve an EKRc of 20 mL/min (plasma urea level = 11.3 ± 4 mmol/L) had outcomes indistinguishable from those in which the EKRc was 13 mL/min (plasma urea levels = 19 ± 6 mmol/L).[24] Note that the lower EKRc dose (13 mL/min) in this study was equivalent to a spKt/V of 1.2 to 1.4 per treatment three times weekly. Thus, the recommended EKRc target is a value of 13 mL/min or higher.[25,26] The nomogram in Fig. 75.3[27] expresses the EKRc at distinct combinations of HD dose and frequency, thus providing a comparison between IKRT and PIKRT dosing.

TABLE 75.1 Essential Formulas Used in Kidney Replacement Therapies

Parameter	Formula	Definitions
Transmembrane pressure (TMP)	$TMP = \frac{(PF + P_r)}{2} - P_e$	P_F = Prefilter pressure P_r = Return pressure P_e = Effluent pressure
Membrane ultrafiltration coefficient (K_{UF})	$K_{UF} = \frac{Q_{UF}}{TMP} \times \frac{1}{A}$	Q_{UF} = Ultrafiltration flow rate A = Membrane surface area
Filter ultrafiltration coefficient (DK_{UF})	$DK_{UF} = K_{UF} \times A$	
Ultrafiltration rate (Q_{UF})	$Q_{UF} = DK_{UF} \times TMP$	
Sieving coefficient (SC)	$SC = \frac{CUF}{(Cpi + Cpo)/2}$	C_{UF} = Solute concentration in UF C_{pi} = Plasma solute concentrations at the inlet C_{po} = Plasma solute concentrations at the outlet
Filtration fraction (FF)	$FF = \frac{QUF}{Q_p}$	Q_p = Plasma flow rate
Convective flux (J_c)	$J_c = \frac{QUF^o}{A} \times Cpi \times SC$	
Solute diffusive flux (J_d)	$Jd = -D\left(\frac{dc}{dx}\right)$	D = Diffusivity coefficientdc = Concentration gradient (dc = C1 – C2) dx = Distance between compartments
Diffusivity coefficient (D)	$D = \frac{kBT}{6\pi\mu R}$	kB = Boltzmann constant T = Absolute temperature μ = Viscosity of the medium R = Effective radius of the molecules
Rejection coefficient	$RC = 1 - SC$	
CVVH postdilution	$K = Q_{UF}\ SC \times 60/\text{body weight}$	
CVVH predilution	$K = Q_{UF} \times SC \times / [Q_{BW}\ (Q_{BW} + Q)] \times 60/\text{body weight}$	Q_{BW} = Blood water flow rate Q_R = Replacement fluid rate
CVVHD	$K = Q_d + S_d$	Q_d = Dialysate rate Sd = Saturation coefficient
CVVHDF	$K = (Q_{UF} + Q_d) \times S_d$	

CVVH, Continuous venovenous hemofiltration; *CVVHD,* continuous venovenous hemodialysis; *CVVHDF,* continuous venovenous hemodiafiltration.

In CKRT the clearance of urea and other small solutes is proportional to the total effluent flow (the sum of the dialysate and Q_{UF}; Fig. 75.4).[28] CKRT dose is thus expressed as effluent volume flow rate per unit of premorbid or pre–intensive care unit (ICU) weight (mL/kg/h). Several early small studies suggested that increasing the CKRT dose from 20 mL/kg/h to more than 35 mL/kg/h may increase survival.[29,30] However, these findings were not replicated in 2 large RCTs. The first, the VA/NIH ATN trial,[22] utilized IKRT and CKRT as mentioned before, whereas the second, the Randomised Evaluation of Normal versus Augmented Level (RENAL) Replacement Therapy,[31] only used CKRT. Based on these studies, there appears to be a dose of CKRT (20–25 mL/kg/h) above which survival becomes dose independent, and thus routine use of higher doses is not warranted. Although a lower dosing limit has not been established, 20 to 25 mL/kg/h is accepted because this was the lowest dose tested in the trials. In clinical practice, interruptions to CKRT due to diagnostic or therapeutic procedures often compromise the dose delivered, thus it is recommended to prescribe 25 to 30 mL/kg/h to ensure adequate dose delivery.

Fluid management is the other essential therapeutic target. Some patients present with fluid overload and simply need its removal. However, fluid management is usually more complex in critically ill patients. Initially, they often require volume resuscitation due to leaky capillaries and hemodynamic compromise. However, care should be given to avoid overzealous fluid administration because it leads to volume overload, increasing the risk for intraabdominal hypertension, poor wound healing, and impairment of oxygenation; indeed, it is associated with increased mortality.[8-10] The resuscitation phase is followed by optimization and de-escalation phases where smaller adjustments are made and fluid may need to be removed. Thus, fluid management is a dynamic process that requires frequent assessment of volume status and targets.

The assessment of volume status is difficult because physical signs are generally not informative and surrogates of cardiac filling (e.g., by central venous filling pressures, cardiac or vena cava dimensions) may be inaccurate in critically ill patients. An alternative approach is to test the effect of therapeutic maneuvers, such as fluid challenge on measures of cardiac filling, stroke volume, and blood pressure. Even after fluid status has been assessed, determining the correct therapeutic goal is difficult and optimal strategies to achieve that goal are uncertain. KRT removes fluid from the intravascular compartment, and thus depends on adequate refilling from the interstitial compartment to maintain adequate hemodynamics. Consequently, close monitoring of hemodynamics is needed and UF targets individualized so that adequate cardiopulmonary and extracellular volume status is achieved while avoiding hypotension. Observational studies have shown that fluid accumulation of greater than 10% of body weight ([(Total input − Total output)/Patient body weight] × 100%) is associated with poor outcomes; thus maintaining it below this threshold should be considered.[32] However, this approach needs to be tested in prospective clinical trials.

ACUTE KIDNEY REPLACEMENT THERAPY MODALITIES

The main modalities of KRT are IKRT, PIKRT, CKRT and PD. Within each one of these modalities there are variations according to the mechanism of clearance, access, and duration (Table 75.3). The choice of modality is largely based on institutional (preference, expertise, and available resources) and patient factors (hemodynamic stability, comorbidities), as several RCTs did not suggest an overall superiority of one modality over another.[33-34] It has also been proposed that patients who are hemodynamically unstable have better organ recovery if they are treated with PIKRT or CKRT.[35,36] However, appropriately powered RCTs have not been designed to test this directly, thus it remains speculative.

However, this does not mean that the modalities are clinically equivalent. For instance, patients on IKRT often require prolonging their therapy time or switching to CKRT because of progressive hemodynamic instability, poor metabolic control, or inability to meet their UF targets.[22,33,34] We consider the different modalities to be complementary therapies with distinct strengths and weaknesses; thus, the choice of modality should be based on clinical context. Indeed, most will transition between modalities as their clinical status changes. For most, the modality choice still depends primarily on the desired rate of solute and fluid removal[23] and on hemodynamic parameters.[37] In addition, there are specific scenarios in which a particular modality may be preferred. For instance, IKRT is the preferred treatment when rapid clearance is desired (e.g., intoxications), whereas PIKRT and CKRT are more desirable when solute disequilibrium should be minimized to avoid water influx into tissues (e.g., patients at risk for dialysis disequilibrium, including those with increased intracranial pressure or abdominal compartment syndrome).[38] PD is provided in a similar manner to ESKD patients. The spectrum of dialytic modalities used in acutely ill patients and their general characteristics are listed in Fig. 75.5.

Economic factors may also play a role, as CKRT can be more expensive. However, economic considerations vary widely between different

programs because of differences in nursing structures, quality of CKRT delivery, and other associated factors.[39] Thus, economic evaluations comparing modalities needs to be conducted locally, with careful consideration of underlying assumptions about costs and outcomes.

BOX 75.2 Measures to Increase Intermittent Hemodialysis Dose

- Maximize hemodialyzer surface area (up to 2–2.2 m^2)
- Maximize hemodialyzer porosity (high flux)
- Maximize blood flow rate
  - Maximize internal lumen diameters of hemodialysis catheter
  - Optimize blood flow
  - Ensure positioning of the hemodialysis catheter tip at the caval atrial junction and IVC as appropriate
  - Use right internal jugular vein approach, particularly in patients with a BMI of ≥27 kg/m^2
- Minimize access recirculation
  - Ensure positioning of the hemodialysis catheter tip at the caval atrial junction or IVC as appropriate
- Maximize dialysate flow rate
- Add postdilution replacement fluid to increase convective clearance (hemodiafiltration)
- Optimize anticoagulation to reduce hemodialyzer fiber bundle clotting
- Increase treatment frequency (up to daily)
- Increased treatment duration and/or consider PIKRT or CKRT
- Optimize patient's hemodynamics to reduce compartmental urea sequestration

BMI, Body mass index; *CKRT,* continuous kidney replacement therapy; *IVC,* inferior vena cava; *PIKRT,* prolonged intermittent kidney replacement therapy.

Intermittent Kidney Replacement Therapy

IKRT, most frequently performed as IHD, makes use of the equipment, methods, and nursing staff established for chronic hemodialysis (HD). It provides rapid solute clearance and UF during relatively brief (3–5 hour) treatments. To achieve this, the Q_b and Q_d are set at relatively rapid rates (Q_b is commonly 300–500 mL/min and Qd 300–800 mL/h). The dialysate can be delivered by either a batch or single-pass system. Water purity is important to avoid back-filtration of bacterial contaminants and other impurities, which can be detrimental to the patient (see Chapter 99). Reference standards for water purity in the ICU setting are the same as those for the ESKD setting. IKRT is the modality that removes solutes the fastest, thus decreasing the time a patient is exposed to the extracorporeal circuit. In IHD, small solutes are removed very quickly, making it an ideal therapy for conditions such as life-threatening hyperkalemia and intoxications. A theoretical disadvantage of IHD is that middle and larger molecules are not removed efficiently because the main mechanism of clearance is via diffusion. However, this can be improved by adding a component of convection, where Q_{UF} is tailored to the desired clearance and replacement fluid delivered to achieve the desired fluid balance (hemodiafiltration [HDF]). The replacement fluid should be sterile and can be the same as those used during CKRT, or generated online as ultrapure dialysate (sterilized via ultrafilters) and infused directly into the extracorporeal blood circuit. Some suggest sterile dialysate for all acute IHD; however, data are insufficient to support a strong recommendation. Finally, high-flux membranes have also been used to provide greater convective removal of middle molecules. Despite the rationale for increasing middle molecule clearance, there is no evidence suggesting improved outcomes.

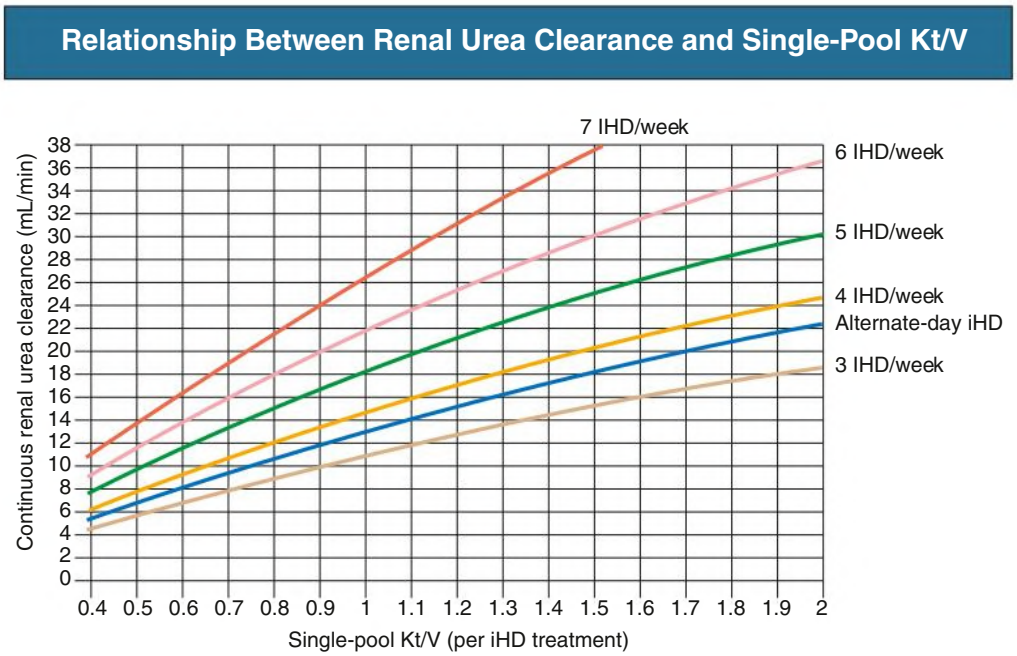

Fig. 75.3 Relationship between corrected continuous kidney urea clearance and single-pool Kt/V (weekly urea clearance/volume of distribution of urea) per treatment for a frequency of three to seven treatments per week. *IHD,* Intermittent hemodialysis. (From Casino F, Lopez T. The equivalent renal urea clearance: a new parameter to assess dialysis. *Nephrol Dial Transplant.* 1996;11:1574–1581.)

Strategies to Reduce Intradialytic Hemodynamic Instability During Intermittent Kidney Replacement Therapy

The consequences of dialysis-related hypotension are not well studied in the critically ill AKI population but may be detrimental to kidney recovery and end organ function. Indeed, the injured kidney is prone to hypoperfusion due to its impaired autoregulatory responses. Moreover, IKRT can precipitate myocardial stunning, a phenomenon reported in patients with AKI (even treated with CKRT), which in turn may further impair kidney perfusion and impair kidney recovery.[40] Axiomatically, the most effective measure to improve hemodynamically stability is increasing the frequency and treatment time, thereby decreasing rates of fluid and solute removal (optimized IKRT). This was one of the main reasons that slower modalities were developed. Studies show better preservation of blood pressure and lower vasopressor requirements in those treated with CKRT and PIKRT compared with IKRT.[41-43] Thus, they have become the preferred option for hemodynamically unstable patients.[23] However, switching modalities is not always possible or desired. Consequently, several strategies, borrowed from the ESKD literature, have been employed to avoid hypotension during IKRT in AKI patients. Although *bicarbonate-based dialysate* is the now the norm, most online dialysate still contains 4 to 8 mmol of acetate, which reportedly may increase blood acetate levels, hypotension, and arrhythmia in certain critically ill patients.[44] *Lowering the dialysate temperature* to the lower limits of normal dialysate temperatures (35–36°C) lowers body temperature, which in turn increases vascular resistances and preserves blood pressure during dialysis without apparent deleterious effect.[45,46] *Blood temperature monitoring* takes this a step further by controlling thermal transfer to and from dialysate in order to maintain blood temperature at a target value, thus avoiding vasodilation. However, the efficacy of modulating dialysate or blood temperature in the ICU setting has not been firmly established. *High dialysate sodium concentrations* (145–150 mEq/L) can prevent the fall in effective circulating volume that accompanies the rapid reduction in serum osmolality instigated by IKRT. *Sodium profiling* further ameliorates this process by inducing water flux into the vascular compartment. A clinical trial showed that intermittent HD with sodium profiling (from 160 to 140 mmol/L) combined with UF profiling improved hemodynamic stability.[47] Similar data exist for PIKRT. *Blood volume monitoring* involves biofeedback systems that automatically adjust Q_{UF} and dialysate [Na^+] in response to a fall in circulating blood volume. Although helpful in the ESKD setting, it has not been shown to prevent intradialytic hypotension in the ICU setting.[48,49] HDF has been suggested to induce less intradialytic hypotension than IHD in the ESKD setting.[38] Finally, if the main therapeutic goal is to remove fluid, isolated UF can be performed.[3]

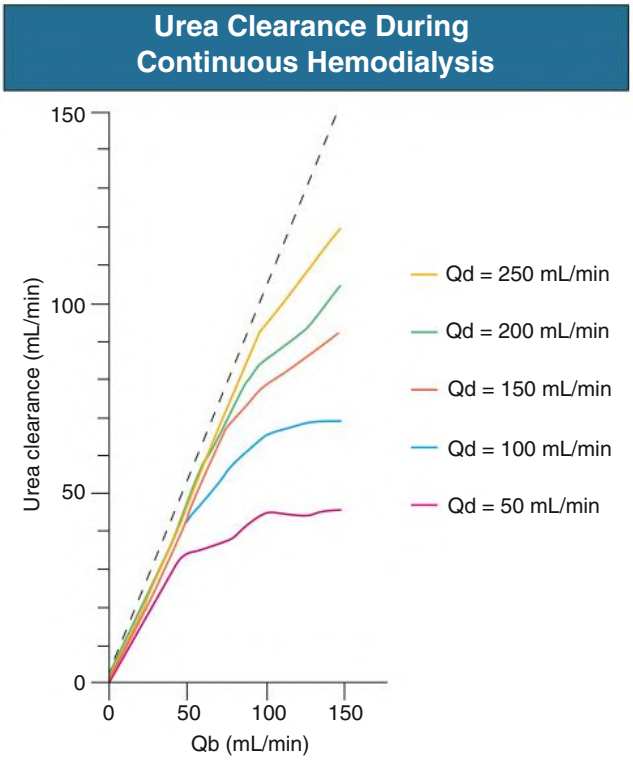

Fig. 75.4 Determinants of Urea Clearance During Continuous Hemodialysis. Relationship among urea clearance, Qb (blood flow), and Qd (dialysate flow) during continuous hemodialysis. The flattening of the urea clearance curves describes the conditions in which increases in Qb do not enhance clearance. (From Kudoh Y, Iimura O. Slow continuous hemodialysis—new therapy for acute renal failure in critically ill patients. Part 1. Theoretical considerations and new technique. *Jpn Circ J.* 1988;52:1171–1182.)

Prolonged Intermittent Kidney Replacement Therapy

PIKRT was developed as a hybrid between IKRT and CKRT; indeed, urea clearance rates are lower than in IKRT but higher than CKRT. It is usually performed using standard IKRT equipment (CKRT equipment can also be used, as was necessary during the COVID-19 pandemic) but with lower solute clearances and Q_{UF} over longer durations. The intent was to provide the advantages of CKRT (slow, gentle solute clearance and Q_{UF}) while using available IKRT equipment, thus

TABLE 75.3 Kidney Replacement Modalities and Their Subtypes

IKRT	PIKRT	CKRT
UF Isolated ultrafiltration (also called sequential ultrafiltration)	EUF Extended ultrafiltration (sometimes called SCUF)	SCUF Slow continuous ultrafiltration
IHD Intermittent hemodialysis	SLED Slow low efficiency dialysis	CVVHD Continuous venovenous hemodialysis
IHF Intermittent hemofiltration	EHF or AVVH Extended hemofiltration or accelerated venovenous Hemofiltration	CVVH Continuous venovenous hemofiltration
IHDF Intermittent hemodiafiltration	EHDF Extended hemodiafiltration	CVVHDF Continuous venovenous hemodiafiltration

Fig. 75.5 The Spectrum of Kidney Replacement Therapies in Acute Kidney Injury and Their General Characteristics. Although any modality may be used, each has advantages and disadvantages. Thus, the therapy may be tailored to the needs of the individual patient (e.g., patients with increased severity of illness and hypotension may benefit from slower therapies). Optimized IKRT represents IHD prescriptions that are a hybrid between PIKRT and IKRT, which is used to better reach patient therapy goals. *AVF,* Arteriovenous fistula; *AVG,* arteriovenous graft; *CKRT,* continuous kidney replacement therapy; *HD,* hemodialysis; *ICU,* intensive care unit; *IHD,* intermittent hemodialysis; *IKRT,* intermittent kidney replacement therapy; *PIKRT,* prolonged intermittent kidney replacement therapy; *RN,* registered nurse.

minimizing the additional equipment and complexities of implementing a CKRT program.[28] PIKRT has the benefit of providing scheduled downtime, which allows the patient to get diagnostic studies, physical therapy, and so forth without compromising dialysis dose. Prescribed correctly, PIKRT provides a high dose of dialysis with minimal urea disequilibrium, excellent control of electrolytes, and good tolerance to UF (Fig. 75.3). PIKRT is usually delivered as a diffusive therapy, although there is increasing experience with combined diffusive and convective clearance. Treatment duration can vary from 6 to 18 hours using a Q_b of 150 to 300 mL/min and Q_d of 50 to 300 mL/min. This wide variation in operating parameters makes it difficult to interpret the literature on PIKRT and hence precisely define its role. In the older descriptions of PIKRT, the duration (12–18 hours) and other operating characteristics (Q_b ≤250 mL/min, Q_d ≤100 mL/min) were closer to those of CKRT, and treatment tolerance was excellent. The typical duration now is closer to 6 to 8 hours with faster Q_b and Q_d, and thus it may not be as well tolerated in high-risk populations, such as those with septic shock.[50] For this reason, we prefer lower efficiency prescriptions (i.e., lower Q_{UF} and slower solute removal) in the less stable patients (an algorithm to assist in prescribing PIKRT is presented in Fig. 75.6). Regardless, as with all forms of KRT, quality metrics for the parameters of interest (e.g., Q_{UF}, electrolyte and acid-base

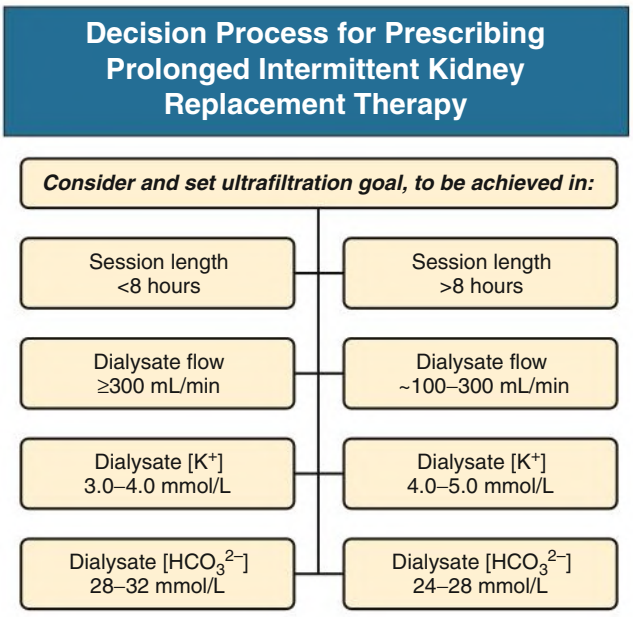

Fig. 75.6 Overview of the decision processes for prescribing prolonged intermittent kidney replacement therapy.

management, anticoagulation, nutrition, medication dosing) should be identified, monitored, and promptly addressed (Table 75.4).

Continuous Kidney Replacement Therapies

CKRT involves the application of low solute clearance and Q_{UF} over 24 hours daily. The lower Q_{UF} provides the best hemodynamic stability of any KRT modality, and the longer treatment duration results in better and more consistent control of uremic solutes, especially for severely catabolic patients. It was first performed in an arteriovenous (AV) configuration in which blood flowed via an arterial catheter, through a simple extracorporeal circuit and filter, and then back to the patient via a venous catheter. This is largely an obsolete practice because of low effectiveness and high complication rate. The technique that is now routinely used is via the venovenous (VV) configuration, where blood is drawn from and returned to the central venous circulation via a mechanical blood pump. CKRT modalities are classified based on their mechanism of molecular clearance (Table 75.3). If the primary mechanism is via convection, it is called continuous venovenous hemofiltration (CVVH); as previously mentioned, the replacement fluid can be returned either prefilter or postfilter. If diffusion is the primary mechanism of clearance, it is called continuous venovenous hemodialysis (CVVHD). A combination of these 2 preceding techniques is called continuous venovenous hemodiafiltration (CVVHDF). The formulas used to calculate small solute clearance were shown in Table 75.1.

The choice of technique depends on whether the primary need is for fluid and/or solute removal, and clinician expertise and preference. For isolated fluid removal (e.g., cardiorenal syndrome), SCUF is used. When solute removal is needed, the physician can choose either the convective or diffusive modalities, as there is clinical equipoise between them.[51] Modern machines are able to provide reliable and rapid Q_b (50–450 mL/min) and dialysate or replacement fluid rates that usually are in the 2 to 4 L/h range, but are capable of running at up to 12 L/h. The major limitations to implementing/sustaining CKRT programs have been cost and complexity. Some contributors to the costs of CKRT include nursing time, filters, and solutions. These are exacerbated by frequent circuit failure (mean operating time for CKRT is reported to be 17–22 h/day), which increases the work load and wastes.[52] However, implementing simple standardized protocols can result in the maintenance of a 2:1 patient:nurse ratio and circuit life spans of more than 60 hours, thus significantly decreasing the cost difference between modalities. For this, careful attention must be paid to the technical considerations of CKRT and a continuous quality program implemented.[53]

Extracorporeal Blood Purification

Critical illness is associated with increased production of cytokines, which are medium and large molecules that modulate the immune response. These trigger an inflammatory state, which is exacerbated in AKI, because cytokine clearance is decreased. Consequently, there has been an ongoing interest developing techniques that reduce cytokines during acute illness, especially sepsis. This interest was accentuated during the COVID-19 pandemic because of the profound inflammation milieu associated with SARS-CoV-2 infection. Cytokines can be removed with high levels of convective clearance, high cutoff hemofilters (membranes with a molecular weight cutoff of 60–150 kDa), bioadsorption devices, and coupled plasma filtration–adsorption (Table 75.5). Note that most of these techniques are not selective: they will remove any circulating substance that meets their clearance characteristics, including proinflammatory and antiinflammatory cytokines, as well as beneficial substances such as medications, including antibiotics. All of these techniques are experimental, supported only by observational studies and pilot trials. Larger multicenter trials are scarce and have not yet provided evidence of benefit. Better techniques are required to identify patients who might benefit from cytokine removal, as well as when and how cytokine removal should be applied.

OPERATIONAL ASPECTS OF ACUTE KIDNEY REPLACEMENT THERAPY

Advances in technology have facilitated the implementation of kidney replacement programs throughout the world. However, ensuring optimal quality and safety remains a challenge. Even now, many institutions lack quality monitoring programs such as monitoring clearance, be it IKRT, PIKRT, or CKRT. The need for defining and standardizing quality metrics in the care of AKI patients was addressed by an Acute Disease Quality Initiative (ADQI) series.[53] They emphasize the need for all institutions to implement a quality initiative comprising integrating, monitoring, and reporting of quality metrics for all their KRT therapies. Table 75.4 provides an example of a quality dashboard that can be adapted to fit an institution's needs. It is important to not only meet the individual benchmarks but to also determine the effect they have on overall efficacy and safety of the KRT program. For instance, the reason to monitor catheter function is to prevent premature circuit failure, which not only results in decreased delivery of the KRT dose but also causes blood loss and waste of disposables, alters delivery of medications and nutrition, and increases nurse workload, all of which increase health care costs.

Vascular Access

A prerequisite for IKRT, PIKRT, and CKRT is reliable vascular access through which blood is delivered to the membrane at an adequate flow rate for waste(s) removal but without clotting and circuit dysfunction. If the patient has an AV fistula or graft, this should be used for IKRT. Uncuffed, short-term HD catheters inserted into a central vein are the most commonly used access for CKRT. Although tunneled dialysis catheters may have better delivery metrics and fewer complications, they are usually reserved for patients who either already have one present or those expected to be on KRT for more than 3 weeks. Short-term HD catheters vary in material, size, lumens (number and lumen shape), catheter shape, and tip characteristics.[53] However, the

TABLE 75.4 Example of a Quality Metric Dashboard for Kidney Replacement Therapy

Quality Indicator	Operational Definition	Proposed Benchmark
Vascular Access Related		
Access site	Right IJ vs. left IJ vs. femoral vein	For monitoring purposes
Tip placement	Tip within 3 cm of caval-atrial junction (for chest lines only)	1.0
Catheter dysfunction and failure	Number of catheters with dysfunction/total number of catheters	0.8
CLABSIs	CLABSIs/Number of catheter-line days	0 events per catheter
Efficacy: Outcomes		
Kt/V in IKRT and PIKRT	Kt/V after first session (weekly Kt/V to be calculated)	3.9 weekly
Filters used per session	Filters used/Number of sessions	1 per session
Filter life in CKRT	Number of filters lasting 60 h/Total number of filters used	>60% filters
Delivered dose	Actual delivered dose/24 h/Prescribed dose/24 h	>80% of dose
Fluid management	UF removed/24 h/Prescribed UF/24 h	>80% of UF
Small solute clearance	[sCr(d1) – sCr(d2)]/sCr(d2)	0
Unplanned time off CKRT	CKRT/24 h	<10% downtime
Downtime	Calculated from machine (e.g., delays in addressing alarms)	<10% downtime
Medication dosing	Appropriate dose adjustments per CKRT	Daily monitoring
Nutrition and supplements	Appropriate nutrition, vitamin, and trace element supplements	Daily monitoring
Safety Indicators		
Adverse events	Number of adverse events/Number of patients on CKRT	0 events
Electrolyte		
Hypophosphatemia	Days with phosphate <2.5/Days of CKRT	0 days
Hypokalemia	Days with potassium <2.5/Days of CKRT	0 days
Hypomagnesemia	Days with magnesium <1.8/Days of CKRT	0 days
Citrate-Related Errors		
Calcium (high or low)	Days with phosphate <2.5/Days of CKRT	0 days
Alkalosis	Days with potassium <2.5/Days of CKRT	0 days
Hypomagnesemia	Days with magnesium <1.8/Days of CKRT	0 days

Structure indicators would be part of the framework of a CKRT quality program and may include a CKRT committee, defined training program, standardized order sets, infrastructure to support and measure these ongoing quality indicators and a process to ensure the proper functioning/maintenance of KRT devices.

TABLE 75.6 Determining the Length of Hemodialysis Catheters

Site	Formula	Accuracy
Right internal jugular	Height/10 cm	90%
Left internal jugular	Height/10 + 4 cm	94%
Right subclavian	Height/10 – 2 cm	96%
Left subclavian	Height/10 + 2 cm	97%

most important factors to ensure low resistance/high Q_b are catheter diameter and location of the tip. Thus, the widest catheter with the shortest length that allows for proper tip placement should be used. The catheter length should be chosen based on the insertion site and height using the Peres formulas (Table 75.6).[54-56] The right internal jugular has usually been considered to be the first-choice insertion site, followed by the left internal jugular and femoral veins.[57] The use of the subclavian vein is not recommended, as cannulation can lead to increased risk of venous stenosis. Several studies have challenged the superiority of the internal jugular approach, suggesting that the femoral vein performs as well as the right internal jugular vein (except in the heaviest tertile) and better than the left internal jugular vein.[58,59] Consequently, the latest guidelines have placed the femoral before the left internal jugular vein. However, it should be noted that the treating center was an independent predictor of short-term HD catheter dysfunction, and it is thus recommended that each center identify their own best practices by monitoring their internal data.[53]

The demands placed on a short-term HD catheter by and PIKRT are somewhat different than during IKRT (see also Chapter 96). On the one hand, the Q_b demands are less than in IKRT: Q_b usually are 300 mL/min or less. But on the other hand, they are being used from prolonged periods during which it is manipulated or mobilized, thereby increasing the risk of complications and so forth. From a functional standpoint, poorly functioning catheters involve either catheter dysfunction or catheter failure. *Catheter dysfunction* in CKRT is when suboptimal catheter function is causing premature circuit failure or inadequate clearance in the absence of frequent alarms or obvious drops in Q_b, and thus may not be readily detected.[54] *Catheter failure* is when the Q_b obtainable through the catheter is insufficient to maintain a functioning CKRT; it is characterized by frequent alarms and stopping of the Q_b pump. Causes of early dysfunction or failure include kinking and suboptimal tip placement. Late dysfunction/failure is more often due to intrinsic or extrinsic obstruction caused by thrombosis. Another complication of dialysis catheters is infection. Although largely preventable, they remain problematic, especially in the ICU setting where patients frequently have other intravenous catheters and lines. Hence, catheter-associated bloodstream infections are still too common. There is ongoing controversy around the risk for infection with different insertion sites, but on balance the internal jugular site is preferred, especially in those with a larger body mass index. However, it is likely that the way the catheter is handled is more important at preventing infection than the site in which it is inserted. Low rates of infection require the adherence to specific clinical guidelines and implementing a formal quality improvement program. There is strong evidence that implementing best practice catheter insertion techniques and maintenance results in a close to zero catheter-related infection rate (the core elements are listed in Box 75.3).[60] The relevant interventional bundles are contained in position statements of the Institute for Healthcare Improvement and the Centers for Disease Control and Prevention Healthcare Infection Control Practices Advisory Committee.[61,62]

BOX 75.3 Best Practices to Minimize Catheter-Associated Bloodstream Infection

Insertion

- Hand hygiene and aseptic technique (including early replacement of catheters inserted in uncontrolled settings if adherence to these measures cannot be ensured)
- Maximum barrier precautions (hat, mask, sterile gloves, sterile gown, and full patient drape)
- Appropriate skin preparation using an alcohol-based chlorhexidine (>0.05%) solution; povidone-iodine (preferably with alcohol) or 70% alcohol can be used in patients with chlorhexidine intolerance
- Avoidance of the femoral site for catheter placement, especially in overweight patients (BMI ≥ 27 kg/m²)
- Avoidance of catheter placement near open wounds

Maintenance

- Daily review of the need for the line, with prompt removal of unnecessary lines
- Appropriate dressing with sterile gauze or a sterile, transparent, semipermeable dressing
- Appropriate schedule for dressing changes according to condition and type of dressing
- Daily review of the catheter exit site with minimal disturbance to the dressing unless clinically indicated
- Appropriate skin preparation before ports are accessed
- Scrub-the-hub protocol for accessing the catheter
- Daily cleansing of patients with a 2% chlorhexidine wash
- Use of a sutureless securing device for catheter stabilization

BMI, Body mass index.

Circuit and Hemofilters

To ensure optimal KRT delivery, a thorough understanding of the circuit and hemofilter is needed. An ideal circuit is characterized by easy priming (low volumes), low resistance to Q_b, biocompatible materials, minimal blood-air interfaces, and easily exchangeable hemofilters (see also Chapter 98). The KRT circuit begins and finishes at the patient's vascular access (Fig. 75.7).[54] It comprises a series of pumps connected by tubing segments containing sensors that enable the monitoring and regulation of blood and other solutions flowing through the circuit. It has 4 major segments: (1) an inflow (prefilter) segment carrying the blood from the patient's vascular access to the hemofilter, (2) the hemofilter/dialysis membrane, (3) an outflow (postfilter or return segment) carrying "cleansed" blood back to the patient, and (4) the circuits carrying the nonblood solutions. The pressure sensors are strategically located to monitor for specific changes in the circuit dynamics. Any change in pressure detected by a sensor, in the absence of prescription change, reflects a change in the resistance along that segment, thereby facilitating early detection of an abnormality to the circuit dynamics. Modern hemofilters are made of synthetic biocompatible materials with surface areas that vary from as low as 0.1 m^2 to over 2 m^2. Although molecular size cutoffs vary between membranes, the primary determinant of size selectivity in standard KRT is the mechanism of clearance (convection vs. diffusion). Although studies have examined the potential benefits of using high cutoff hemofilters to clear more middle molecules (e.g., cytokines), they have not been shown to improve outcomes.

Replacement Fluids and Dialysate

CKRT requires sterile replacement fluid or dialysate for blood purification, with composition that is determined by the clinical requirements

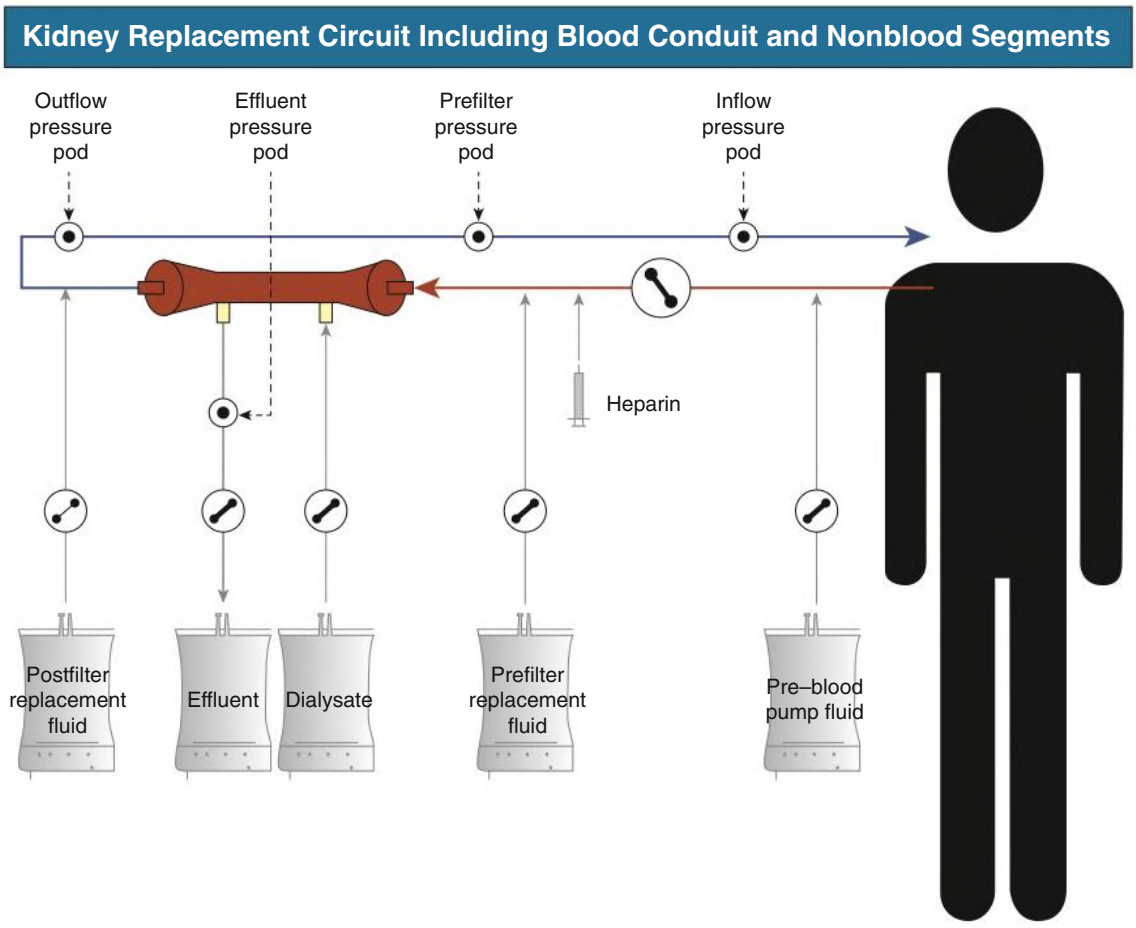

Fig. 75.7 Typical continuous kidney replacement therapy circuit including the blood conduit and nonblood segments. (From Juncos LA, Chandrashekar K, Karakala N, Baldwin I. Vascular access, membranes and circuit for CRRT. *Semin Dial.* 2021;34[6]:406–415.)

for acid-base control and electrolyte management (see also Chapter 98). Commercially available fluids are the norm, but appropriate fluids can also be prepared derived from peritoneal dialysate and standard intravenous fluids if commercial products are unavailable. Moreover, bagged dialysate solutions for CKRT machines have been generated using single-pass dialysis machines during periods of severe shortages, such as during the COVID-19 pandemic.[63] In general, the generation of fluid via pharmacy compounding is avoided because of the increased costs and potential for human error. *Bicarbonate* buffered solutions are now preferred because they provide superior acid-base control, hemodynamic stability, urea generation, cerebral dysfunction, and may improve survival in select patient groups.[64] Bicarbonate concentrations in fluid are typically 32 to 35 mmol/L, but 22 to 25 mmol/L concentrations are available for when using citrate anticoagulation. *Potassium* concentrations vary from 0 to 4 mEq/L. The vast majority of the time a 4 mEq/L solution is sufficient to maintain normokalemia in CKRT, unless the delivered dose is insufficient. The lower potassium concentrations are used when initiating hyperkalemic patients or in those with elevated redistribution of potassium from the intracellular compartment due to tissue breakdown (e.g., rhabdomyolysis). Despite its commercial availability, we do not believe the use of a 0 mEq/L solution is ever warranted in IKRT or PIKRT and is only beneficial in very select/rare circumstances during CKRT. *Calcium* comes in 2.5, 3, 3.5, or 0 mEq/L configurations. Intravenous calcium replacement is necessary when using the lower calcium concentrations and citrate anticoagulation. *Magnesium* comes in 1.0 to 1.5 mEq/L configurations, and therefore periodic repletion of the patient's magnesium levels may be necessary. While *phosphate*-containing solutions are becoming increasingly available, most continue to lack phosphate; thus supplementation is almost always required after the first few days of CKRT to avoid hypophosphatemia. Phosphate replacement should begin as soon as plasma levels approach low-normal levels and can be accomplished by (1) initiating a continuous infusion (e.g., starting at approximately 1 to 1.5 mmol/h and titrating to maintain normal plasma levels), (2) provding phosphate via the gastrointestinal tract 2 to 3 times daily, or (3) adding appropriate quantities of phosphate into the dialysate.[65] Because hypophosphatemia has been associated with muscle weakness, including respiratory muscle weakness accompanied by longer duration of mechanical ventilation and mortality, its prevention is an important quality metric to monitor. Finally, dextrose-free solutions may induce euglycemic ketoacidosis; therefore, patients being treated with these solutions should be monitored for this complication.[65]

Anticoagulation in Acute Kidney Replacement Therapy

Most ICU patients can avoid any anticoagulation during intermittent HD because of short treatment duration, but most on PIKRT or CKRT benefit from anticoagulation. Although numerous protocols with anticoagulants have been developed, the most commonly used are based on unfractionated heparin and citrate (see also Chapter 98).[66] *Unfractionated heparin* can be used by infusing heparin either via the syringe in the KRT device, along the inflow segment of the circuit, or systemically. A common protocol starts with an initial bolus dose of 25

to 30 U/kg followed by an infusion of 5 to 20 U/kg/hr titrated to keep the activated partial thromboplastin time (APTT) in the venous blood line 1.5 to 2 times the control value. Advantages of unfractionated heparin include low cost, relative safety, and ease of monitoring. Risks include bleeding in up to 25% to 30% of patients, hyperkalemia, elevated hepatic transaminases, and heparin-induced thrombocytopenia (HIT) in 3% to 5% of patients. To decrease the bleeding risk, a regional heparin/protamine sulfate anticoagulation protocol was proposed in which 1 mg of protamine for every 100 U heparin is infused into the venous line, thus reversing heparin's effect.[67] However, rebound bleeding can occur when the neutralization with protamine wears off faster than the anticoagulation from heparin. Furthermore, protamine may cause sudden hypotension, bradycardia, or anaphylactoid reactions.

Regional citrate anticoagulation is suggested as the first line strategy by KDIGO guidelines.[68] It provides the greatest prolongation of filter life and lowest rates of hemorrhage. Regional citrate anticoagulation comprises calcium chelation in the extracorporeal blood circuit and with a calcium infusion either into the return segment or intravenously to restore systemic calcium levels. For intermittent HD and PIKRT, this involves an infusion of 4% trisodium citrate into the arterial blood line, a zero/low-calcium dialysate. For CKRT, either 4% trisodium citrate or anticoagulant citrate dextrose A (ACD-A) is infused into the inflow segment. The rate of citrate is calculated so that blood citrate levels are between 3 and 4 mmol/L or postfilter ionized calcium is less than 0.35 mmol/L. Because the 4% trisodium citrate solution is hypertonic, its use will require an additional infusion of hypotonic fluid or the use of dialysate that is hyponatremic to avoid hypernatremia. Although the ACD-A solution is also hypernatremic, it is not sufficient to induce significant hypernatremia when using appropriate infusion and clearance rates. Both solutions require the use of the lower bicarbonate solutions (22–25 mEq/L) to prevent the alkalosis caused by the subsequent metabolism of the infused citrate into bicarbonate in the liver (in a 1:3 ratio). Frequent monitoring and titration of citrate dose have been advocated to keep the ionized calcium within a therapeutic range. However, many centers now use a simplified fixed-dose anticoagulant citrate dextrose, which minimizes the need to measure postfilter calcium or adjust the citrate infusions. Major complications of regional citrate anticoagulation include systemic hypocalcemia and metabolic alkalosis from citrate toxicity. There is increasing experience with commercial replacement solutions containing citrate as buffer; this chelates calcium in the blood without the need for a separate citrate infusion. Some CKRT devices allow for direct coupling of citrate and calcium infusions, such that a change in Q_b leads to an automatic change in the infusion rates of citrate and calcium. This does not obviate monitoring for systemic hypocalcemia and metabolic alkalosis but is expected to be safer and will likely become the standard approach in the future.

Protocols with other anticoagulants have also been described, but are used less frequently. *Low-molecular-weight heparin* is theoretically advantageous because of increased antithrombotic activity. However, disadvantages include a prolonged half-life (approximately doubled in Acute Kidney Injury Network [AKIN] stage 3, with no significant clearance during KRT), incomplete reversal with protamine, and limited availability of appropriate monitoring by serial anti–factor Xa determinations (recommended level 0.25–0.35 U/mL). Most experience is with dalteparin administered as a single bolus of approximately 20 to 30 U/kg for intermittent HD, followed by an infusion of approximately 10 U/kg/h for PIKRT or CKRT. Overall, the evidence does not support its use over unfractionated heparin in the critically ill AKI setting. *Argatroban* does not cross-react with heparin antibodies and is the preferred approach for HIT because of its hepatic clearance (half-life ~35 minutes, no significant clearance during KRT[69]) and ease of monitoring with APTT. It is administered as a 0.1 to 0.25 mg/kg bolus before intermittent HD or an infusion of 0.1 to 0.2 mg/kg/h during PIKRT or CKRT, titrated according to APPT. Bivalirudin may be used as an alternative to argatroban in patients with combined kidney and liver failure. Prostacyclin is another effective anticoagulant, but causes variable but occasionally marked falls in BP. Moreover, there is a risk for worsening ventilation-perfusion mismatch and lactic acidosis in patients with multiorgan dysfunction and a risk for increasing intracranial pressure in patients with combined liver and kidney failure. Other less frequently used approaches include antithrombin-dependent factor Xa inhibitors (e.g., fondaparinux) and serine protease inhibitors (nafamostat mesilate).

Drug Dosage in Acute Kidney Replacement Therapy

The effect of AKI and KRT modalities on pharmacokinetics and pharmacodynamic responses remains inadequately studied. Medication dosing data is largely derived from patients with ESKD undergoing IHD and are extrapolated to patients with AKI using the same pharmacologic principals (e.g., size, degree of protein binding, volume of distribution, lipophilicity vs. hydrophilicity). Calculating KRT dosing can be helpful in determining appropriate dosing regimens. For instance, a 70-kg male on CKRT at 25 mL/kg/h (which is 1750 mL/h) corresponds to a glomerular filtration rate (GFR) of approximately 30 mL/min, and the dose of drugs should be calculated accordingly. Drugs with wide therapeutic indices should be used when possible, and drug levels, particularly of those with low therapeutic indices, should be periodically monitored (when possible).

EXTRACORPOREAL KIDNEY THERAPY IN HEART FAILURE AND MECHANICAL CIRCULATORY AND VENTILATORY SUPPORT

Nephrologists are frequently involved in management of patients with heart failure (HF) complicated by diuretic resistance (i.e., failure to reach the therapeutically desired reduction in edema despite adequate and escalating diuretics) and/or kidney dysfunction. The rationale for this is not only because of our expertise in removing fluid (be it by optimizing diuretics or providing KRT) but also because the pathophysiology of HF with diuretic resistance is intimately related to progressive kidney dysfunction (Fig. 75.8). Activation of neurohumoral pathways and venous congestion are of particular importance. The neurohormonal pathways most implicated are the sympathetic nervous system (SNS) and the renin-angiotensin-aldosterone system (RAAS). Activation of these systems induces vasoconstriction of the renal arterioles, alters the autoregulatory curve (shifting it downward and to the right), and promotes sodium retention. Venous congestion exacerbates these maladaptive changes by inducing preglomerular myogenic responses, narrowing the arterial-to-venous pressure gradient, and increasing kidney interstitial pressure, all of which lower kidney perfusion and GFR. Indeed, kidney function in decompensated HF correlates better with central venous pressures than ejection fraction or cardiac index and is associated with increased mortality.[70] The interplay between the neurohumoral systems and venous congestion is also important when considering mechanisms of decompensation and responses to therapy. That is, because the venous system contains approximately 70% of the circulatory volume, venous vasoconstriction (causing decreased capacitance) can increase preload and decompensate HF without there being an actual increase in body weight.[71] Conversely, increasing venous capacitance can ameliorate HF symptoms despite the absence of fluid removal. This variation in the venous reservoir volume complicates the interpretation of efficacy of fluid removal strategies in HF.

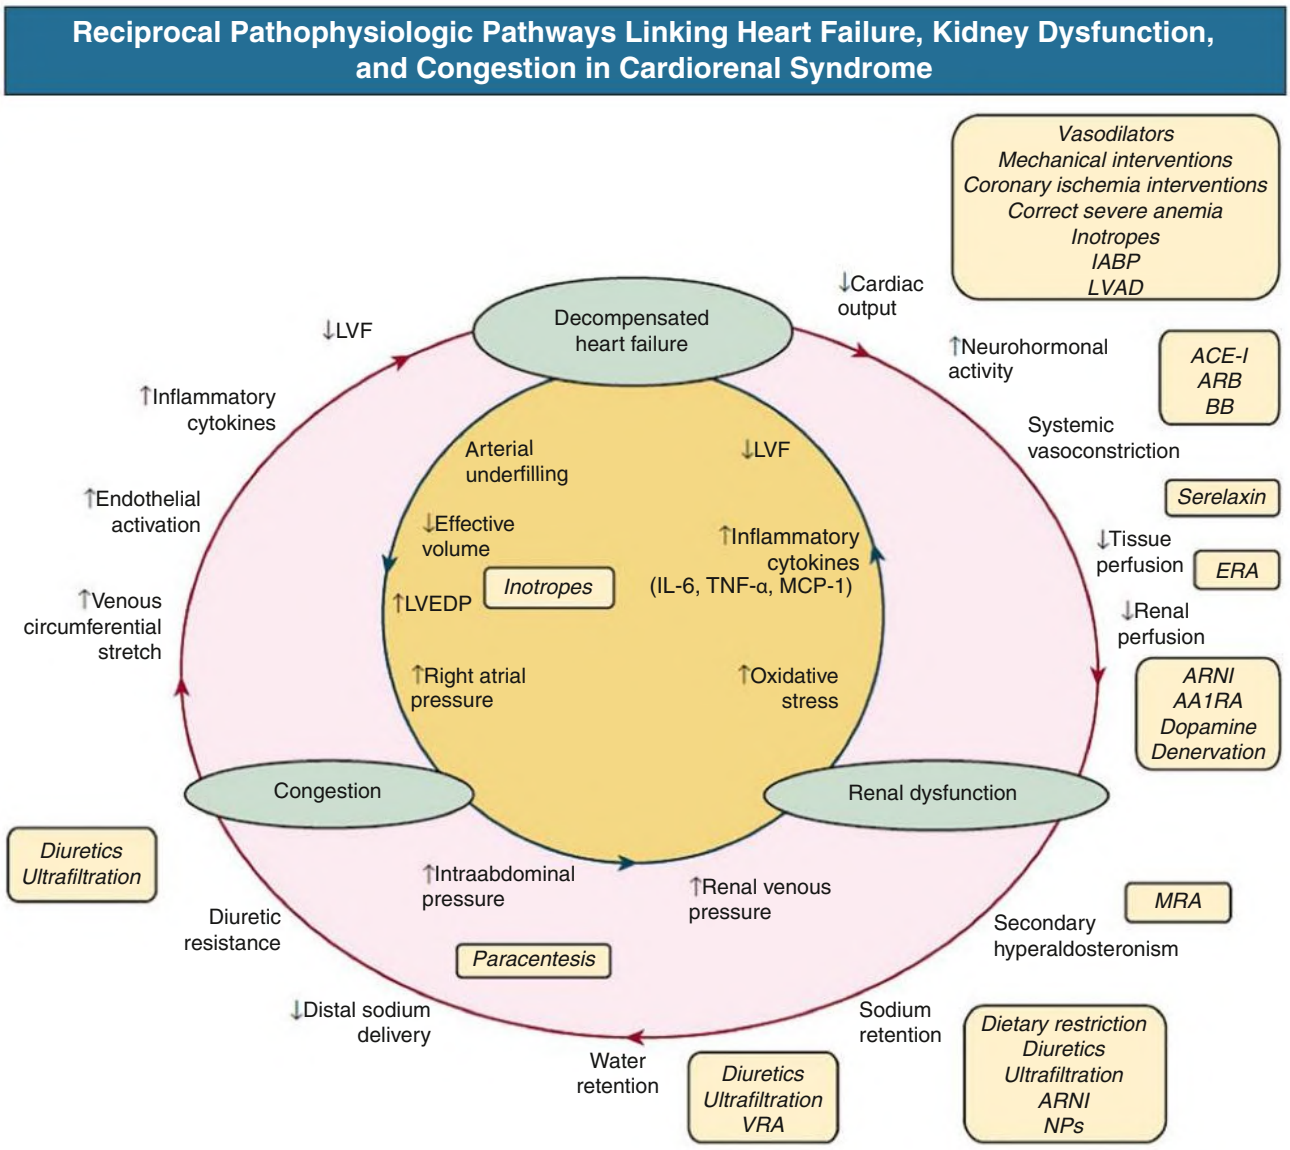

Fig. 75.8 Reciprocal Pathophysiologic Pathways Linking Heart Failure, Kidney Dysfunction, and Congestion in Cardiorenal Syndrome. Decompensation of heart failure can lead to deterioration in kidney function via exacerbated neurohormonal activity and/or kidney venous congestion. The impact of various pharmacologic and nonpharmacologic therapeutic options on the underlying pathophysiologic mechanisms is illustrated. *AA1RA,* Adenosine A1 receptor antagonist; *ACE-I,* angiotensin-converting enzyme inhibitor; *ARB,* angiotensin receptor blocker; *ARNI,* angiotensin receptor neprilysin inhibitor; *BB,* β-blocker; *ERA,* endothelin receptor antagonist; *IABP,* intraaortic balloon pump; *IL-6,* interleukin-6; *LVAD,* left ventricular assist device; *LVEDP,* left ventricular end-diastolic pressure, *LVF,* left ventricular function; *MCP-1,* monocyte chemoattractant protein-1; *MRA,* mineralocorticoid receptor antagonist; *NP,* natriuretic peptide; *TNF-α,* tumor necrosis factor-α; *VRA,* vasopressin receptor antagonist.

Therapeutic Options for Venous Congestion

Diuretics

Treatment of HF requires addressing treatable causes, instituting diet and lifestyle changes, titrating pharmacologic therapies, and considering mechanical options. The cornerstone of HF therapy for nephrologists revolves around volume management. Indeed, more than 90% of patients admitted with HF are fluid overloaded; the prerenal picture is due to venous congestion, not intravascular volume depletion. Hence, intensifying the diuretic regimen by increasing the dose is the first step. Increasing the frequency or starting a continuous drip are alternative strategies in those with suboptimal responses. RCTs have demonstrated clinical equipoise between approaches, thus one can tailor it to individual patient responsiveness. A reasonable approach is that used in the DOSE study,[72] in which the outpatient diuretic dose was increased 2.5-fold and then titrated per clinical responsiveness. Because the dose-response curve to loop diuretics is logarithmic, doubling the dose is warranted until a diuretic response is achieved or the maximal dose reached. In the absence of an adequate response, the reason for resistance should be identified and strategies to improve diuretic responsiveness implemented. Blocking adjacent nephron segments using other diuretics, most commonly thiazide-like agents, may increase natriuresis. Urine sodium monitoring may assist in guiding diuretic regimens. Despite optimization of diuretic regimens, many patients ultimately require other forms of volume removal.

Extracorporeal Ultrafiltration

Intermittent isolated UF and SCUF are characterized by isolated fluid removal; solute clearance is minimal. This was initially reserved for patients with advanced HF and diuretic resistance. Enthusiasm for its use increased greatly following development of commercially available devices that facilitated the procedure and results of early studies.[73-74] Consequently, more definitive studies were attempted. The UNLOAD trial[75] compared early UF versus intravenous diuretics. Despite the UF group having greater weight loss and fewer rehospitalizations (it was not sufficiently powered to establish this endpoint though), there were no differences in secondary endpoints (dyspnea scores, kidney function, 6-minute walking tests, or mortality). The CARRESS-HF study[76] did not show superiority of UF to diuretics (using a stepped-based algorithm); it did not improve weight loss, dyspnea, well-being scale scores, or diuretic dose, but had a higher rate of adverse events (kidney failure, bleeding, and catheter-related complications). There were no differences in mortality, emergency visits, or rehospitalizations between groups at 60 days.[76] These studies led to decreased interest. Indeed, the AVOID-HF trial[77] was stopped after just 224 (of a planned 810) hospitalized patients were enrolled. Early flexible UF therapy was found to have a greater net fluid loss compared with diuretics without obvious evidence signs of kidney dysfunction. However, the study was underpowered to draw any definitive conclusions regarding hard outcomes. Although several metanalysis have been performed, the differences between study protocols limit their interpretation. Consequently, isolated UF techniques should now be reserved for patients in whom diuretics are insufficient to achieve/maintain adequate volume status.

Peritoneal Dialysis

PD to treat patients with HF has been used for more than 70 years. When used primarily for UF, PD regimens are simpler than in ESKD; fewer daily exchanges or therapy days per week are needed and thus easily implemented and sustained.[78] PD catheters can be placed under local anesthesia and used immediately (using low dwell volumes), but laparoscopic insertion, using general anesthesia, is often performed without problems.[79] Use of PD is associated with improvement in various parameters including electrolytes, fluid status (reduced body weight and diuretic responsiveness), New York Heart Association class, 6-minute walk capacity, hospitalization days, quality of life, cardiac hemodynamics, and HF biomarker levels (BNP, aldosterone); and it does so without activating the SNS or RAAS.[80] However, this evidence is limited to observational studies and cohorts. Thus, it is possible that the purported benefits of PD may simply reflect patient selection or the extra care provided by the PD/research teams. Available evidence suggests that PD is well tolerated and has a low rate of complications, and thus may be offered as a selective therapy to improve fluid status and symptoms in HF patients with advanced CKD.

Kidney Replacement Therapy in Mechanical Cardiopulmonary Support

The two forms of mechanical circulatory support that are most commonly encountered by nephrologists are extracorporeal membrane oxygenation (ECMO) and ventricular assist devices (VADs). In ECMO, deoxygenated blood is taken from a central vein and pumped through an oxygenator back into either a central vein (VV) or the arterial system (venoarterial), thereby providing respiratory or cardiorespiratory support, respectively. VADs assist the left (LVAD) and right ventricles (RVAD) in patients with refractory heart failure or cardiogenic shock. They are used as a bridge to recovery or transplantation or as destination therapy for patients ineligible for transplantation. Continuous flow devices have almost completely supplanted the earlier pulsatile flow pumps. Another modality of respiratory support available in some countries is extracorporeal carbon dioxide removal ($ECCO_2R$). It removes carbon dioxide via a minimally invasive approach that requires lower blood flow and smaller cannulas than ECMO. $ECCO_2R$ can also be achieved, albeit with varying success, via a modified CKRT system linked to a gas exchange membrane.[81]

AKI is common in patients with circulatory and/or respiratory failure. If hypoperfusion is causing AKI, initiating mechanical cardiopulmonary support (MCS) may improve kidney function.[82] However, the incidence of intrinsic AKI (and the need for acute KRT) is high because patients requiring MCS are sicker, and MCS can be complicated by periprocedural hypotension, inflammation, thromboembolism, and hemolysis. Although scant data are available regarding the use of KRT during MCS, the general principles are similar to those for other ICU patients. However, prolonged or continuous acute KRT modalities may be especially advantageous during MCS because they allow for more effective management of patients receiving large fluid volumes. Maintaining adequate volume balance facilitates weaning of MCS, whereas volume overload is associated with worse outcomes.

Technical Aspects of Kidney Replacement Therapy During Mechanical Cardiopulmonary Support

The available modalities for providing KRT during MCS are the same as in other situations: PD, IKRT, PIKRT, and CKRT. Preferences vary according to the type of MCS provided. In ECMO, the preferred modality is usually CKRT because it facilitates volume management with less hemodynamic compromise. This is now usually delivered via the standard CKRT devices via HD catheters, or by directly integrating into the ECMO circuit (Fig. 75.9).[83] An alternative method, which is simple but less precise, is to provide CKRT by creating a shunt that contains a hemofilter in the ECMO circuit. Blood flow through the shunt is driven by the pressure gradient between these two segments, while infusion pumps regulate dialysate, replacement fluid, and UF rates. PD, which was usually used in infants, is now less common.

The preferred KRT in critically ill patients with VADs, particularly in the postimplantation period, is usually CKRT. This is eventually transitioned to IHD or PD once the patient is hemodynamically stable. Either modality can be continued in the outpatient setting. The most commonly used modality is IHD. This is initially done via a dialysis catheter, but this carries a high risk of infection and should thus be changed over to an AV access as soon as possible. AV grafts are preferred because the fistulas may not mature adequately in the nonpulsatile environment. Another challenge in providing KRT to patients with LVADs is the monitoring and maintenance of adequate preload and afterload during IHD.[84] This is of vital importance because the function of LVADs depends greatly on these parameters, both of which can change quickly during an IHD session. Afterload is monitored by measuring blood pressure, which is difficult in patients with continuous-flow VADs due to their minimal pulses, thus rendering standard plethysmography unsuitable. Instead, it is measured using Doppler ultrasonography or specialized cuffs with low pulsatility modes.[84] Stringent blood pressure control is desirable to avoid increased afterload-induced decreases in LVAD pump flow. Preload can be assessed by central venous pressure, echocardiogram, or the pulsatility index (in the Heartmate II). KRT-associated decreases in preload may lead to left ventricular collapse with subsequent fall in MCS flow, pump overdrive, hypotension, and ventricular arrhythmias. This is corrected by gentle volume administration, as other causes of preload reduction (e.g., bleeding, sepsis) are considered. Decreasing the pump speed and treating arrhythmias usually should be performed only after consultation with appropriate VAD personnel.

PD is an underutilized modality in patients with VADs, mainly because of the common misconception that it is contraindicated

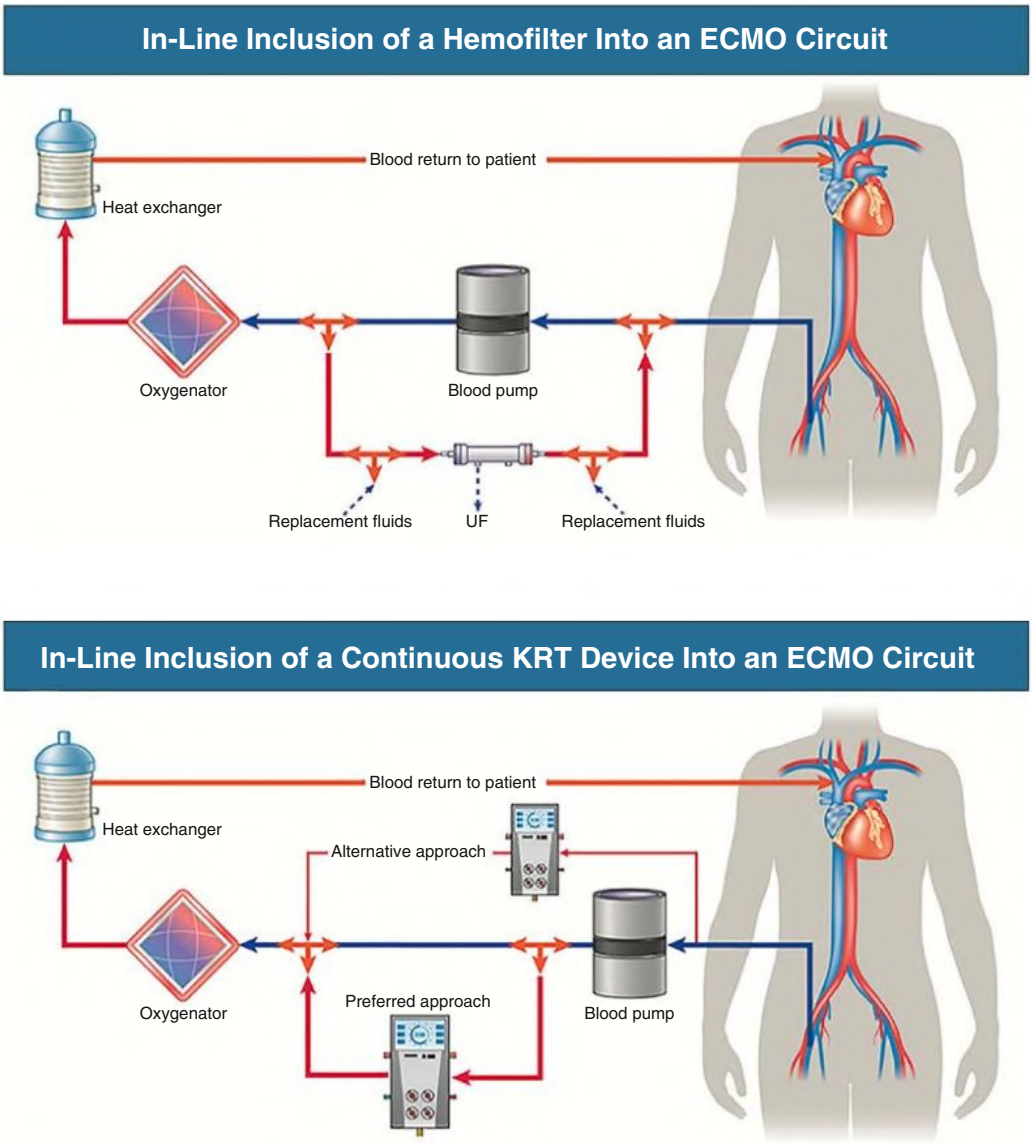

Fig. 75.9 Extracorporeal Membrane Oxygenation (ECMO) Circuit With an In-line Hemofilter *(Top Panel)* or Continuous Kidney Replacement Therapy Device Integrated Into the ECMO Circuit. Two potential connections (preferred and alternative) are illustrated in the bottom panel. *CKRT,* Continuous kidney replacement therapy; *UF,* ultrafiltration. (From Karakala N, Juncos LA. Providing continuous renal replacement therapy in patients on extracorporeal membrane oxygenation. *Clin J Amer Soc Nephrol.* 2020;15[5]:704–706.)

because of increased risk of infection. This concept originated from older generations of VADs, which were implanted into the peritoneal cavity or abdominal wall, and thereby susceptible to infection. However, newer LVADs are extraperitoneal and thus devoid of this intravascular infection risk. Benefits of PD include gentle UF with no abrupt changes in preload, no abrupt electrolyte shifts, and low risk of bacteremia from catheter infections. Moreover, it is performed at home, which precludes the problem of finding an outpatient dialysis center that will accept them, as most are not comfortable in accepting LVAD patients. More experience is needed to determine the optimal provision of KRT in these patients.

SELF-ASSESSMENT QUESTIONS

1. Which of the following statements is *true* with regard to the different acute KRT modalities?
   - **A.** The routine use of CKRT rather than IKRT is associated with improved survival.
   - **B.** When opting for IKRT, one should routinely use a daily rather than thrice-weekly treatment schedule in order to improve survival.
   - **C.** The best available data suggest delivering a minimum dose of 20 mL/kg/h (for CRRT) or a single-pool Kt/V of ≥1.2 thrice weekly in critically ill patients receiving hemodialysis.
   - **D.** Using higher doses of continuous KRT has been shown to increase cytokine removal and improve outcomes in patients with septic shock and AKI.

2. Which of the following is *true* regarding initiating KRT in critically ill patients?
   - **A.** A positive test for *TIMP2/IGFBP7* predicts the future development of severe AKI; thus the patient should be prepared for initiation of acute KRT.
   - **B.** The use of biomarkers of AKI (e.g., neutrophil gelatinase–associated lipocalin) improves diagnosis and facilitates deciding who should receive KRT.
   - **C.** Using the furosemide stress test to assist in the decision to initiate KRT was found to improve clinically meaningful patient outcomes and prevent the unnecessary initiation of KRT in patients who rapidly recovered renal function.
   - **D.** The available randomized trials have failed to identify markers that dictate the initiation of KRT in a manner that has a favorable effect on meaningful clinical outcomes.
3. Which of the following statements is *true* regarding central venous catheters for acute KRT in critically ill patients?
   - **A.** Temporary nontunneled dialysis catheters placed in the femoral vein have the same catheter dysfunction and infection rates as those placed in the internal jugular veins.
   - **B.** Tunneled dialysis catheters are associated with better function and fewer infections than temporary nontunneled dialysis catheters in critically ill patients. Thus, evidence-based guidelines recommend that they be used in patients expected to require KRT for more than 7 days.
   - **C.** Catheters should be placed and used in all critically ill patients requiring KRT, regardless of the presence of arteriovenous fistulas or grafts.
   - **D.** Internal jugular catheters are routinely preferred to femoral ones.
4. Which of the following interventions is *not* recommended to reduce central venous catheter–associated bloodstream infection during KRT for critically ill patients?
   - **A.** A formal quality improvement framework and program for catheter insertion and maintenance
   - **B.** Cleaning of catheter tips with a chlorhexidine-based solution
   - **C.** Routine use of antibiotic locks
   - **D.** Routine placement of catheters in the internal jugular site in obese patients
5. Which of the following statements is *false* regarding anticoagulation for acute KRT in critically ill patients?
   - **A.** Patients receiving anticoagulation with heparin have a lower incidence of circuit failure but a higher incidence of bleeding complications compared with to no anticoagulation.
   - **B.** Argatroban is a preferred approach in those with heparin-induced thrombocytopenia.
   - **C.** A high calcium gap (citrate lock) is a common adverse event associated with citrate use.
   - **D.** Periodic flushing of the circuit with saline has been found to prolong circuit life in patients who are not on anticoagulation.

Hepatorenal Syndrome

Javier Fernández, Vicente Arroyo

DEFINITION

Hepatorenal syndrome (HRS) is a potentially reversible functional kidney failure that occurs in patients with acute or chronic liver disease, advanced hepatic failure, and portal hypertension. Although it may occur in patients with subacute liver failure or severe acute alcoholic hepatitis, HRS is mainly observed in patients with advanced cirrhosis. HRS is characterized by impaired kidney function and marked abnormalities in the arterial circulation and endogenous vasoactive systems. In the kidney, there is pronounced vasoconstriction resulting in low glomerular filtration rate (GFR). In the splanchnic circulation, there is marked arteriolar vasodilation resulting in reduction of systemic vascular resistance and arterial hypotension.[1–3] Along with cardiocirculatory dysfunction secondary to portal hypertension, systemic inflammation also plays a major role in the pathogenesis of HRS.[4] Two forms of HRS can be identified on the basis of the progression of the disease (Box 76.1). The acute form (type 1) is characterized by an acute and rapid deterioration in GFR that occurs in the setting of intense systemic inflammation and multiorgan failure (acute-on-chronic liver failure [ACLF]), whereas the chronic form (type 2) has an insidious onset and is characterized by less severe systemic inflammation and moderate kidney failure that follows a steady or slowly progressive course.[1–4]

PSEUDOHEPATORENAL SYNDROME

Pseudohepatorenal syndrome describes concurrent hepatic and kidney dysfunction secondary to a wide variety of infectious, systemic, circulatory, genetic, and other diseases or after exposure to a variety of drugs and toxins (Table 76.1).[5] These entities must be excluded before the diagnosis of HRS can be established. In these conditions, the liver does not play a causal role in the pathogenesis of kidney failure. Pseudohepatorenal syndrome is usually easy to exclude because the causal agent is frequently known and both kidney and liver functional abnormalities are often found at the initial presentation, without evidence of advanced liver failure or portal hypertension. In contrast, HRS invariably occurs after liver failure and portal hypertension are fully established and frequently develops when the patient is undergoing treatment for these conditions or their complications.

PATHOPHYSIOLOGY AND PATHOGENESIS

Circulatory Dysfunction: Kidney and Systemic Hemodynamic Changes

In HRS, reduction in GFR occurs mainly because of kidney cortical hypoperfusion after intense cortical renal vasoconstriction, which can be demonstrated angiographically as marked beading and tortuosity of the interlobular and proximal arcuate arteries and the absence of a distinct cortical nephrogram and vascular filling of the cortical vessels (Fig. 76.1). Intense renal vasoconstriction is the final consequence of marked systemic circulatory dysfunction, characterized by progressive splanchnic arterial vasodilation, reduction of the effective arterial blood volume, hypotension, and homeostatic activation of the vasoconstrictor systems.[3] This further compromises kidney perfusion because intense vasoconstriction results in blunting of the autoregulation of blood flow, so that kidney perfusion becomes more pressure dependent. In HRS, filtration fraction is also reduced, reflecting a dominant increase in afferent arteriolar tone and a decrease in the ultrafiltration coefficient. Serial systemic hemodynamic studies showed that HRS occurs in the setting of reduced mean arterial pressure (MAP), cardiac output, and wedge pulmonary pressure without change in systemic vascular resistance. These findings suggest that an inability to increase cardiac output to compensate for a decrease in preload (secondary to the accentuation of splanchnic arterial vasodilation) also contributes to the pathogenesis of HRS.[6] Vasoconstriction is not confined to the renal vascular bed. In HRS it is also observed in other extrasplanchnic territories, including the liver, brain, muscle, and skin.[2,3]

Neurohumoral Abnormalities

The renal and systemic hemodynamic changes that characterize HRS are a direct consequence of neurohumoral disturbances.[2,3] Activation of the vasoconstrictor systems (the renin-angiotensin-aldosterone system [RAAS], the sympathetic nervous system [SNS], and vasopressin) is the cause of kidney vasoconstriction; meanwhile, activation of the vasodilator systems occurs mainly in the splanchnic circulation and leads to splanchnic vasodilation. Increases in the serum and urinary levels of vasoconstrictors and in the plasma level of vasodilators are observed in patients with HRS. The vasoconstrictors include renin, norepinephrine, neuropeptide Y, arginine vasopressin, endothelin and F_2 isoprostanes, and urinary cysteinyl leukotrienes; the vasodilators include plasma endotoxin, nitrite (end-product of nitric oxide [NO] metabolism), and glucagon. The sympathetic discharges through the renal nerves are also markedly increased.

In contrast to increased plasma and urinary levels of vasoconstrictors and plasma level of vasodilators, decreased urinary levels of vasodilators have been observed in HRS. These include prostaglandin E_2, 6-keto-prostaglandin F_1 (a stable metabolite of renal prostacyclin), and kallikrein. Because the urinary level of these vasodilators is normal in compensated cirrhosis and higher than normal in decompensated cirrhosis with ascites and normal kidney function, it is postulated that a reduction in the renal synthesis of vasodilators is the final event that leads to the development of HRS.[3]

Most of these neurohumoral abnormalities found in HRS are also detected, albeit to a lesser extent, in decompensated cirrhosis (with ascites) with normal kidney function and in compensated cirrhosis (without ascites). These findings support the hypothesis that HRS

most likely represents one end of the spectrum of homeostatic abnormalities that occur in liver failure and portal hypertension.

Systemic Inflammation and Metabolic Derangement

Type 1 HRS is often precipitated by bacterial infections, particularly if these infections trigger a severe inflammatory response.[3] Inflammation represents a major pathogenic factor for HRS. There is now evidence that type 1 HRS is part of a complex syndrome (ACLF) characterized by the development of organ failure(s) (kidneys, liver, brain, heart, peripheral circulation, gut, lungs, adrenal glands, defensive mechanisms against infections).[4,7] The mechanism of ACLF has been related to intense systemic inflammation, activation of cytokines, NO and other mediators, oxidative stress, acute deterioration of systemic circulation, and organ failure. Systemic inflammation in cirrhosis mainly derives from the translocation of viable bacteria and/or pathogen-associated molecular patterns (PAMPs) from the intestinal lumen into the intestinal mucosa and the systemic circulation with or without overt bacterial infection. "Sterile" inflammation can also be caused by the release of danger-associated molecular patterns (DAMPS) by dying hepatocytes in acute hepatic processes (i.e., alcoholic and viral hepatitis). The subsequent sustained activation of innate host immunity leads to the release of proinflammatory cytokines and oxidative stress that impair cardiovascular function and could also damage the kidney and other organs, impairing their function.[4] Systemic inflammation is associated with blood metabolite accumulation in ACLF, indicating marked alterations in major metabolic pathways, in particular mitochondrial dysfunction, which is involved in the development of kidney and extrarenal organ failure.[8]

BOX 76.1 Main Clinical Characteristics of Type 1 and Type 2 HRS

Type 1 HRS

- Acute and rapid deterioration in glomerular filtration rate
- Occurs in parallel with the failure of other organs or systems (e.g., coagulopathy, hepatic encephalopathy)
- In cirrhosis, is a form of acute-on-chronic liver failure
- Frequently follows a precipitating event, mainly bacterial infection
- Rapidly fatal without treatment: mean survival 2 to 3 weeks

Type 2 HRS

- Moderate stable kidney impairment (average serum creatinine 2 mg/dL [176 μmol/L])
- Mainly causes refractory ascites
- Mean survival without treatment: 6 months

HRS, Hepatorenal syndrome.

Summary of Pathogenesis

Fig. 76.2 shows the pathogenesis of HRS. Liver failure and portal hypertension through pathologic bacterial translocation and endotoxemia increase systemic inflammation and vascular production of vasodilators, including NO, carbon monoxide, and glucagon in the splanchnic circulation, leading to the initiating event of splanchnic arteriolar vasodilation (the peripheral arterial vasodilation hypothesis). Splanchnic vasodilation leads to a decrease in systemic vascular resistance, but MAP is initially maintained by an increase in cardiac output, resulting in a hyperdynamic circulation. Splanchnic vasodilation also decreases arterial filling and reduces the effective arterial blood volume. The subsequent stimulation of the central volume baroreceptors leads to compensatory activation of the vasoconstrictor systems, in particular the arginine vasopressin system, RAAS, and SNS (including its hormones norepinephrine and neuropeptide Y), which help restore effective arterial blood volume. This restoration is achieved in patients with compensated cirrhosis but not in patients with decompensated cirrhosis, in whom progressive splanchnic arteriolar vasodilation leads to increased splanchnic capillary pressure, resulting in an increase in lymph formation that exceeds reabsorption capacity. In parallel, further contraction of the effective arterial blood volume leads to reduction of systemic MAP and further stimulation of the vasoconstrictor systems, resulting in sodium and water retention. The net result of these combined effects is continuous ascites formation (the forward theory of ascites formation).[2,3]

TABLE 76.1 Causes of Pseudohepatorenal Syndrome

Potential Causes	Predominantly Tubulointerstitial Involvement	Predominantly Glomerular Involvement
Infections	Sepsis, leptospirosis, brucellosis, tuberculosis, Epstein-Barr virus, hepatitis A virus	Hepatitis B and C viruses, HIV infection, *Schistosoma mansoni,* liver abscess
Drugs	Tetracycline, rifampin, sulfonamide, phenytoin, allopurinol, fluroxene, methotrexate (high dose), acetaminophen overdose	
Toxins	Carbon tetrachloride, trichloroethylene, chloroform, elemental phosphorus, arsenic, copper, chromium, barium, amatoxins,[a] raw carp bile toxins[b]	
Systemic diseases	Sarcoidosis, Sjögren syndrome	Systemic lupus erythematosus, vasculitis, cryoglobulinemia, amyloidosis
Circulatory failure	Hypovolemic or cardiogenic shock	
Malignancy	Lymphoma, leukemia	
Congenital and genetic disorders	Polycystic liver and kidney disease, nephronophthisis, congenital hepatic fibrosis	
Miscellaneous	Fatty liver of pregnancy, Reye syndrome	Eclampsia, HELLP syndrome, cirrhotic glomerulopathy

[a]Accidental poisoning after ingestion of mushrooms of the *Amanita* genus.
[b]Accidental poisoning after ingestion of the raw gallbladder or bile of the grass carp (a common practice in rural East Asia).
HELLP, Hemolysis, elevated liver enzymes, low platelet count; *HIV,* human immunodeficiency virus.

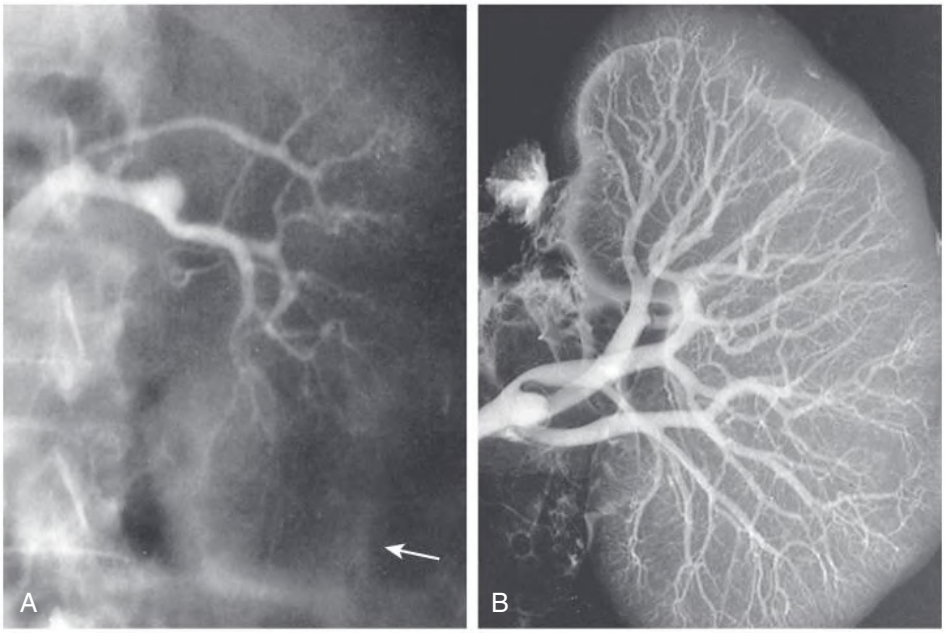

Fig. 76.1 Kidney arteriography of a patient with hepatorenal syndrome (HRS). (A) Kidney angiogram (*arrow* marks the edge of the kidney). (B) Angiogram performed in the same kidney at autopsy. Note complete filling of the kidney arterial system throughout the vascular bed to the periphery of the cortex. The vascular attenuation and tortuosity seen previously (A) are no longer present. The vessels are also histologically normal; this indicates the functional nature of the vascular abnormality in HRS. (From Levenson D, Korecki KL. Acute renal failure associated with hepatobiliary disease. In: Brenner BM, Lazarus JM, eds. *Acute Renal Failure*. Churchill Livingstone; 1988:535–580.)

The splanchnic circulation is resistant to the effects of vasoconstrictors because of local release of vasodilators; progressive splanchnic vasodilation continues to occur as liver failure and portal hypertension progress. This leads to continued contraction of effective arterial blood volume, which, together with the progressive inability of the cirrhotic heart to respond to reduced preload, results in further reduction of MAP and more intense stimulation of the vasoconstrictor systems. Normally, the effect of vasoconstrictors on the kidney circulation is counterbalanced by the reactive production of intrarenal vasodilators. It is postulated that HRS develops when the balance between vasoconstrictors and vasodilators finally breaks down. The likelihood that this will occur increases with progressive or acute deterioration in liver function or increasing severity of portal hypertension (e.g., after acute alcoholic hepatitis) and is precipitated by events that lead to further volume contraction and reduction of the effective arterial blood volume (e.g., spontaneous bacterial peritonitis [SBP]; see later discussion).

Recently the peripheral arterial vasodilation hypothesis has been revisited. This hypothesis did not take into account that patients with cirrhosis and HRS frequently develop other types of organ failure (e.g., liver, brain, coagulation). This syndrome, known as ACLF, is characterized by systemic inflammation and high short-term mortality.[4,7] The sustained activation of the innate immune system caused by an abnormal translocation of bacteria and bacterial products from the intestinal lumen (PAMPs) or by DAMPs would lead to the persistent activation of the innate pattern recognition receptors and subsequent chronic inflammation. This inflammatory process would have two major consequences: first, splanchnic arterial vasodilation secondary to local release of endogenous vasodilators, a feature impairing systemic hemodynamics and organ perfusion, and second, the extension of splanchnic inflammation to the peripheral blood and organs, a feature that could damage these organs, contributing to multiple organ failure (Fig. 76.3).[4] Therefore, severe systemic inflammation and vasodilation are considered key pathogenic events in the development of HRS in the revisited hypothesis.

EPIDEMIOLOGY

The incidence of HRS in the cirrhotic patient is estimated to be 18% at 1 year and 39% at 5 years.[9] Neither the cause nor the Child-Pugh score or the model for end-stage liver disease (MELD) score (www.mdcalc.com/child-pugh-score-for-cirrhosis-mortality/) predicts the incidence of HRS. Rather, independent predictors of HRS include dilutional hyponatremia, impaired systemic hemodynamics (high plasma renin activity, noradrenaline concentration, and low cardiac output),[6,9] abnormal kidney duplex Doppler ultrasound study findings (resistive index > 0.7),[10] and low GFR.[3]

CLINICAL MANIFESTATIONS

Type 1 and type 2 HRS are considered to be different syndromes rather than different expressions of a common underlying disorder.[2,3] Type 1 HRS is characterized by a rapid decline in GFR (see Box 76.1) and is observed in patients with acute decompensation of advanced cirrhosis, severe acute alcoholic hepatitis, or subacute liver failure. In addition to developing rapidly progressive acute kidney injury (AKI), patients also develop multiorgan dysfunction, including severe hepatic failure (jaundice, coagulopathy), brain failure (hepatic encephalopathy), and frequently relative adrenal insufficiency. Oliguria is a universal finding, hyponatremia is almost always present, and arterial blood pressure is usually low. Type 1 HRS may be precipitated by bacterial infections (especially spontaneous bacterial peritonitis), severe gastrointestinal (GI) bleeding, or total paracentesis without albumin administration. Left untreated, type 1 HRS tends to rapidly progress, resulting in death of the patient within 2 to 3 weeks.[9]

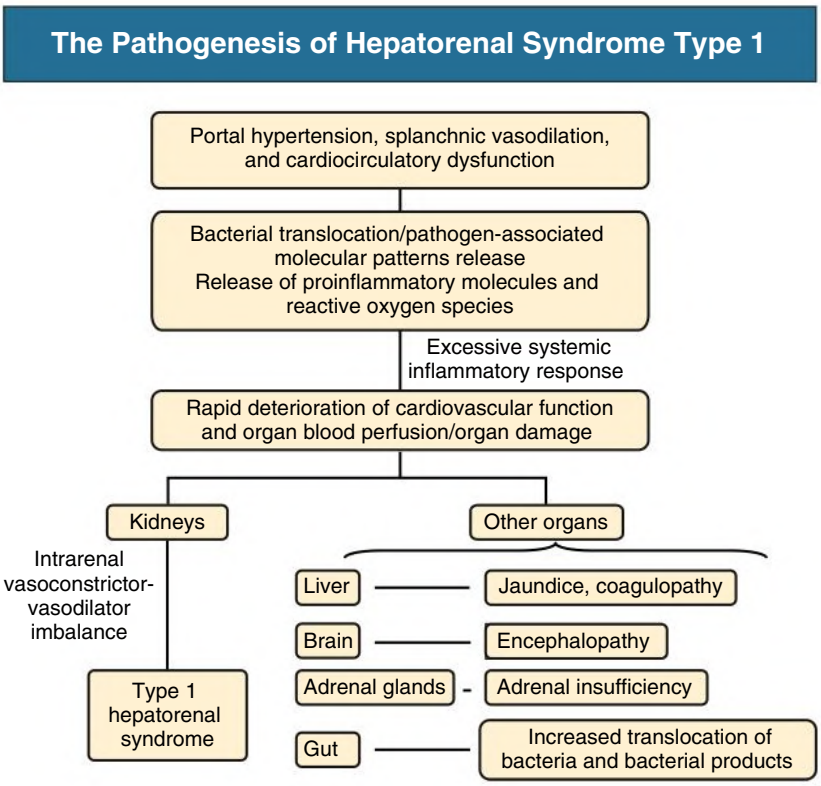

Fig. 76.2 Pathogenesis of Type 1 Hepatorenal Syndrome (HRS). Mechanisms leading to type 1 HRS and multiorgan failure. Patients with cirrhosis and ascites present with severe cardiocirculatory dysfunction that may be further aggravated by infection through the exacerbation of systemic inflammation. Although circulatory dysfunction predominantly affects the kidneys and leads to the development of type 1 HRS, it also decreases the perfusion of other organs and systems such as the liver, with marked impairment in hepatic function and aggravation of portal hypertension; the brain, with the development of hepatic encephalopathy; the adrenal glands, with the development of relative adrenal dysfunction; and the gut, decreasing intestinal motility and promoting intestinal bacterial overgrowth and bacterial translocation. Intense systemic inflammation could also contribute to direct organ damage (immunopathology). (Modified from Arroyo V, Fernandez J, Ginès P. Pathogenesis and treatment of hepatorenal syndrome. *Semin Liver Dis.* 2008;28:81–95; Arroyo V, Fernandez J. Management of hepatorenal syndrome in patients with cirrhosis. *Nat Rev Nephrol.* 2011;7:517–526; and Bernardi M, Moreau R, Angeli P, et al. Mechanisms of decompensation and organ failure in cirrhosis: from peripheral arterial vasodilation to systemic inflammation hypothesis. *J Hepatology.* 2015;63:1272–1284.)

Type 2 HRS is characterized by insidious onset and slowly progressive deterioration of GFR. This is most often observed in patients with cirrhosis and portal hypertension. These patients tend to be less severely jaundiced and mainly present with refractory ascites caused by poor response to diuretics. Low-normal arterial blood pressure, modest prolongation of prothrombin time, and moderate or marked hypoalbuminemia and hyponatremia are usually present. Type 2 HRS tends to progress over months, which most likely reflects the natural course of the disease because additional precipitating factors are not usually identified.[2,3,9] Mean survival time after onset of type 2 HRS is 6 months.

PATHOLOGY

HRS is mainly a functional kidney disorder, and the presence of significant glomerular and/or tubular disease excludes the diagnosis. However, glomerular abnormalities, including mesangial expansion, capillary wall thickening, mesangial and capillary wall electron-dense deposits, and immune deposits of C3 and immunoglobulin A (IgA), IgM, and IgG, are frequently found in cirrhotic patients with normal kidney function and minimal urinary abnormalities. The presence of such glomerular abnormalities in a cirrhotic patient, therefore, does not exclude the diagnosis of HRS. Protrusion of the proximal tubular epithelium into Bowman's space (glomerulotubular reflux) is not specific for HRS and is found in other conditions associated with profound kidney ischemia and terminal hypotension. Although early autopsy studies demonstrated normal tubular morphology in patients who had died of HRS, detailed light and electron microscopic studies have documented proximal tubular lesions consistent with ischemic injury. However, these lesions do not explain the low GFR in HRS patients.[3] Finally, bile salt-related tubular damage can be observed in patients with HRS and severe cholestasis.[11]

DIAGNOSIS AND DIFFERENTIAL DIAGNOSIS

HRS is mainly a diagnosis of exclusion and should be suspected in any patient with subacute or chronic liver disease with advanced liver failure and portal hypertension who develops progressive kidney impairment. In patients with preexisting liver failure, portal hypertension, and kidney failure, the use of nephrotoxic agents (e.g., nonsteroidal anti-inflammatory drugs [NSAIDs] and aminoglycosides) must be stopped, and other conditions leading to kidney failure must be excluded by careful history, physical examination, urine examination, and ultrasound study before the diagnosis of HRS can be considered.

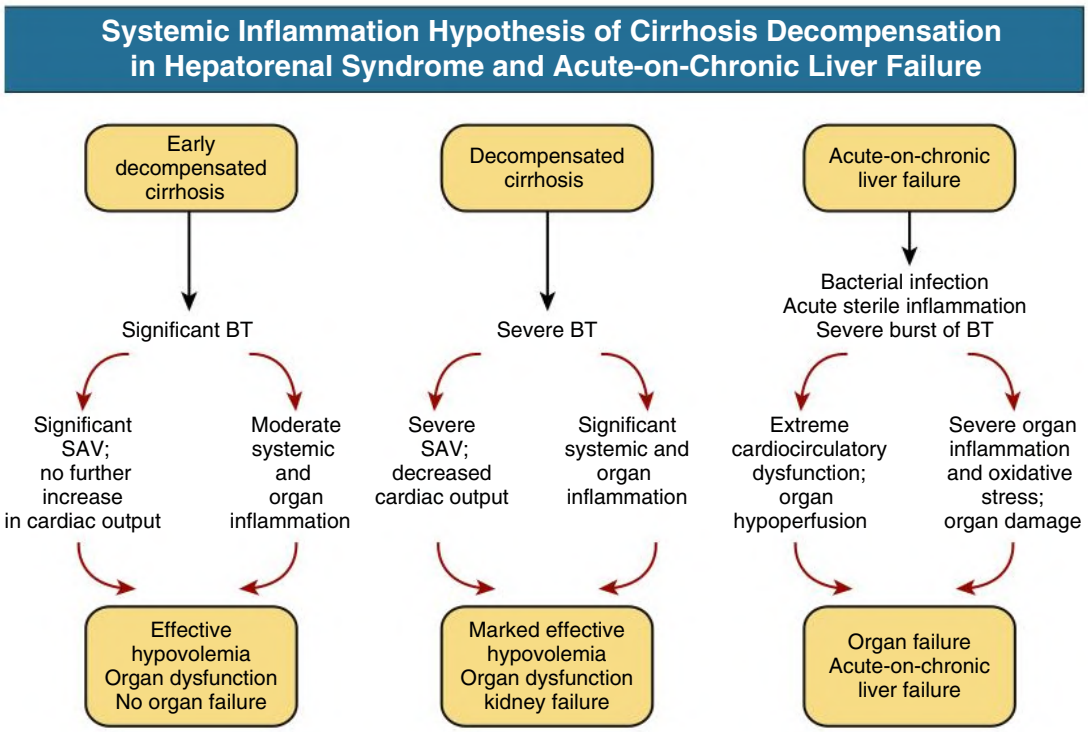

Fig. 76.3 Systemic Inflammation Hypothesis of Cirrhosis Decompensation in Hepatorenal Syndrome and Acute-on-Chronic Liver Failure (ACLF). According to the systemic inflammation hypothesis, bacterial translocation (BT) progressively affects the natural course of cirrhosis, from the compensated stage to hepatorenal syndrome and ACLF. An abrupt increase in systemic inflammation represents the pathophysiologic background for ACLF. *SAV,* Splanchnic arterial vasodilation. (Modified from Bernardi M, Moreau R, Angeli P, et al. Mechanisms of decompensation and organ failure in cirrhosis: from peripheral arterial vasodilation to systemic inflammation hypothesis. *J Hepatology.* 2015;63:1272–1284.)

The absence of shock or GI bleeding and excess loss of extracellular fluid from the GI tract or urine or from equestration of ascites in the peritoneal cavity must be documented. Prerenal AKI must be excluded by withdrawal of diuretics and fluid challenge with albumin 1 g/kg body weight per day up to the maximum of 100 g/day for 2 days. Proteinuria of less than 500 mg/day and absence of microhematuria help exclude significant coexisting glomerular or tubulointerstitial disease leading to kidney failure and supports the diagnosis of HRS.

The diagnostic criteria for HRS were established by the International Ascites Club in 1996[1] and were revised in 2007, 2015, and 2019.[11–13] The main revisions were the exclusion of creatinine clearance as a measure of kidney function (because of the difficulty in obtaining accurate urine collection data), the removal of ongoing bacterial infection as an exclusion criterion (so that treatment of HRS is not delayed), the substitution of saline by albumin as the preferred fluid for plasma volume expansion, the removal of the minor criteria and, more importantly, the removal of a fixed cut-off value of serum creatinine (>1.5 mg/dL [132 μmol/L], >2.5 mg/dL [220 μmol/L] in cases of type 1 HRS) to establish the diagnosis of HRS. This definition of HRS-1 still requires that the diagnosis be established at an advanced stage of AKI (at least stage 2). The most recent revision allows the diagnosis of HRS-AKI in the presence of small increases in serum creatinine (≥ 0.3 mg/dL within 48 hours), therefore promoting the early initiation of vasoconstrictors plus albumin (Box 76.2).[11]

Serum creatinine and blood urea nitrogen (BUN) are poor markers of GFR in cirrhosis.[3] Patients with cirrhosis may have significantly reduced GFR despite normal serum creatinine or BUN because they are frequently malnourished, with reduced lean body mass, and often have a low urea generation rate because of liver failure and low protein intake. Severe hyperbilirubinemia, which is often present in patients with HRS, interferes with the Jaffe reaction (picric acid) for creatinine quantification and may cause falsely low results. Enzymatic creatinine assays are less susceptible to high bilirubin levels. In cases of uncertainty, GFR may be assessed with use of iodine-125–iothalamate or chromium-51–labeled ethylenediaminetetraacetic acid (^{51}Cr-labeled EDTA). Small studies suggest that serum cystatin C could be an accurate GFR marker in the cirrhotic population,[14] but this requires confirmation.

The most important differential diagnosis for kidney failure in cirrhosis is between type 1 HRS (HRS-AKI) and AKI with acute tubular necrosis (ATN-AKI) because they require rapid therapeutic decisions with different treatments. The parameters traditionally used to differentiate ATN from functional kidney failure (urinary sodium excretion and urinary-plasma osmolality ratio) are classically considered of no value in patients with cirrhosis and ascites.[3] However, a fractional excretion fraction of sodium less than 0.2% may help distinguish HRS from ATN.[11] Granular casts may be found in the urinary sediment in both HRS and ATN. Recent data suggest that the determination of the urinary levels of neutrophil gelatinase–associated lipocalin (NGAL), a biomarker of tubular damage, could be helpful to differentiate these two entities. More specifically, a cut-off value of 220 μg/g of creatinine has been reported to have the best predictive accuracy for ATN diagnosis.[11,15] Most patients with ATN-AKI have values greater than this threshold, whereas those with HRS-AKI usually have values less than it.[11] However, further studies are needed to confirm this finding because this biomarker also can be increased in prerenal acute injury[16] and HRS can progress to ATN. In patients with prolonged HRS-AKI, the kidney is damaged because of chronic ischemia and sustained inflammation. In these cases, granular casts can be observed.

BOX 76.2 New Diagnostic Criteria Hepatorenal Syndrome (HRS-AKI) According to the International Ascites Club

- Cirrhosis, acute liver failure, acute-on-chronic liver failure
- Increase in serum creatinine ≥ 0.3 mg/dL within 48 hours or ≥ 50% from baseline value according to ICA consensus document and/or urinary output ≤ 0.5 mL/kg body weight ≥ 6 hours[a]
- No full or partial response, according to the consensus document, after at least 2 days of diuretic withdrawal and volume expansion with albumin. The recommended dose of albumin is 1 g/kg of body weight per day to a maximum of 100 g/day.
- Absence of shock
- No current or recent treatment with nephrotoxic drugs (e.g., nonsteroidal anti-inflammatory drugs, aminoglycosides, iodinated contrast media)
- Absence of parenchymal disease as indicated by proteinuria > 500 mg/day, microhematuria (>50 red blood cells per high-power field), urinary injury biomarkers (if available), and/or abnormal kidney ultrasonography[b]
- Suggestion of renal vasoconstriction based on a fractional excretion of sodium of < 0.2% (with levels < 0.1% being highly predictive)

[a]Requires a urinary catheter.
[b]This criterion is not applicable in cases of known preexisting structural chronic kidney disease (e.g., diabetic or hypertensive nephropathy).
From Angeli P, Garcia-Tsao G, Nadim MK, et al. News in pathophysiology, definition and classification of hepatorenal syndrome: a step beyond the International Club of Ascites [ICA] consensus document. *J Hepatology*. 2019;71:811–822.

NATURAL HISTORY

Without treatment, the median survival rate for type 1 HRS is about 2 weeks; that of type 2 HRS is about 4 to 6 months.[3,9] Patients with type 1 HRS usually die in the setting of multiple organ failure and are now considered to have ACLF, a syndrome recently redefined and characterized by the presence not only of organ failure(s) and high mortality rate but also of systemic inflammation.[7] Severe hepatic encephalopathy, GI bleeding, and sepsis are common final events in these patients. Patients with type 2 HRS are at higher risk for type 1 HRS after the development of a precipitating event.[3]

PREVENTION AND TREATMENT

General Principles in the Prevention of Acute Kidney Injury

In patients with cirrhosis and ascites, excessive diuretic therapy results in volume contraction and AKI. To avoid the latter, a stepwise approach to the treatment of ascites is recommended. All patients are advised to follow a low-sodium diet (60–90 mmol/day, equivalent to about 3.5–5 g of salt per day). After this, spironolactone is prescribed at increasing doses (100 mg/day as initial dose; if there is no response within 4 days, 200 mg/day). If required, furosemide is then added at increasing doses every 2 days of 40 to 80 mg/day. Maximum doses of spironolactone and furosemide are 400 and 160 mg/day, respectively. In patients with diuretic resistance, therapeutic paracentesis is indicated but must be combined with plasma volume expansion with use of albumin (8 g/L of ascites removed) to decrease the incidence of circulatory dysfunction after treatment and to prevent development of HRS. The use of renin-angiotensin system blockers and potentially nephrotoxic agents, including NSAIDs, aminoglycosides, and radiocontrast media, should be avoided as much as possible.[2,3] β-Blockers, used for primary or secondary prophylaxis of variceal bleeding, reduce MAP and GFR and must be used cautiously in patients with cirrhosis and ascites. Kidney function should be closely monitored, especially in patients with refractory ascites. β-Blockers may increase short-term mortality in this specific cirrhotic subpopulation and should therefore be replaced by band ligation of varices.[17]

Preventive Measures

Accepting the hypothesis that HRS represents one end of the spectrum of the homeostatic abnormalities in liver failure and portal hypertension and that it is precipitated by clinical events as volume contraction or bacterial infection, it follows that a major focus of treatment must be to prevent such events and to treat them promptly when they occur. There should be a low threshold for antibiotic therapy for suspected infection in cirrhosis. Spontaneous bacterial peritonitis must be excluded by regular examination of ascites whenever a patient is admitted to the hospital or clinically deteriorates. This infection must be treated not only with broad-spectrum antibiotics but also with albumin infusion (1.5 g/kg at diagnosis and 1 g/kg at day 3) because the latter prevents the subsequent development of HRS and improves short-term survival.[18] A recent randomized controlled trial (RCT) also shows that long-term albumin administration prevents kidney dysfunction and HRS-AKI in patients with cirrhosis and ascites.[19] In contrast, albumin administration is not effective in the prevention of HRS in patients with non-SBP infections nor in hospitalized subjects with acute decompensation and hypoalbuminemia.[20,21] Primary prophylaxis with norfloxacin has been shown to prevent SBP, delay the development of HRS, and improve survival in cirrhotic patients at high risk for complications (low ascitic protein level <15 g/L; advanced liver failure with Child-Pugh score ≥9 and serum bilirubin ≥3 mg/dL or impaired kidney function with serum creatinine ≥1.2 mg/dL or serum sodium ≤130 mmol/L).[22] Norfloxacin is thought to exert its renoprotective effect by reducing the subclinical translocation of viable bacteria and bacterial products from the intestine, systemic inflammation, and NO generation, which, in turn, leads to improved hemodynamics. Prophylactic use of pentoxifylline 400 mg orally three times per day also prevents the development of HRS in patients with acute alcoholic hepatitis, probably by inhibiting the synthesis of tumor necrosis factor-α.[23]

General Approach to Treatment

In patients with preexisting liver failure, portal hypertension, and kidney failure, nephrotoxic agents must be stopped. The absence of shock or GI bleeding, as well as fluid loss, must be documented. Prerenal AKI must be excluded by withdrawal of diuretics and fluid challenge with albumin (1 g/kg per day to a maximum of 100g/day for up to 48 hours). Absence of microhematuria and proteinuria also should be confirmed.

Once HRS-AKI has been diagnosed, patients should be assessed for orthotopic liver transplantation (OLT). Suitable candidates should be placed on the waiting list for deceased donor or, if possible, living donor liver transplantation. Bridge treatments are also needed. Pharmacotherapy (see later), transjugular intrahepatic portosystemic shunt, extracorporeal liver support therapy, and (in patients with advanced uremia) kidney replacement therapy should be considered.

Pharmacotherapy

The most promising pharmacotherapy appears to be vasoconstrictors in combination with albumin, targeted at reversal of splanchnic arteriolar vasodilation and restoration of the effective arterial blood volume (Box 76.3). Vasodilators (aiming to reverse renal vasoconstriction) are

BOX 76.3 Pharmacologic Options in the Treatment of Hepatorenal Syndrome

Terlipressin + albumin[a]: Terlipressin in IV boluses (0.5–1 mg/4–6 h to start, increasing to a maximum of 2 mg/4 h) or as continuous infusion (starting from 2 mg/24 h to maximum dose of 12 mg/24 h). Treatment is maintained until serum creatinine has reached a final value within 0.3 mg/dL of the patient's baseline serum creatinine. Maximum duration of treatment: 14 days.

Norepinephrine + albumin[a]: Norepinephrine IV infusion at 0.5 mg/h to start, increasing the dose by 0.25 to 0.5 mg/h every 4 h up to a maximum of 3 mg/h to achieve an increase in MAP of at least 10 mm Hg. Maximum duration of treatment: 14 days.

Vasopressin + albumin[a]: Vasopressin IV infusion at 0.01 U/min to start, increasing the dose upward to a maximum of 0.8 U/min to achieve an increase in MAP of at least 10 mm Hg. Maximum duration of treatment: 11 days.

Midodrine + octreotide + albumin[a]: Oral midodrine—2.5 to 7.5 mg/8 h + subcutaneous octreotide 100 μg/8 h to start, increasing midodrine dose to a maximum of 12.5 mg/8 h and octreotide dose to a maximum of 200 μg/8 h to achieve an increase in MAP of at least 15 mm Hg. Maximum duration of treatment: 14 days.

[a]Albumin dose: 1 g/kg on day 1 (up to 100 g) followed by 20 to 40 g/day. Central venous pressure monitoring is advised (but not mandatory) to achieve a value of 10 to 15 mm Hg.
IV, Intravenous; *MAP,* mean arterial pressure.

contraindicated in HRS because they are ineffective and can induce marked hypotension.

Vasopressin analogs exhibit preferential vasoconstrictor action on the splanchnic versus the kidney vascular bed. Terlipressin (triglycyllysine vasopressin) is a synthetic analog of vasopressin that, in addition to having a greater effect on the vascular vasopressin receptors (V_1) than the kidney vasopressin receptors (V_2), as a prodrug requiring transformation to the active form (lysine vasopressin), has a prolonged half-life and can be given as an intravenous (IV) bolus or as continuous IV infusion. Continuous administration improves the tolerability of the treatment (lower incidence of systemic ischemic side effects) and improves its effectiveness (treatment is effective at lower doses).[3,24] Prospective studies[25–27] and a large retrospective study[28] in patients with type 1 and type 2 HRS have shown that terlipressin combined with daily albumin infusion improved kidney function in 60% of the treated patients, with 37% surviving beyond 1 month (60% of them without OLT). Reversal of HRS was associated with improved survival.[26,28] The efficacy of terlipressin in the treatment of HRS has been confirmed in five RCTs (Table 76.2).[29–33] Terlipressin was given at a starting dose of 2 to 6 mg/day, and in three studies the dose was titrated upward on the basis of response to a maximum dose of 12 mg/day. Both treated patients and controls were given daily albumin infusion of 20 to 40 g/day. Reversal of HRS was associated with improved survival in only one study.[31] The inclusion of patients with more severe kidney failure in the treated group[30] and the unexpected high response and survival rates in controls[32] may explain why some of these studies did not show a survival benefit of treatment despite success in reversing HRS. The latter is likely a result of the more aggressive use of albumin infusion in these studies because such an approach has been shown to reverse HRS in a high proportion of patients. A meta-analysis confirms that terlipressin plus albumin prolongs short-term survival in patients with type 1 HRS.[34] Response to therapy is characterized by a slow and sustained reduction in serum creatinine and improvement in systemic hemodynamics (marked suppression of the plasma levels of renin and norepinephrine, increase in MAP), urine volume, and serum sodium concentration. Median time to reversal of HRS is 7 days and depends on pretreatment serum creatinine.[3]

Recurrence of HRS after successful treatment tends to be more common in type 2 (around 50%) than in type 1 HRS (20%).[25–27,30,32] Retreatment with terlipressin is successful in most patients.[26,30] Younger age,[28,31] lower baseline serum creatinine level,[32] Child-Pugh score of 12 or lower,[28,31] administration of albumin,[26] serum bilirubin less than 10 mg/dL, and increase in MAP by more than 5 mm Hg after initiation of terlipressin[35] are independent predictors of a successful response to treatment. In patients with severe alcoholic hepatitis, the absence of underlying cirrhosis increases the probability of response to treatment. Child-Pugh score (<12)[26,28,30,31] and MELD score[32] are independent predictors for survival. Transient abdominal pain and diarrhea after the first dose of terlipressin treatment are common. Significant ischemic side effects attributed to terlipressin occurred in an average of 4% to 12% of patients.[25–32] A recent RCT reported a higher rate of severe adverse events, including respiratory failure, in patients receiving terlipressin as IV boluses (10% vs. 3%).[33] Close clinical monitoring of patients (including central venous pressure measurement or noninvasive echocardiographic evaluation of cardiac volume status and function if possible) and administration of terlipressin as continuous infusion are therefore recommended to prevent or rapidly detect the development of any serious adverse event during treatment.

IV vasopressin has been used as an alternative to terlipressin in the treatment of HRS in countries where the latter is not available and was successful in reversing type 1 and type 2 HRS in 42% of patients in a retrospective study.[36] Responders had significantly lower mortality and a higher liver transplantation rate than nonresponders. No adverse effect related to therapy was observed.

IV norepinephrine combined with IV albumin and furosemide reversed type 1 HRS in 10 of 12 patients; 3 survived with OLT, and 4 survived for a median of 332 days without OLT.[37] With use of a similar dosage regimen, two randomized comparative studies showed that norepinephrine is as effective as terlipressin in the treatment of type 1 and type 2 HRS (see Table 76.2).[38,39] All recurrences were successfully retreated with the original regimen. Significant treatment-related side effects were low, and the cost of treatment with norepinephrine was 3 and 15 times lower, respectively, than with terlipressin.

Administration of midodrine (an oral vasoconstrictor with α-adrenergic effect), subcutaneous octreotide, and albumin infusion is less effective in improving kidney function in patients with HRS than the combination of terlipressin plus albumin. In a recent RCT, reversal of HRS was achieved in 56% of patients receiving terlipressin plus albumin compared with only 5% in those receiving octreotide plus midodrine and albumin.[40] If these results are confirmed, octreotide plus midodrine and albumin should be considered the last treatment alternative for patients with type 1 HRS, with terlipressin or norepinephrine combined with IV albumin being the preferred options.

In countries where terlipressin is not available, patients with type 1 HRS should be treated with α-adrenergic drugs (IV norepinephrine or oral midodrine plus subcutaneous octreotide) administered with albumin.

Transjugular Intrahepatic Portosystemic Shunt

Portal hypertension is central in the pathogenesis of the homeostatic abnormalities in HRS. The high operative mortality precludes side-to-side portacaval shunts in HRS patients. The transjugular intrahepatic portosystemic shunt (TIPS) creates a parenchymal tract between branches of the hepatic and portal vein (Fig. 76.4).

TABLE 76.2 Randomized Controlled Trials of Terlipressin or Norepinephrine in Hepatorenal Syndrome

Study	Treatment	Vasoconstrictor Dose	Patients[a]	Reversal of HRS[b] (%)	Survival at 3 Months (%)	Survival at 6 Months (%)

HRS, Hepatorenal syndrome.

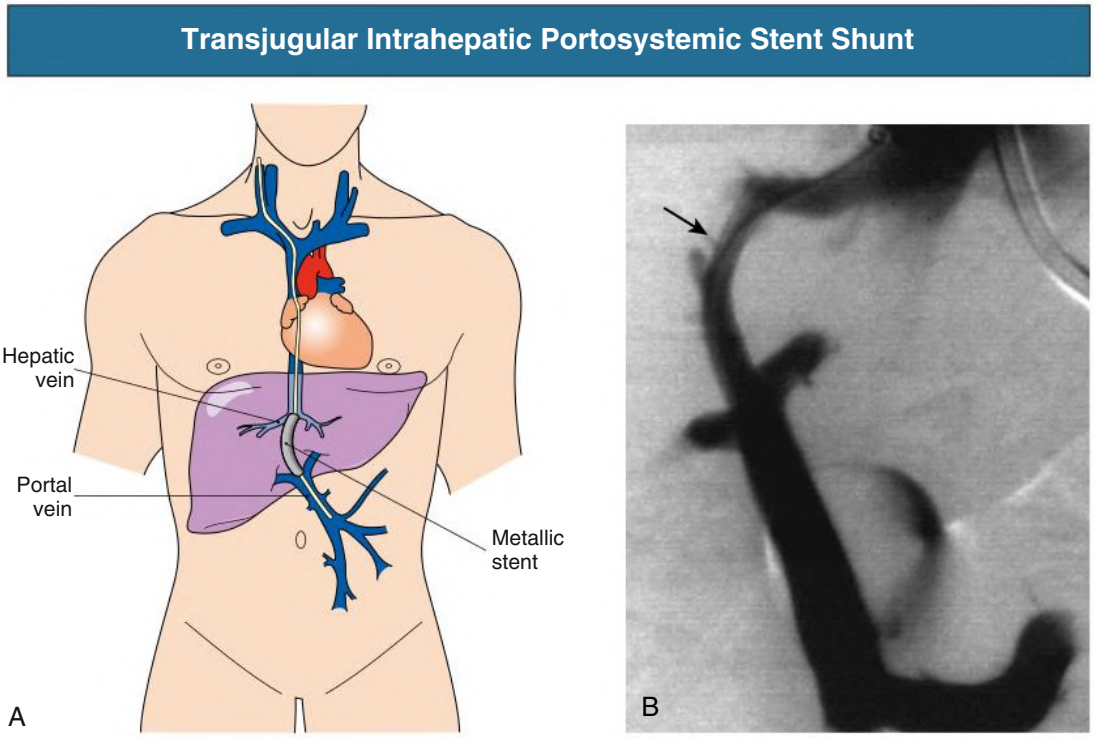

Fig. 76.4 Transjugular Intrahepatic Portosystemic Shunt. (A) An intrahepatic tract has been created between the hepatic vein and the right portal vein. (B) The tract is dilated *(arrow)* and stented, creating a shunt as demonstrated on shuntogram. (Courtesy Dr. W.K. Tso, Queen Mary Hospital, Hong Kong.)

In experienced hands, operative mortality rates are 1% to 2%, and the morbidity rate is 10%. Procedure-related complications include intra-abdominal bleeding, cardiac arrhythmia, shunt migration and thrombosis, hemolytic anemia, fever, infection, and reactions to radiocontrast media (including nephrotoxicity). The resultant diversion of portal blood flow from the liver to the systemic circulation may result in transient deterioration of liver function. Shunt stenosis and hepatic encephalopathy are the main long-term complications of TIPS. Exceptionally, TIPS induces disabling encephalopathy. In these cases, closure of the shunt should be performed.[41] In an

earlier study, TIPS improved kidney function in 6 of 7 HRS patients (all with Child-Pugh score <12) and achieved a mean survival of 4.7 (0.3–17) months.[42] A long-term study of 31 cirrhotic patients with HRS (14 type 1 and 17 type 2) who were not transplant candidates and did not have severe liver failure confirmed that TIPS improved kidney function and survival compared with controls.[43] Shunt stenosis and occlusion occurred in 7 patients (treated in 6 by balloon dilation or stent prolongation), and 11 developed hepatic encephalopathy during follow-up. TIPS therefore could be an alternative treatment of type 1 HRS in patients without response to terlipressin/norepinephrine plus albumin.

Combined TIPS and IV terlipressin therapy was performed in nine patients with type 2 HRS.[27] All seven patients who responded to terlipressin and relapsed after treatment cessation responded to TIPS. In another study, TIPS was performed in five patients with type 1 HRS after successful treatment with midodrine, octreotide, and albumin.[44] Complete normalization of kidney function was observed in all patients at 12 months after TIPS. In both studies, improvement or elimination of ascites was an added benefit.

Extracorporeal Liver Support Therapy

Extracorporeal liver support therapy, as a bridge to OLT, relies on biologic (hepatocytes from human or animal source in an ex vivo perfusion system) or nonbiologic methods, including plasma exchange and albumin dialysis systems. Albumin dialysis (molecular adsorbent recirculating system [MARS] or fractionated plasma separation and adsorption [FPSA]) may have beneficial effects in patients with type 1 HRS. In a small RCT, a mean of five treatments with MARS effectively removed albumin-bound toxic metabolites (i.e., bilirubin and bile acids), improved kidney function, and prolonged survival in eight patients (mean survival, 25 ± 5 days) with type 1 HRS and severe liver failure compared with five control patients treated only with hemodiafiltration (mean survival, 5 ± 2 days).[45] In another study of eight encephalopathic patients with acute alcoholic hepatitis (five with type 1 and two with type 2 HRS), MARS improved kidney function, bilirubin, prothrombin time, grade of encephalopathy, MAP, systemic vascular resistance, and cardiac output, with four patients still alive without OLT at 3 months.[46] Three large RCTs have evaluated albumin dialysis in patients with ACLF.[47–49] In the first study, albumin dialysis with MARS was found to be more effective than standard medical therapy in the management of patients with grade 3 or 4 hepatic encephalopathy. Most patients had HRS, and the treatment was found to be safe.[47] The two other trials compared albumin dialysis with standard medical therapy in patients with type 1 HRS (MARS) or with type 1 and 2 HRS (FPSA). A significant beneficial effect on hepatic encephalopathy was observed in the MARS study but not on survival.[48] In the FPSA trial, no effect on survival was observed in the whole group or in patients with type 1 HRS, but a significant improvement was observed in patients with high MELD score (>30 points). The administered dosage of dialysis was very low in both studies (six sessions of 6 hours in 21 days). In these studies, therapy was well tolerated.[48,49] Further studies are needed to ascertain the potential role of albumin dialysis in type 1 HRS. Patients with type 2 HRS are usually treated by total paracentesis or TIPS.

Kidney Replacement Therapy

Hemodialysis and peritoneal dialysis are difficult in HRS patients with advancing uremia. Conventional hemodialysis is hampered by the invariable systemic hypotension, and the efficacy and safety of peritoneal dialysis have not been well evaluated in these patients. Continuous venovenous hemofiltration (CVVH) or continuous venovenous hemodiafiltration (CVVHDF) has been advocated for the treatment of advancing uremia in HRS,[50] especially patients with fulminant hepatic failure in whom intermittent dialysis can increase intracranial pressure. Anticoagulation should be minimized or avoided (especially in patients with severe coagulopathy) by giving the replacement fluid in the predilutional mode. When anticoagulation is needed, conventional heparin is generally recommended. Regional citrate anticoagulation is not recommended in advanced cirrhosis because the liver plays a significant role in citrate metabolism. If used, dose adaptation and close metabolic monitoring are required, especially after prolonged use. Close serum calcium monitoring is mandatory because hypocalcemia is common because of impaired citrate clearance. Bicarbonate should be used instead of lactate as the buffer for the replacement solution to minimize metabolic acidosis. MARS may be combined with either CVVH or hemodialysis for the treatment of HRS, especially in patients with severe hepatic encephalopathy.

Liver Transplantation

Liver transplantation is the treatment of choice in patients with advanced cirrhosis, including those with type 1 and type 2 HRS.[2,3,51,52] The hemodynamic and neurohormonal abnormalities associated with HRS disappear within the first month after liver transplantation. For this reason, calcineurin inhibitors should be withheld in the first few days after OLT to give the ischemic kidneys a chance to recover. Patients with HRS who undergo transplantation have more complications, spend more days in the intensive care unit, and have a higher in-hospital mortality rate than transplantation patients without HRS. The long-term survival of patients with HRS who undergo liver transplantation, however, is good (3-year survival 60%) compared with transplantation in patients without HRS (70%–80%).[51] Although kidney function improves after transplantation in HRS patients, it never reaches that observed in non-HRS patients.[53] The incidence of end-stage kidney disease in patients with HRS is slightly higher than that observed in transplantation recipients without HRS (7% vs. 2%). Thus, OLT is associated with comparable liver outcome but inferior kidney outcome in patients with HRS. This problem cannot be overcome by performing combined kidney and liver transplantation in HRS, which overall produces outcomes no better than with OLT alone.[54] However, in the rare subgroup of patients with HRS who required prolonged pretransplant dialysis for more than 2 months, combined kidney and liver transplantation did confer an advantage in patient survival and use of hospital resources. These infrequent patients usually have normal kidney size and morphology on ultrasound but develop some additional indications of organic nephropathy during follow-up (mild proteinuria or microhematuria).[55]

The main problem with liver transplantation in type 1 HRS is that most patients die before transplantation. The introduction of the MELD score for listing has partially solved the problem because patients with HRS are prioritized for transplantation. As mentioned earlier, treatment of HRS with vasoconstrictors and albumin improves survival in the group of patients with response to treatment, increasing the number of patients reaching liver transplantation. In addition, reversal of HRS before transplantation may decrease early morbidity and mortality after transplantation and prolong survival.[52]

Therapeutic Algorithm

Fig. 76.5 shows the recommended algorithm for the management of HRS. Recent recommendations have been published by the

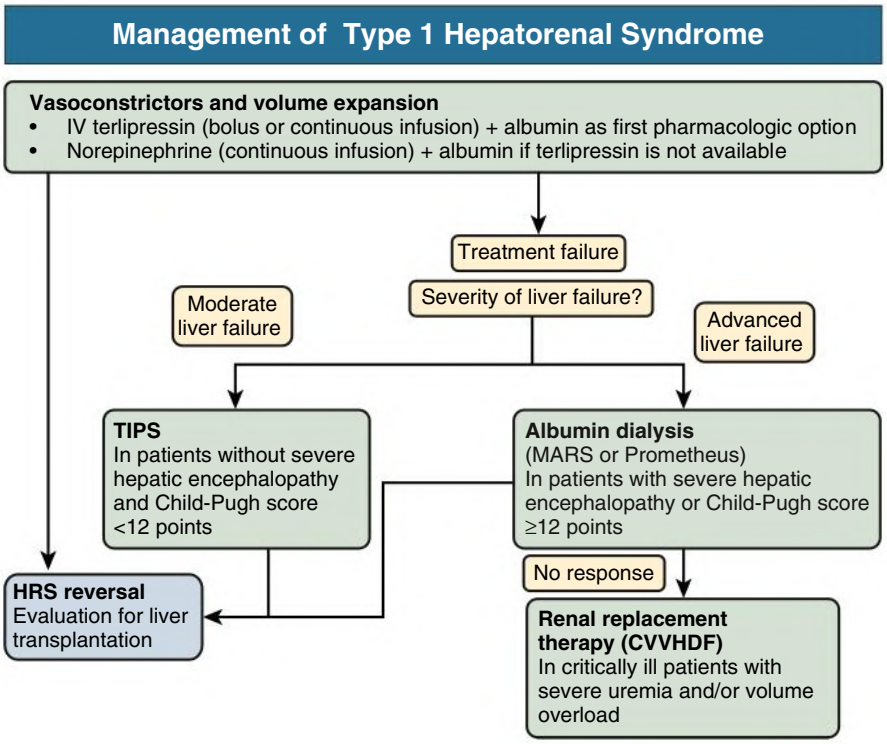

Fig. 76.5 Algorithm for the Management of Type 1 Hepatorenal Syndrome (HRS). Initial treatment is based on the use of vasoconstrictor therapies plus albumin. Intravenous (IV) terlipressin is the most established and is the preferred therapy. If terlipressin is not available, continuous IV norepinephrine should be used. Patients with history of significant atherosclerotic or cardiovascular disease should be treated with norepinephrine. If pharmacologic therapy fails, the severity of liver failure should be assessed. In patients with less severe liver dysfunction (bilirubin < 5 mg/dL or 85.5 μmol/L and Child-Pugh score < 12) without severe hepatic encephalopathy (grade ≤ 2) or history of recurrent encephalopathy, transjugular intrahepatic portosystemic shunt (TIPS) should be considered. In patients with more severe liver failure (Child-Pugh score ≥ 12) and/or severe hepatic encephalopathy (grade > 2), albumin dialysis (molecular adsorbent recirculating system [MARS] or fractionated plasma separation and adsorption [FPSA]) should be considered. In critically ill cirrhotic patients with advancing kidney failure, continuous venovenous hemodiafiltration (CVVHDF) is the treatment of choice.

International Ascites Club.[11,56] OLT is undoubtedly the treatment of choice for patients with HRS, but other treatments described earlier must be used as a bridge to OLT and may improve the kidney outcome after successful OLT. In patients who are not transplantation candidates, these treatments are their only chance for increased survival and in some cases may improve their condition to an extent that may allow them to be reconsidered for transplantation. The choice of therapeutic modalities depends on the availability of resources and expertise on the one hand and the severity of underlying kidney and liver failure and the general condition of the patient on the other. All patients should be considered for vasoconstrictor therapy combined with albumin infusion. Among the vasoconstrictor therapies, IV terlipressin, combined with daily albumin infusion, is most established and is the preferred therapy.[2,3,56] In countries where terlipressin is not available, continuous IV norepinephrine or vasopressin may be used as an alternative. Patients with a history of significant atherosclerotic or cardiovascular disease should be treated with norepinephrine plus albumin. Oral midodrine combined with subcutaneous octreotide and albumin is another alternative in the treatment of HRS, especially in patients with type 2 HRS. In patients with relatively well-preserved liver function (serum bilirubin <5 mg/dL or 85.5 μmol/L and Child-Pugh score <12) without severe hepatic encephalopathy (grade ≤2) or history of recurrent encephalopathy, concurrent severe bacterial infection, or serious cardiovascular or pulmonary disease, TIPS should be considered, especially in patients with recurrence after vasoconstrictor therapy, a situation more commonly observed in HRS type 2 patients.[3] In these patients, TIPS may have the added benefit of relieving refractory ascites. TIPS also appears to achieve complete normalization of kidney function in selected patients after an initial successful response to vasoconstrictor therapy. In patients with severe liver failure (Child-Pugh score ≥12) and severe hepatic encephalopathy (grade >2), MARS should be considered. In critically ill cirrhotic patients with advancing kidney failure, CVVH is the treatment of choice and may be combined with other therapeutic modalities, especially MARS or FPSA.

SELF-ASSESSMENT QUESTIONS

1. Which of the following pathogenic events is/are usually not observed in patients with HRS?
   - **A.** Splanchnic vasodilation
   - **B.** Cardiac dysfunction
   - **C.** Systemic inflammation and mitochondrial dysfunction
   - **D.** Tubular and glomerular lesions
2. Diagnosis of HRS is established by which one of the following?
   - **A.** Liver biopsy
   - **B.** Kidney biopsy
   - **C.** Measurement of plasma renin activity
   - **D.** It is a clinical diagnosis and is established by exclusion.
3. Which affirmation(s) is/are incorrect in patients with hepatorenal syndrome?
   - **A.** It occurs in patients with subacute or chronic liver failure and portal hypertension.
   - **B.** Patients are normally hypertensive.
   - **C.** Plasma renin activity is usually high.
   - **D.** It can be observed in patients with and without ascites.
   - **E.** Patients can be infected.
4. Which affirmation(s) is/are incorrect regarding the treatment of patients with HRS?
   - **A.** The combination of terlipressin and albumin is the preferred treatment.
   - **B.** TIPS is an alternative treatment.
   - **C.** Patients must undergo early dialysis.
   - **D.** Albumin dialysis can be used in patients in whom pharmacologic treatment has failed.
   - **E.** The combination of midodrine, octreotide, and albumin is a very effective pharmacologic option.
5. Which affirmation(s) is/are correct in the prophylaxis of hepatorenal syndrome?
   - **A.** Norfloxacin prevents the development of HRS in patients with advanced cirrhosis and low-protein ascites.
   - **B.** Albumin infusion (1.5 g/kg at diagnosis and 1 g/kg at day 3) prevents the development of HRS and improves short-term survival in patients with SBP.
   - **C.** Albumin infusion prevents HRS in patients with infections other than SBP.
   - **D.** Oral midodrine prevents HRS.

Principles of Drug Therapy, Dosing, and Prescribing in Chronic Kidney Disease and Kidney Replacement Therapy

Matthew J. Cervelli, Terry E. Jones, Sanja Mirkov

Reduced glomerular filtration rate (GFR) can alter drug pharmacokinetics and, consequently, patients with chronic kidney disease (CKD) are at greater risk of adverse effects. In addition, these patients take multiple drugs and are at higher risk for drug interactions and drug-related problems.[1] To prescribe safely and effectively, clinicians should be familiar with the pharmacokinetics of drugs in varying stages of CKD and kidney replacement therapy (KRT) and ideally rely on data from these populations. Unfortunately, such information is not always available, and exclusion of these patients from clinical studies can lead to restrictive recommendations. This chapter describes pharmacokinetic principles and highlights common prescribing issues in patients with CKD, dialysis, and transplantation. Specific dose recommendations and pharmacokinetic data are not included but can be obtained elsewhere.[2–5]

PHARMACOKINETIC PRINCIPLES

Pharmacokinetics describes the behavior of a drug (or metabolite) in the body in terms of its absorption, distribution, metabolism, and elimination (Fig. 77.1 and Table 77.1).[6,7]

Absorption

Bioavailability

Bioavailability (F) is the portion of the drug dose that appears in the systemic circulation after administration. Drugs given intravenously have 100% bioavailability, whereas drugs given by alternative routes pass through a series of biologic membranes before entering the systemic circulation so that only a fraction may reach the circulation. After oral administration, the liver can metabolize a drug during first pass as it is being absorbed or later as it is delivered via systemic blood flow. First-pass metabolism can significantly reduce absorption. The gastrointestinal (GI) mucosa can also influence absorption by the presence of drug-metabolizing enzymes and drug efflux pumps including P-glycoprotein.[8]

CKD can theoretically influence drug absorption, although these effects are difficult to quantify, and clinical examples are limited. GI edema can limit oral drug absorption (e.g., furosemide in nephrotic syndrome). Nausea and vomiting from uremia can impair absorption and contact time between a drug and GI mucosa. In advanced uremia, the alkalinizing effect of salivary urea may decrease absorption of drugs optimally absorbed in an acid milieu. Commonly prescribed metallic divalent ion phosphate binders (e.g., aluminum, calcium, and magnesium salts) can decrease drug absorption by forming nonabsorbable complexes with drugs (Table 77.2).[9] Changes in cardiac output can reduce the rate and extent of absorption for drugs with significant first-pass metabolism.

Increased absorption in patients with CKD from reduced first-pass metabolism is seen with some β-blockers, dextropropoxyphene, and dihydrocodeine. Comorbidities in CKD patients also can have an effect (e.g., erratic absorption because of diabetic GI neuropathy).

Distribution

Volume of Distribution

After absorption, drugs may distribute from plasma to an extravascular compartment. Each drug has a characteristic volume of distribution (V_D), which does not correspond to an anatomic space but instead relates the amount of drug in the plasma to the amount in tissue. A high V_D means a relatively smaller amount remains in plasma and more is in tissues. V_D is used to calculate the loading dose to achieve a desired plasma concentration (V_D = dose/[plasma]). Water-soluble drugs tend to be restricted to the extracellular fluid space and have a relatively small V_D. Lipid-soluble drugs penetrate body tissues and have a large V_D. Increases in V_D can occur with edema, ascites, or infection, particularly for water-soluble drugs. If usual doses are given, low concentrations result. Conversely, muscle wasting or volume depletion can decrease the V_D of water-soluble drugs, and usual doses produce high concentrations.

Plasma Protein Binding

Some drugs bind extensively to plasma proteins.[10] It is only the free (unbound) fraction that exerts a pharmacologic effect. If protein binding is reduced, a greater free fraction is available for any given total drug concentration, which may increase drug activity. Organic acids usually have a single binding site on albumin, whereas organic bases have multiple binding sites on glycoproteins. Protein binding can be altered in CKD, especially when serum albumin is low (e.g., nephrotic syndrome) or when uremic toxins displace drugs from binding sites (Table 77.3). Predicting the effect of changes in protein binding is difficult and effects may be transient after acute displacement. For example, phenytoin has marked decreases in protein binding in patients

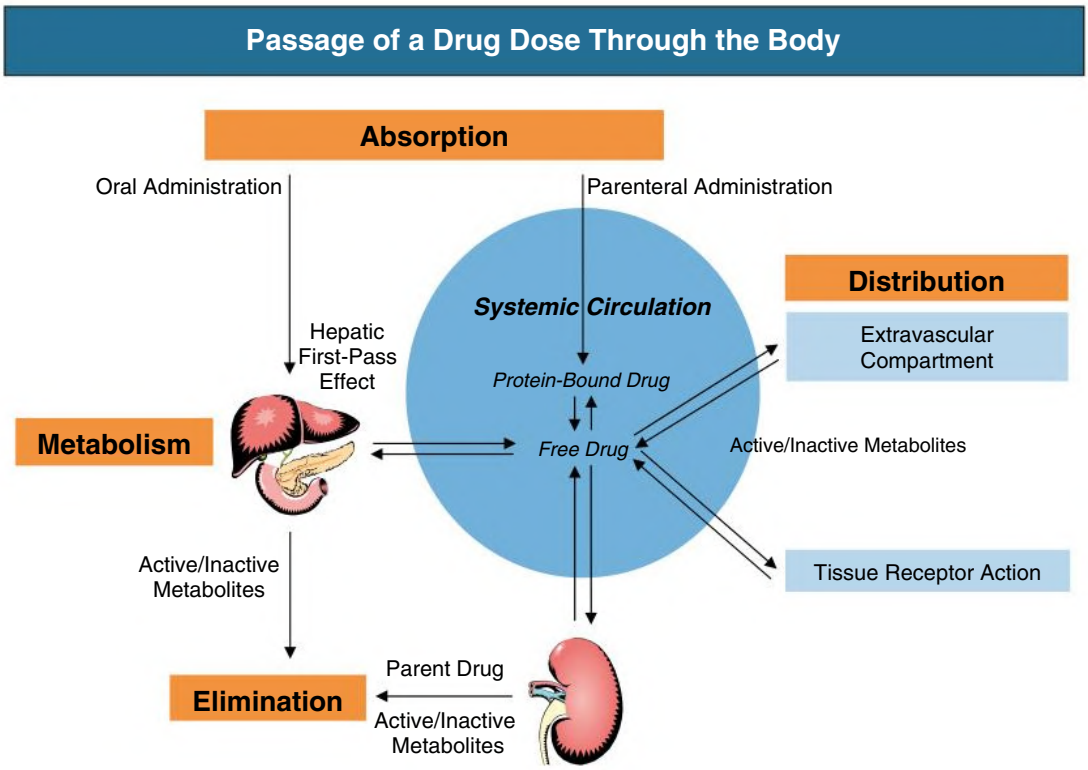

Fig. 77.1 Passage of a drug dose through the body.

TABLE 77.1 Pharmacokinetic Parameters

Parameter	Definition	Application
Bioavailability *(F)*	Percentage of a dose that appears in the systemic circulation after administration.	Determines the amount of drug reaching the systemic circulation. Determines intravenous and oral dose sizes.
Volume of distribution (V_D)	Proportionality constant relating the amount of drug in the body at a given time to a simultaneously occurring drug concentration in plasma or blood. A primary pharmacokinetic parameter.	Determines the size of loading doses. Explains the percentage of the total drug residing in plasma.
Clearance	Volume of blood cleared of the drug in a unit of time; a primary pharmacokinetic parameter.	Determines the "daily" maintenance dose and frequency of dosing.
Half-life ($t_{1/2}$)	Time taken for the drug concentration in plasma to fall to half its current value. A derived parameter calculated from both clearance and V_D.	Determines the frequency of administration and time to steady state.

with CKD, and toxicity can occur despite normal or low total plasma concentrations because of an increase in the free fraction. With albuminuria, bound drug may also be lost, which partially explains the refractoriness of nephrotic patients to diuretics. In CKD, high plasma levels of α_1-acid glycoprotein are induced in acute and chronic inflammation, which can increase drug binding.

Metabolism

Drug metabolism is primarily a hepatic function by which drugs are converted to more water-soluble entities, which promotes elimination by the kidneys and bile. Despite the assumption that extra renal clearance is unchanged, reduced GFR can alter and slow drug metabolism.[11] Importantly, some drugs have active or toxic metabolites that are cleared by the kidney and such metabolites can accumulate in patients with CKD. The kidneys also have a metabolic role with insulin and imipenem.

Elimination

The kidney is the most important organ for drug and metabolite elimination. Terms to describe drug clearance are shown in Box 77.1. Total drug clearance is expressed as the volume of blood or plasma from which the drug is cleared per unit of time and can be calculated by dividing dose by the area under the drug concentration curve (AUC). *Half-life* describes the time taken for plasma concentrations to halve and is affected by both V_D and clearance. Quantitation of drug elimination by the kidney is expressed as kidney clearance, which depends on renal blood flow and the innate ability of the kidney to remove the drug. Renal drug clearance is the sum of its removal by GFR and tubular secretion, minus that reabsorbed via tubular reabsorption. Glomerular filtration depends on molecular size (<10 kDa), charge, and free fraction. Tubular secretion of drugs may change with kidney disease, but measurement of tubular function is difficult. As GFR decreases, drugs dependent on tubular secretion are also excreted more

TABLE 77.2 Effect of Food and Phosphate Binders on Oral Drug Absorption

Drug	Effect of Food
Captopril	Decreases serum drug levels
Bisphosphonates (oral)	Significantly reduce drug absorption
Cinacalcet	Significantly increases drug absorption
Iron (oral)	Decreases absorption
Ketoconazole or itraconazole	Increase absorption with reduced pH
Sirolimus	High-fat meals increase absorption
Tacrolimus	Reduces drug absorption
Bisphosphonates (oral)	Calcium-containing binders significantly reduce absorption
Fluoroquinolones	Reduction in absorption
Tetracycline	Reduction in absorption
Thyroid hormones	Reduction in absorption

BOX 77.1 Mathematics of Drug Elimination

$$\text{Total body clearance} = \text{Drug dose/AUC}$$

$$\text{Renal clearance} = \text{Total amount of drug in urine/plasma drug concentration}$$

$$\text{Total amount of drug in urine} = [\text{Drug}] \times \text{Volume of the sample collected in a fixed time}$$

$$\text{Drug half-life } (t_{1/2}) = V_D \times 0.693/\text{Clearance}$$

AUC, Area under the concentration-time curve; V_D, volume of distribution (dose/blood concentration).

slowly, although tubular secretion may be relatively spared and total kidney clearance may be much higher than would be predicted from estimating GFR alone (e.g., penicillins). For a given level of extra renal clearance, as GFR falls, clearance of drugs (and metabolites) eliminated by the kidney also falls and half-life is prolonged.

PRESCRIBING PRINCIPLES FOR CHRONIC KIDNEY DISEASE AND KIDNEY REPLACEMENT THERAPY

Ideally, drug doses should be modified based on published data on drug kinetics in varying stages of CKD. However, lack of reliable data and individual patient factors limit this.[12] Dose nomograms, tables, and computer recommendations can guide dose modifications, but they are only a guide and therapeutic drug monitoring and clinical acumen are important too.

Initial Assessment and Laboratory Data

A targeted history is important in assessing dose in CKD patients. Previous drug efficacy or toxicity should be determined and the current prescribed medications reviewed for potential interactions or nephrotoxins. Physical and laboratory parameters indicate volume status, height, weight, and extrarenal disease (e.g., liver).

Estimating Renal Function for Drug Dosage

Estimating kidney function is essential to guide drug dosing in patients with CKD. The Cockcroft-Gault equation estimates creatinine clearance and is individualized for each patient (by body weight) and has been the most widely used and accepted method for drug dosage calculation. The Modification of Diet in Renal Disease (MDRD) formula and Chronic Kidney Disease–Epidemiology Collaboration (CKD-EPI) formula can give different estimates of kidney function, especially if not corrected for body surface area because they are not individualized and are normalized for body surface area (mL/min/1.73 m^2). These equations can lead to recommendations different from those obtained by the Cockcroft-Gault equation. An important limitation of all kidney function estimates is inaccuracy of single-point estimates when kidney function is rapidly changing (and creatinine concentration is not at steady state). This may lead to overestimation or underestimation of kidney function and underdosing or overdosing. In patients with rapid-onset severe acute kidney injury (AKI), the decline in GFR is so rapid that patients may require doses for GFR below 10 mL/min. The opposite is true in rapidly improving kidney function after AKI or early posttransplant where there is a risk of underdosing.

Whether estimated using creatinine clearance or GFR, the greater the degree of reduction in kidney function, the greater the potential need for dose modification. With exceptions, dose modification usually is not clinically necessary until GFR (or creatinine clearance) is less than 30 mL/min/1.73m^2. Assessment of kidney function for drug dosing is not a precise science. What is important for clinical decision making is awareness that kidney function is impaired, and approximately to what extent, rather than knowledge of the precise GFR.[13] Using the extent of reduction in GFR to classify CKD severity is discussed in Chapters 3 and 80.

TABLE 77.3 Protein Binding of Drugs in Renal Disease

Major Effects	Minor Effects
Albumin: Binding Sites for Acidic Compounds	
Barbiturates (↓)	Ascorbic acid (↑)
Benzodiazepine (↑)	Valproate (↓)
Carbamazepine (↑)	Fatty acids (↑)
Fibrates (↑)	Nafcillin (↑)
Furosemide (↓)	Phenylbutazone (↓)
Mycophenolate mofetil (↑)	Probenecid (↑)
Penicillins (↑)	Thiopental (↓)
Phenytoin (↓)	Warfarin (↓)
Sulfonamides (↓)	Thyroxine (↓)
Globulins: Binding Site for Basic Compounds	
Digoxin (↓)	Adenosine (↑)
Methadone (↑)	Amitriptyline (↑)
Propranolol (↑)	Chloramphenicol (↑)

↓ Indicates reduced protein binding in chronic kidney disease (CKD) patients; ↑ indicates increased protein binding in CKD patients. However, the therapeutic effect is not easily predicted (see text).

Activity and Toxicity of Metabolites

It is important to consider the activity and/or toxicity of drug metabolites in addition to that of the parent drug when determining drug selection and dosing in patients with CKD because metabolites that are normally cleared by the kidney can accumulate, leading to enhanced drug action or toxicity (Table 77.4).

Fraction of Active Drug (and Active or Toxic Metabolite) Excreted Unchanged in Urine

The greater the fraction of active drug or metabolite excreted unchanged by the kidneys (f_e), the greater is the need for dose modification. It is usually only clinically necessary to modify doses if the f_e is greater than 25% to 50%. When ascertaining f_e, it is important to note that values are often obtained from studies that do not distinguish between parent

TABLE 77.4 Drugs With Active or Toxic Metabolites That Accumulate in Patients With Reduced Glomerular Filtration Rate

	Active Metabolite	Consequence
Allopurinol	Oxypurinol	Nil
Cefotaxime	Desacetyl cefotaxime	
Glyburide	4-*trans*-Hydroxyglibenclamide 3-*cis*-Hydroxyglibenclamide	Hypoglycemia
Morphine	Morphine-6-glucuronide	CNS side effects
Tramadol	*O*-Desmethyltramadol	CNS side effects
Venlafaxine	*O*-Desmethylvenlafaxine	CNS and cardiovascular side effects
	Toxic Metabolite	**Consequence**
Dapsone	Monoacetylated metabolite	
Meperidine (pethidine)	Normeperidine (norpethidine)	CNS (seizures)
Nitroprusside	Thiocyanate	Cyanide toxicity
Procainamide	*N*-Acetylprocainamide (NAPA)	Arrhythmia
Propoxyphene	Norpropoxyphene	Cardiac toxicity

CNS, Central nervous system.

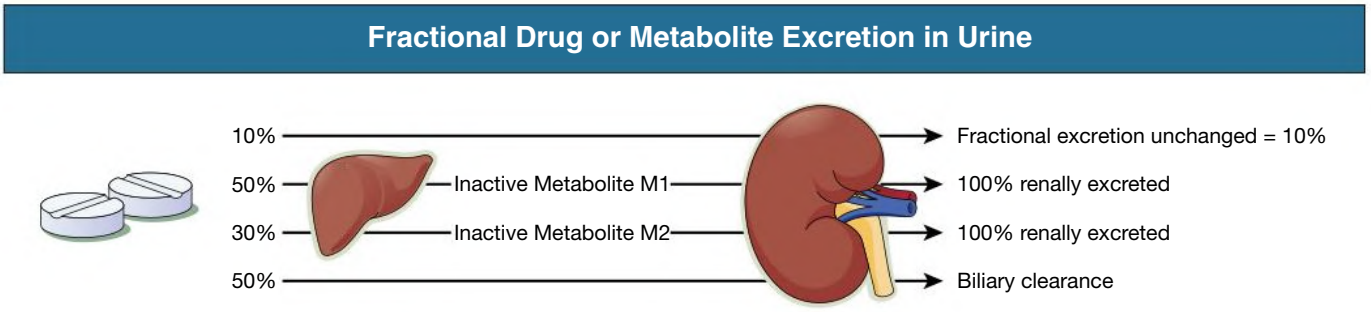

Fig. 77.2 Fraction of Drug or Metabolite Excreted in Urine. In this hypothetical example, 10% of the dose is excreted unchanged in urine (f_e = 10%); 50% of the dose is metabolized to inactive metabolite M1, which is then all renally excreted; 30% of the dose is metabolized to inactive metabolite M2, which is all renally excreted; and the remaining 10% is excreted unchanged in bile. For this drug, the total excretion of drug dose in urine is 90%. However, this 90% includes 10% as parent drug and 80% as inactive metabolites, and dose modification is probably not essential even in severe chronic kidney disease. Total kidney excretion of the dose is 90%; however, the clinically significant fraction of active drug excreted in urine is 10%.

drug and metabolites. The contribution of inactive/nontoxic metabolites to overall kidney drug elimination may exaggerate the potential for harm. Active or toxic metabolites should be assessed separately for their dependence on kidney elimination in the same way as the parent drug (Fig. 77.2).

Therapeutic Index of the Drug or Metabolites

The decision to modify dosage in CKD patients is influenced by the therapeutic window or index of the drug. The *therapeutic window* is the range of plasma drug concentrations between the minimum concentration for clinical efficacy and minimum concentration for toxicity. The *therapeutic index* is the ratio of these concentrations (Fig. 77.3). If the therapeutic window is wide (e.g., many penicillins), there may be no clinical need for dose modification despite much higher plasma concentrations found in CKD patients. If the therapeutic window is narrow (e.g., digoxin), dose modification is more important. Clinicians should judge the clinical relevance of increased exposure to drug or metabolites.

Avoiding Nephrotoxic Drugs

A wide range of drugs can cause nephrotoxicity (Table 77.5). Idiosyncratic nephrotoxicity (e.g., interstitial nephritis; see Chapter 64) is unpredictable and independent of dose. Predictable hemodynamic-related nephrotoxicity can occur with any drug that reduces blood

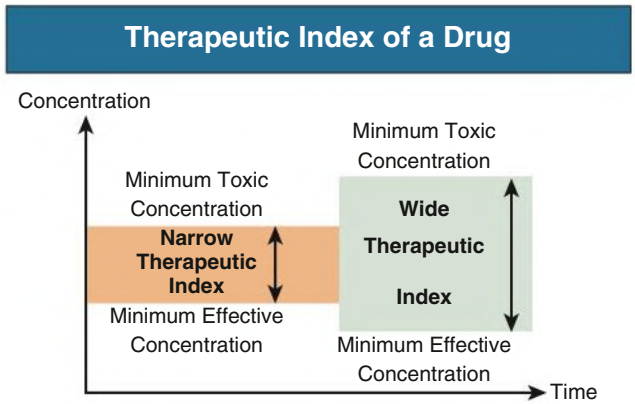

Fig. 77.3 Therapeutic Index of a Drug. Example of a drug with a narrow therapeutic index *(left),* and a drug with a wide therapeutic index *(right).*

volume, systemic blood pressure, or glomerular pressure because these affect the amount of blood delivered to the kidneys. These include all antihypertensives but especially angiotensin-converting enzyme (ACE) inhibitors and angiotensin receptor blockers (ARBs), nonsteroidal anti-inflammatory drugs (NSAIDs), diuretics, and laxatives. Many of these compounds result in a decrease in estimated GFR (eGFR) without structural injury and the eGFR reverses on stopping the drug

TABLE 77.5 Examples of Nephrotoxic Drugs

Examples	Mechanism	Prevention and Management
ACE inhibitors, ARBs	Impair angiotensin II–mediated afferent arteriole dilation during kidney hypoperfusion	Withdraw in kidney hypoperfusion (e.g., extracellular volume depletion)
Aminoglycosides (amikacin, gentamicin, tobramycin)	In proximal tubules, aminoglycosides bind to anionic phospholipid, are delivered to megalin, are taken up into the cell, accumulate, and cause direct toxicity.	Alternative if possible Monitor drug concentrations Avoid multiple daily doses Withdraw if SCr rises
Antifungals (amphotericin)	Afferent vasoconstriction and direct action to reduce GFR Distal tubular injury via creation of pores that increase membrane permeability leading to hypokalemia, hypomagnesemia, metabolic acidosis caused by tubular acidosis, polyuria from nephrogenic diabetes insipidus	Avoid use Administer slowly with hydration Use liposomal preparations
Antivirals		
Acyclovir	High drug levels result in drug crystals causing intratubular obstruction and foci of interstitial inflammation	Avoid bolus dose Reduce dose in CKD Hydrate during therapy
Cidofovir	Induces apoptosis in proximal tubule leading to tubular dysfunction, diabetes insipidus, kidney failure	Oral probenecid and hydration
Foscarnet	Direct tubular toxicity leading to acute tubular necrosis, nephrogenic diabetes insipidus Crystals in glomerular capillary lumen and proximal tubular lumen	Hydration
Indinavir	Crystal neuropathy, nephrolithiasis leading to obstructive AKI	Hydration
Calcineurin inhibitors (cyclosporine, tacrolimus)	↓ PG and ↑ 20-HETE acid production leading to vasoconstriction, generation of H_2O_2 resulting in depleted glutathione leading to decreased GFR, ischemic collapse or scarring of the glomeruli, vacuolization of the tubules, and focal areas of tubular atrophy and interstitial fibrosis	Measure plasma concentrations Avoid interacting drugs Withdraw drug (switch to mTOR inhibitor)
Chemotherapeutics		
Cisplatin	*Cis* chloride replaced by H_2O leading to highly reactive OH radical leading to DNA injury, tubular cell death, nephrogenic diabetes insipidus, hypomagnesemia (may be persistent)	Forced diuresis and hydration
Ifosfamide	Direct tubular injury and mitochondrial damage leading to kidney tubular acidosis, Fanconi-like syndrome, nephrogenic diabetes insipidus, hypokalemia	
Intravenous immunoglobulin (sucrose-containing products)	Accumulation of sucrose in proximal convoluted tubules Increased osmolarity leading to cell swelling, vacuolization, and tubular luminal occlusion	Infusion rate < 3 mg sucrose/kg/min Avoid radiocontrast Avoid sucrose-containing product Hydration
Lithium	Impairment of collecting duct concentrating ability leading to diabetes insipidus Chronic tubulointerstitial nephropathy (tubular atrophy and interstitial fibrosis)	Measure plasma concentrations Prevent dehydration Avoid thiazides Avoid NSAIDs
NSAIDs	Hemodynamically induced AKI caused by vasoconstriction via reduced prostaglandin production Recruitment and activation of lymphocytes leading to acute and chronic tubulointerstitial nephritis, with or without nephrotic syndrome	Avoid use Withdraw during hypoperfusion Withdraw (add corticosteroids)
Proton pump inhibitors	Allergic acute interstitial nephritis	Withdraw (add corticosteroids)
Radiocontrast media	High osmolarity, medullary vasoconstriction, ↑ active transport in thick ascending loop of Henle leading to ↑ O_2 demand	Hydration preprocedure and postprocedure acetylcysteine
Sulfonamides	Intrarenal precipitation leading to kidney stone formation	Fluid intake > 3 L/day; monitor urine for crystals Alkalinize urine to pH > 7.15 if crystals seen

ACE, Angiotensin-converting enzyme; *AKI,* acute kidney injury; *ARBs,* angiotensin receptor blockers; *CKD,* chronic kidney disease; *GFR,* glomerular filtration rate; *20-HETE acid,* 20-hydroxyeicosatetraenoic acid; *H_2O_2,* hydrogen peroxide; *mTOR,* mammalian target of rapamycin; *NSAIDs,* nonsteroidal anti-inflammatory drugs; *PG,* prostaglandin; *SCr,* serum creatinine.

(especially sodium-glucose cotransporter-2 [SGLT2] inhibitors and ACE inhibitors), but if perfusion pressure is sufficiently reduced, ischemic injury might occur. Direct tubular nephrotoxins include aminoglycosides, vancomycin, amphotericin, cisplatin, calcineurin inhibitors (CNIs), and radiographic contrast media. Obstructive uropathy can occur with crystallization of acyclovir or creatinine phosphokinase from statin-induced rhabdomyolysis. In dialysis patients with no significant residual kidney function, use of nephrotoxic drugs may be acceptable. Drug nephrotoxicity is discussed further in Chapter 70.

Drugs That Aggravate the Metabolic/Biochemical Effects of Reduced Glomerular Filtration Rate

Some drugs have no direct adverse effect on kidney function but when used in CKD patients can aggravate the metabolic/biochemical consequences of reduced GFR. Hyperkalemia is exacerbated by potassium supplements, potassium-sparing diuretics, aldosterone antagonists, and blockers of the renin-angiotensin system. The catabolic effects of tetracycline can exacerbate uremia. Sodium-containing drugs and those that promote sodium and water retention (e.g., corticosteroids) should be used cautiously because they may provoke fluid overload and hypertension.

Effect of Reduced Glomerular Filtration Rate on Pharmacodynamic or Physiologic Mechanisms

CKD may alter a pharmacodynamic response or physiologic process, which, in turn, affects clinical response. For example, the inability of impaired kidneys to activate vitamin D precursors means that vitamins D_2 and D_3 may be less effective. Also, CKD patients often have a coagulopathy from the effects of uremia on platelet function and may be more prone to the bleeding complications of anticoagulant and antiplatelet therapy.

Effect of Reduced Glomerular Filtration Rate on the Concentration of Drug at the Site of Action

Reduced GFR can alter drug concentration at the site of action. Some diuretics (furosemide) and antibiotics (nitrofurantoin) are less effective in CKD patients because they do not achieve adequate concentrations at their site of action within the lumen of the kidney tubules (furosemide) or bladder (nitrofurantoin).

Location of Drug Action

Drugs that have negligible bioavailability and those that are used for a local or topical effect may be given safely at normal dose despite toxicity with systemic doses. These include topical NSAIDs, nebulized gentamicin, and oral vancomycin.

Method of Administration

In fluid-restricted patients, administration of intravenous (IV) drug infusions with approved fluid volumes may be undesirable. When the volume needed to administer IV drugs impacts on daily fluid restrictions, consider alternative drugs or more concentrated solutions, provided that physiochemical parameters allow. Similarly, oral drug administration that requires large fluid volumes (e.g., bisphosphonates) may be problematic. In patients with severe nausea and vomiting, "essential" drugs (e.g., immunosuppressants) should be administered intravenously.

Drug Interactions

Pharmacokinetic drug interactions are frequently problematic, and awareness of clinically significant interactions is essential, especially in patients taking transplant immunosuppressants. The most important of these are cyclosporine, tacrolimus, everolimus, and sirolimus, which are substrates of both the cytochrome P450 (3A4) drug metabolizing enzyme system and P-glycoprotein drug efflux system that is expressed in GI mucosa, kidney, and liver (Fig. 77.4).[14] Coprescription of drugs that inhibit these systems (e.g., some azole antifungals, calcium channel blockers, macrolides, and grapefruit juice) can increase absorption and reduce clearance of the immunosuppressant, causing toxicity. Conversely, drugs that induce these systems (e.g., barbiturates, phenytoin, carbamazepine, rifampicin, and St. John's wort *[Hypericum]*) can reduce absorption and increase clearance and therefore increase the risk for rejection (see Fig. 77.4). All drug changes in patients receiving transplant immunosuppression should be considered for their potential to interact, and appropriate dose modifications or alternatives should be used. In addition, enzymes in the epithelial cells of the proximal tubules show an activity similar to the corresponding liver enzymes. Therefore, the kidneys can produce inactive, active, or nephrotoxic metabolites (e.g., metabolites of paracetamol).

Clinical Condition of the Patient

Patient welfare should override theoretical concerns. Higher-than-recommended doses may be appropriate when there is a strong clinical indication. For example, excessive reduction in initial antibiotic doses based on kidney function may be inappropriate in patients with life-threatening infection when the consequences of failed therapy are greater than those of potential toxicity.

METHODS OF DOSE REDUCTION IN CHRONIC KIDNEY DISEASE PATIENTS

Loading Doses

In general, steady-state drug concentrations are achieved after five drug half-lives. Steady-state can be achieved "earlier" by administering loading doses. If an appropriate (i.e., adjusted for GFR) dose is administered from the outset, attainment of steady state will be further prolonged (because half-life is longer). When a drug equilibrates rapidly with the tissues it diffuses into, the loading dose (mg/kg) is equal to the product of the desired plasma concentration (mg/mL) and V_D (mL/kg) and is independent of clearance. If a drug equilibrates slowly with the tissues it diffuses into, several smaller loading doses will be needed (e.g., vancomycin loading doses rarely achieve steady state concentrations after the first loading dose). Provided the desired concentration and V_D are unchanged, loading doses do not require modification in CKD patients. If V_D increases and it is important to achieve a desired plasma concentration quickly, then a larger loading dose might be needed even though the affected drug is renally cleared (and hence subsequent, maintenance doses are lower than normal).

Maintenance Doses

When specific pharmacokinetic information is not available, and assuming no change in nonrenal clearance, maintenance doses should be reduced in proportion to the extent of reduction in GFR. For example, if kidney function is 50% of normal and the drug is 100% renally excreted, a maintenance dose of 50% is required. If the drug is 50% cleared by the kidney and GFR is 20% of normal, the dose should be 60% of normal. The dose reduction factor is estimated from first principles or the following formula:

$$\text{Fraction of normal kidney function dose to use in kidney impairment} = 1 - fe\,(1 - \text{Fraction of normal kidney function})$$

where f_e is the fraction of active drug excreted unchanged in urine.

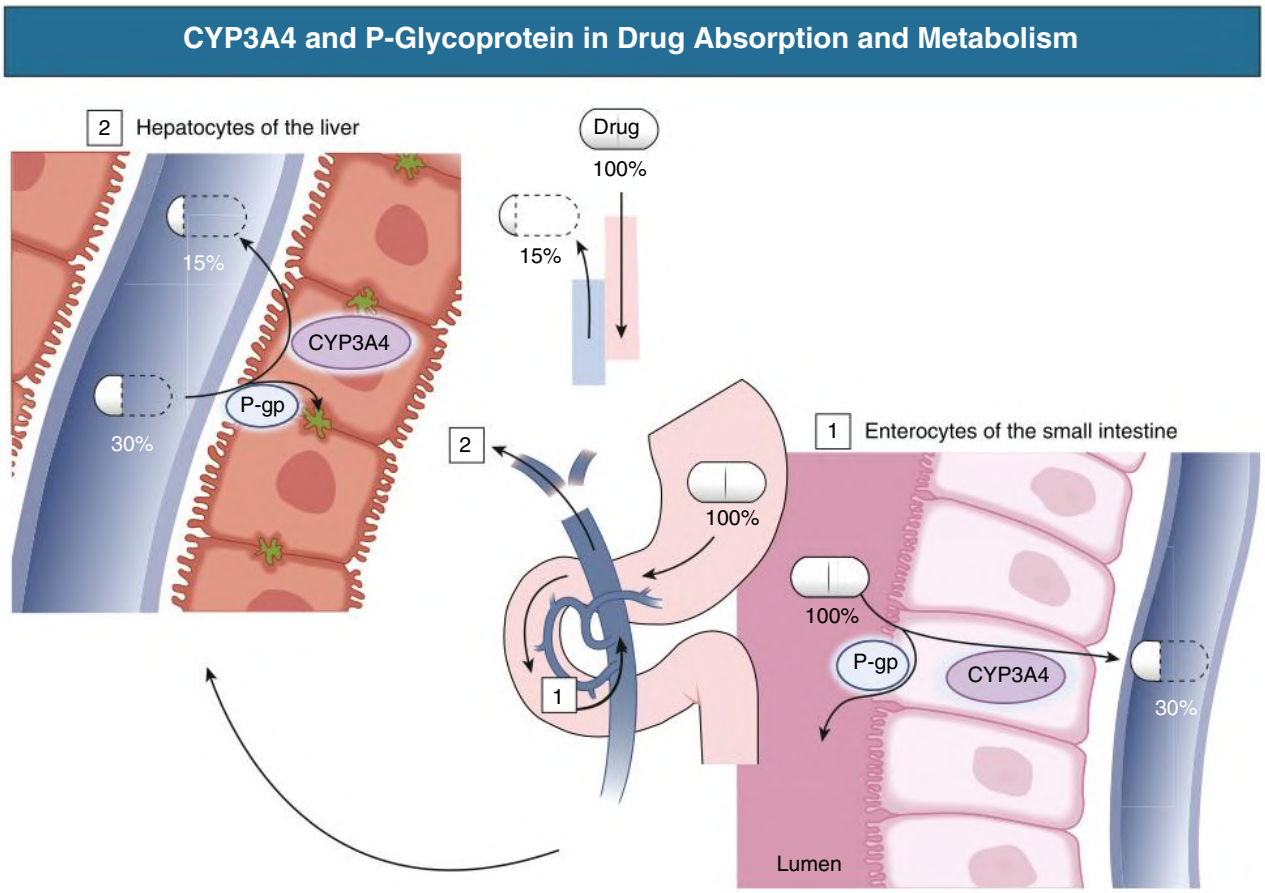

Fig. 77.4 CYP3A4 and P-Glycoprotein *(P-gp)* in Drug Absorption and Metabolism. Schema for absorption and metabolism of drugs that are substrates for CYP3A4 and P-gp. Overall, approximately 15% of ingested drug reaches the systemic circulation. *(1)* Enterocyte: P-gp on the apical surface of enterocytes prevents drug absorption, maintaining drug in the gastrointestinal lumen; CYP3A4 in enterocytes metabolizes drug. The net effect is that approximately 30% of ingested drug reaches the portal circulation. *(2)* Hepatocyte: P-gp on the cell surface prevents drug entry into hepatocytes; CYP3A4 in hepatocytes metabolizes the drug. The net effect is that drug entry to the systemic circulation is further reduced.

Once a daily dose reduction factor has been determined, the clinician must decide on a dose reduction method. Two methods are used, either alone or in combination (Fig. 77.5).

Interval Method

Using this method, the usual dose is administered at prolonged intervals where the extent of prolongation is similar to the extent to which GFR is reduced. This method is particularly useful when peak blood concentrations are important for efficacy (e.g., aminoglycosides) and when therapeutic concentrations need to be achieved early (oseltamivir). If this method is used, practical dose intervals should be recommended rather than inconvenient or complex intervals.[15]

Dose Method

Using this method, a smaller dose is given at the usual interval. This method is common, especially when peak concentrations are less critical for efficacy. If this method is used, clinicians should consider the availability of smaller dose formulations and the ability of the patient to accurately and safely divide available dosage forms.

Combination Method

Sometimes, especially for drugs with a narrow therapeutic index, for which tight control of concentrations is required (e.g., digoxin), a combination of the dose and interval methods is used.

Ongoing Assessment

Even with appropriate dose modification in CKD patients, clinicians should always remain vigilant and closely monitor the response to therapy to guide dose titration.

Therapeutic Drug Monitoring

Therapeutic drug monitoring can provide objective information to guide dosing and is valuable for drugs with a narrow therapeutic window such as aminoglycosides, glycopeptides, digoxin, lithium, antiepileptics, and immunosuppressants (see Table 77.6). Assays usually measure total blood concentrations and may significantly underestimate plasma concentrations of the active or free concentration of the drug.

Clinical Response

Ultimately, clinical response should influence the need to modify doses. Doses should be carefully titrated according to response and adverse effects. Measures of response include blood pressure for antihypertensives, blood glucose concentration and hemoglobin A_{1c} (HbA_{1c}) for oral hypoglycemics/insulin, and kidney function for toxicity from ACE inhibitors, and ARBs and urine output for loop diuretics.

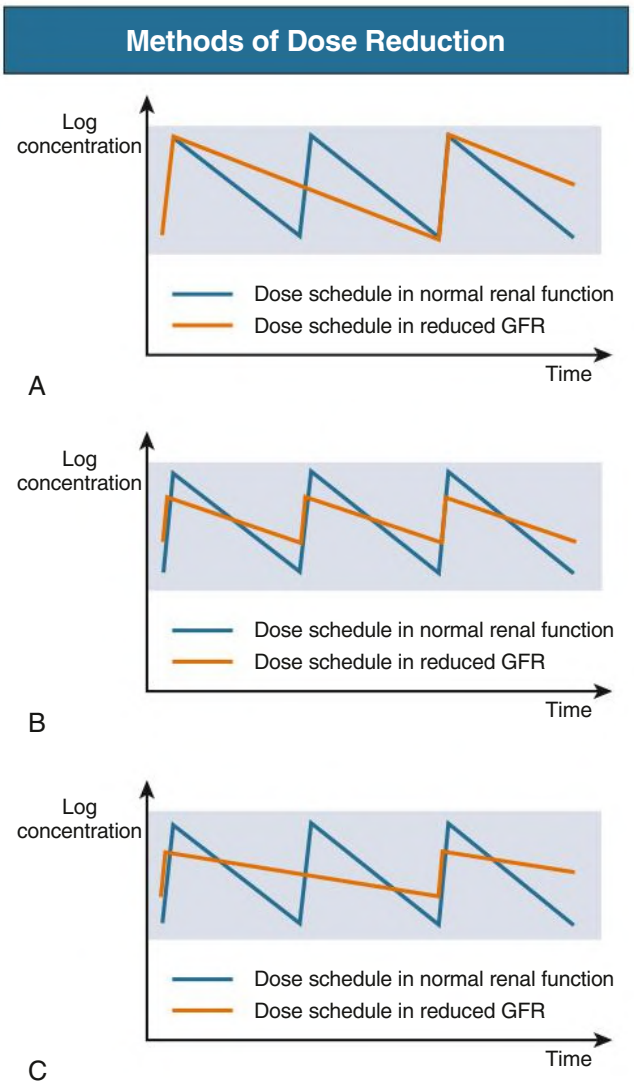

Fig. 77.5 Methods of Dose Reduction. (A) Interval method. (B) Dose method. (C) Combination method. *GFR,* Glomerular filtration rate.

EXTRACORPOREAL DRUG LOSSES

Failure to consider dialysis drug clearance may significantly reduce drug efficacy.[5,7] Alternatively, dialysis may be used in overdose to assist drug removal (see Chapter 103). For example, some β-blockers have high dialysability and so are efficiently removed by dialysis (e.g., atenolol, acebutolol, metoprolol).[16] In contrast, β-blockers with low dialysability are bisoprolol and propranolol. Studies of drug clearance with KRT modalities have often used variations in dialysis technique that make it difficult to compare results. Many studies before the 1990s report data from standard hemodialysis (HD) with low-flux membranes, which are less efficient at drug removal than the high-flux membranes now widely used. Many recommendations report the need for supplemental doses, although clinically, supplemental doses are rarely used, especially if less than 30% of the drug is cleared or the drug has a wide therapeutic window. Rather, drugs known to be significantly cleared by dialysis should be administered after dialysis (Table 77.7). When drugs are given in multiple daily doses, at least one of the daily doses should be administered soon after the completion of dialysis.

TABLE 77.6 Therapeutic Drug Monitoring in CKD

Drug	Therapeutic Range and When to Draw Sample
Aminoglycosides (24-h Dosing)	Peak (30 min after a 30-min infusion) to ensure adequate peak concentration Trough to guide time of next dose (2–3 half-lives post-dose), noting that half-life will be increased in approximate proportion to degree of reduction in GFR
Gentamicin	Peak: >10 mg/L Trough: Depends on time after dose 0.5–2 mg/L
Tobramycin	Peak: >10 mg/L Trough: Depends on time after dose 0.5–2 mg/L
Amikacin	Peak: >30 mg/L Trough: depends on time after dose 1.5–6 mg/L
Immunosuppressants	
Cyclosporine	C_0 (trough): 150–250 μg/mL C_2 (2 h after dose): 1200–1500 μg/mL AUC_{0-4} >4400 μg/mL/h
Tacrolimus	C_0 (trough): 4–12 μg/mL
Sirolimus	C_0 (trough): 5–15 μg/mL
Antiarrhythmics	
Digoxin	0.8–2.0 μg/mL (trough at least 6 h after dose)
Lidocaine	1–5 μg/mL 8 h after IV infusion starts or is changed
Antipsychotics	
Lithium	Acute: 0.8–1.2 mmol/L (trough) Chronic: 0.6–0.8 mmol/L (trough)
Antiepileptics	
Carbamazepine	4–12 μg/mL (trough before administration)
Phenytoin	10–20 μg/mL (trough before administration)
Free phenytoin	1–2 μg/mL (trough before administration)
Phenobarbital	15–40 μg/mL (trough before administration)
Valproic acid	40–100 μg/mL (trough before administration)
Vancomycin	Trough: 15–20 mg/L (12 or 24 h trough)

Target levels are dependent on assay methodology and clinical context. *CKD,* Chronic kidney disease; *GFR,* Glomerular filtration rate; *IV,* Intravenous.

Hemodialysis

Hemodialysis drug clearance occurs mainly by passive diffusion from blood (high concentration) to dialysate fluid (low concentration) but can also occur by convectional movement of dissolved drug in ultrafiltrated plasma.[7,17] The efficiency of drug removal depends on its physiochemical properties. As molecular size decreases (typically <500 kDa) and water solubility increases, drug removal increases. Conversely, as protein binding and V_D increase, the percentage of drug contained in plasma falls and dialysis clearance decreases. HD factors influencing drug removal include membrane type and surface area, blood and dialysate flow rates, and dialysis frequency and duration. HD sometimes removes drug from plasma faster than it can redistribute from tissue, so drug concentrations determined from samples drawn soon after beginning or completion of HD may be artificially low. Samples should preferably be drawn before dialysis or about 1 to 2 hours after to allow drug redistribution from tissues into plasma.

TABLE 77.7 Dialysis Clearance of Drugs

Drugs Significantly Cleared by Hemodialysis That Require Administration After Dialysis or a Supplement After Dialysis	Drugs Not Significantly Cleared by Hemodialysis and That Do Not Require Administration After Dialysis or a Supplement After Dialysis or That Must Be Administered at Specific Times Independent of Hemodialysis
Analgesics	**Anemia**
Morphine 6-glucuronide (in toxicity)	Erythropoietins
Aspirin, high dose (contraindicated)	Iron
Antibiotics	**Analgesics**
Aminoglycosides	Paracetamol
Amikacin	Fentanyl
Gentamicin	Oxycodone
Tobramycin	NSAIDs
Cephalosporins	**Antibiotics**
Cefotaxime	Penicillins
Cefazolin	Flucloxacillin
Ceftazidime	Fluoroquinolones
Carbapenems	Moxifloxacin
Imipenem	Rifamycins
Meropenem	Rifampin
Metronidazole	Rifabutin
Penicillins	Glycopeptides
Amoxicillin	Vancomycin (oral administration)
Ticarcillin	Tetracyclines
Piperacillin	Tetracycline
Fluoroquinolones	Doxycycline
Ciprofloxacin	Minocycline
Glycopeptides	**Antifungals**
Vancomycin (high-flux dialyzers)	Amphotericin
Teicoplanin	Voriconazole
Miscellaneous antibiotics	Ketoconazole
Ethambutol	Itraconazole
Cotrimoxazole	**Antiviral**
Antifungal	Amphotericin
Fluconazole	**Antiepileptic**
	Carbamazepine
Antivirals	**Cardiovascular Agents**
Acyclovir	Amiodarone
Cidofovir	Perhexiline
Famciclovir	Nitrates
Foscarnet	**Anticoagulants**
Ganciclovir	Heparin
Ribavirin	Warfarin
Valganciclovir	LMWH
Zidovudine	Rivaroxaban
Antineoplastics	Apixaban
Cyclophosphamide	**Antiplatelet Drugs**
Methotrexate	Low-dose aspirin
Anticoagulant	Clopidogrel
Lepirudin	Dipyridamole
Dabigatran (in overdose)	**Immunosuppressants**
Antiepileptics	Azathioprine
Gabapentin	Cyclosporine and tacrolimus
Pregabalin	Mycophenolate
Levetiracetam	Prednisolone

TABLE 77.7 Dialysis Clearance of Drugs—cont'd

Drugs Significantly Cleared by Hemodialysis That Require Administration After Dialysis or a Supplement After Dialysis	Drugs Not Significantly Cleared by Hemodialysis and That Do Not Require Administration After Dialysis or a Supplement After Dialysis or That Must Be Administered at Specific Times Independent of Hemodialysis
Cardiovascular Agent	Sirolimus and everolimus
Sotalol	T cell–depleting antibodies
Antidiabetic	Rituximab
Metformin (in overdose)	Anti-CD25 antibodies
Vitamins	**Antidiabetics**
Water-soluble B, C, and folate	Sulfonylureas
Psychotropic	**Musculoskeletal Agents**
Lithium	Bisphosphonates
	Antiepileptics
	Sodium valproate
	Carbamazepine
	Antidepressants
	SSRIs (administer in morning)
	Vitamins
	Fat-soluble vitamins A, D, E, K

LMWHs, Low molecular weight heparins; *NSAIDs,* nonsteroidal antiinflammatory drugs; *SSRIs,* selective serotonin reuptake inhibitors.

Peritoneal Dialysis

Many drug properties that affect removal by HD also apply to peritoneal dialysis (PD), but PD is usually less efficient.[18] For significant removal by PD, the drug must have a very low V_D and low protein binding. For most drugs, there is little evidence of significant removal during chronic PD. A few studies have examined drug clearance from automated PD that uses large volumes of short dwells overnight, often accompanied by one or more longer daytime dwells. Clearance of some drugs via automated PD is increased because of the increased drug concentration gradient between blood and dialysate. Increased drug dialyzability may occur with increased peritoneal dialysate flow rates or during peritonitis, although overall efficiency of drug and metabolite clearance is often reduced by peritonitis because of scarring of the peritoneal membranes, thereby reducing effective surface area.

Continuous Kidney Replacement Therapy

Drug clearance by continuous KRT (CKRT) with hemofiltration, HD, or hemodiafiltration differs from that by intermittent HD.[19] Relying on continuous ultrafiltration of plasma, CKRT can remove large quantities of ultrafilterable drug. CKRT generally uses membranes with larger pore sizes and involves convective transport of solute. Hence, CKRT allows the passage of larger molecules (up to 5000 Da). A large V_D and protein binding still prevents removal by CKRT. Protein binding and the filtration rate determine the rate of removal. A series of sieving coefficients is available that allows calculation of the amount of drug actually lost if the ultrafiltration flow rate is known.[5] The sieving coefficient is the ratio of drug concentration in the ultrafiltrate to the prefilter plasma drug concentration. The closer the sieving coefficient is to 1.0, the more it passes across the filter. There are few detailed studies of drug clearance with use of these methods, and clinicians must rely on estimates from HD, known physiochemical properties, and clinical response.

POLYPHARMACY AND DEPRESCRIBING

Patients receiving dialysis typically receive 10 to 12 medications. Polypharmacy increases the risk of medicine-related problems, including adverse drug reactions and nonadherence. Polypharmacy may be systematically addressed through "deprescribing," an evidence-based,[20] patient-centered[21] process that enables identification and elimination of unnecessary or inappropriate medications. In elderly patients on dialysis, consideration for deprescribing should be given to quinine, diuretics, α_1-blockers, proton pump inhibitors, and statins.[22] In older adults with CKD, medication optimization and deprescribing should focus on proton pump inhibitors, oral hypoglycemic agents, and statins.[23]

Electronic Medical Record

The implementation of electronic medical record (EMR) should improve health outcomes of kidney patients through improved clinical decision making, medication safety, patient education, and quality improvement and research. EMR should incorporate the design and development of clinical care pathways for patients with kidney disease. Medication therapy assessment and monitoring tools should be a part of computerized provider order entry (CPOE) for medication safety to provide evidence-based advice about drug interactions and dose adjustments for patients with kidney disease or transplantation. Furthermore, interactive educational programs and tools to aid medication adherence should be integrated into the patient EMR to improve health literacy and patient outcomes in vulnerable populations. Moreover, EMR data could be used in pharmacoepidemiology research to provide the best available evidence for treatment outcomes in the patient population that is frequently excluded from the randomized controlled studies.[24]

SELF-ASSESSMENT QUESTIONS

1. What percentage of the dose used in patients with normal kidney function should be given for a hypothetical drug that is 80% renally cleared unchanged in urine to a person with 25% of normal kidney function?
   A. 20%
   B. 30%
   C. 40%
   D. 60%
   E. 80%
2. Which of the following factors or drug characteristics does *not* increase the likelihood of drug removal by hemodialysis?
   A. High-flux membranes
   B. Low protein binding
   C. Low volume of distribution
   D. Large molecular weight
3. Which of the following drugs does *not* require clinically relevant dose modification in patients with reduced GFR?
   A. Amoxycillin
   B. Ribavirin
   C. Digoxin
   D. Sotalol
   E. Enoxaparin
4. Which of the following drug combinations is *least* likely to cause clinically significant drug interactions?
   A. Adding clarithromycin to the regimen of a patient on sirolimus
   B. Adding phenytoin to the regimen of a patient on prednisolone
   C. Adding fluconazole to the regimen of a patient on tacrolimus
   D. Adding roxithromycin to the regimen of a patient on cyclosporin
   E. Adding verapamil to the regimen of a patient on everolimus

Common Issues in Prescribing in Kidney Disease and Kidney Replacement Therapy

Matthew J. Cervelli, Terry E. Jones, Sanja Mirkov

Appropriate prescribing for people with kidney disease is underpinned by the principles discussed in Chapter 77. Even experienced physicians will frequently need to check reference sources to be sure of the correct prescribing approach to medications with which they are less familiar. Up-to-date reference databases should be used to inform prescribing in patients with chronic kidney disease (CKD), those on dialysis, and after kidney transplantation.[1-4]

ANALGESICS

Various analgesics are excreted by the kidney, and dose modification or avoidance is required in people with impaired kidney function.[5] Fear of adverse effects often prevents use of sufficient doses.

Acetaminophen (Paracetamol)

Despite suggestions that acetaminophen is nephrotoxic and has modest analgesic potency, its lack of platelet inhibition and gastrointestinal toxicity make it a safer base analgesic in CKD and renal replacement therapy than nonsteroidal antiinflammatory drugs (NSAIDs) and opioids. Acetaminophen is hepatically metabolized and does not require dose adjustment in dialysis or transplant patients.

Opioid Analgesics

Several opioids have active/toxic metabolites that are removed by the kidney,[6] and accumulation of these metabolites prolongs drug action and predisposes to central nervous system (CNS) toxicity (sedation, respiratory depression, confusion, hallucinations, and seizures). Regular opioid use in fluid-restricted kidney patients can exacerbate constipation. Opioids should be used cautiously in CKD, with adequate doses given to establish control and titrated to the smallest effective dose. Morphine is metabolized to two active metabolites (morphine 3-glucuronide and morphine 6-glucuronide) that can accumulate in CKD, causing CNS toxicity, respiratory depression, and sedation. Meperidine (pethidine) should be avoided in moderate to severe CKD because it is metabolized to a metabolite (normeperidine) that accumulates in CKD and can cause CNS toxicity (seizures, myoclonus, opisthotonus, mental state changes, respiratory depression, and psychosis).[7] Dextropropoxyphene should be avoided because it is metabolized to the metabolite norpropoxyphene, which is removed by the kidney and can cause cardiac toxicity.

Hydromorphone is metabolized to hydromorphone 3-glucuronide, which has minor activity and does not accumulate substantially. Buprenorphine is metabolized to relatively inactive metabolites which are excreted in bile, and it is therefore relatively safe. Weaker opioids (codeine, dihydrocodeine, and hydrocodone) can still cause CNS and respiratory depression. With appropriate titration, alfentanil, fentanyl, sufentanil, methadone, and oxycodone are relatively safer choices because their metabolites are largely inactive. For this reason, fentanyl (parenteral and topical) and oxycodone (oral) are usually preferred opioids in CKD. The partial opioid tramadol is metabolized to an active metabolite, *O*-desmethyltramadol, whose half-life doubles in CKD and predisposes to seizures, respiratory depression, and other CNS adverse effects. In opioid intoxication, naloxone may be used at normal dose for reversal.

Nonsteroidal Antiinflammatory Drugs

The most frequent nephrotoxic effect of NSAIDs is acute kidney injury (AKI) caused by prevention of prostaglandin-mediated, afferent arteriolar vasodilation (see Chapter 70). In healthy individuals, cyclooxygenase (COX) inhibition has little effect on kidney function, but in individuals with CKD, nephrotoxicity is more likely to occur due to the greater dependence on prostaglandins to maintain kidney perfusion. Combining NSAIDs with angiotensin-converting enzyme (ACE) inhibitors, angiotensin receptor blockers (ARBs), diuretics, or other antihypertensives increases the potential for nephrotoxicity, and such combinations should be prescribed cautiously.[8] If essential, in stable patients with CKD, NSAIDs should be used at the lowest effective dose for the shortest period with monitoring of kidney function. Increases in plasma potassium and sodium, as well as fluid retention, also may occur. NSAIDs (especially fenoprofen) can cause a rare idiosyncratic reaction that may present with acute interstitial nephritis or nephrotic syndrome with a glomerular lesion resembling minimal change disease. Because COX-2 is expressed in the kidney, COX-2–selective agents offer no advantage in kidney toxicity over nonselective inhibitors.[9] The potential for cardiovascular (CV) complications of COX-2 inhibitors is also undesirable in kidney patients at high risk of CV disease.

Drugs for Neuropathic Pain

Low-dose tricyclic antidepressants are used at normal doses in patients with reduced glomerular filtration rate (GFR), although they may be more sensitive to anticholinergic side effects. Low-dose valproate and carbamazepine are used at normal doses. Extreme caution and dose reductions are required with gabapentin[10] and pregabalin[11] because they are extensively removed by the kidney and can cause significant CNS adverse effects (somnolence, lethargy, dizziness, myoclonus, and ataxia).

ANTIMICROBIAL AGENTS

The kidneys excrete many antiinfective agents, and dose reduction is often required in severe CKD or those undergoing extended therapy.[12] Many other antiinfectives have a wide therapeutic window, and dose adjustment is often clinically unnecessary despite their reliance on kidney excretion. An important principle of antiinfective therapy is to initiate effective drugs at sufficient doses rather than using conservative dose reductions that fail to achieve effective drug concentrations.

Normal or larger than expected doses based on kidney function may be appropriate when treating less susceptible organisms or when drug distribution to the site of infection is reduced (e.g., meningitis and urinary tract infections [UTIs]). Severe infection, especially in severely immunocompromised patients, may require extended therapy. In patients with UTI and severe CKD (e.g., GFR <30 mL/min/1.73 m^2), antiinfectives that are only filtered by the kidneys are unlikely to achieve adequate concentrations in the urinary tract and are therefore unlikely to result in clinical cure. Because plasma concentrations will also be elevated, systemic toxicity is more likely (e.g., trimethoprim and nitrofurantoin). Administering a reduced dose of such antiinfectives is illogical because concentrations in the urinary tract will be further decreased and efficacy further reduced. Antiinfectives that are secreted by the tubules in addition to being filtered (e.g., penicillins) are more likely to achieve adequate concentrations in the urinary tract in advanced CKD and preferred agents.

Antibacterials

Aminoglycosides

Aminoglycosides are excreted unchanged by the kidneys and can cause nephrotoxicity, vestibular toxicity, and ototoxicity that can be severe and irreversible.[13] When use is required, the total daily dose should be reduced, treatment courses kept to a minimum, and serum concentrations and kidney function monitored. Because aminoglycosides achieve high urine concentrations even in advanced CKD, lower doses may be appropriate for uncomplicated UTIs.

Aminoglycoside dosage schedules. Despite short half-lives (2–3 hours in normal kidney function), aminoglycosides are usually given once daily rather than in divided daily doses. This is based on two properties, namely, concentration-dependent killing and postantibiotic effect. The former requires that a high peak concentration (ideally 4–5 times the pathogen minimum inhibitory concentration [MIC]) is achieved. The latter allows the plasma concentration to fall below the MIC for much of the dosing interval without compromising efficacy. This "larger dose given less frequently" approach has been shown to be more efficacious and less toxic. The required dose regimen depends on volume of distribution (V_D) and kidney clearance. Determining the best dose regimen in CKD involves reducing the normal daily dose (5–7 mg/kg/day)[14] for gentamicin/tobramycin or 15 mg/kg for amikacin in proportion to kidney function (e.g., with 25% remaining kidney function, corresponding to GFR of ~25 mL/min/1.73 m^2 or creatinine clearance [CrCl] of 25 mL/min, reduce total daily dose to 25% of normal). Aminoglycosides should be administered at a minimum effective dose (≥3 mg/kg for gentamicin and tobramycin; ≥7.5 mg/kg for amikacin) to achieve effective peak serum concentrations (>10 μg/mL for gentamicin and tobramycin; >30 μg/mL for amikacin). It is often necessary to increase the interval between doses (to >24 hours) to allow for an adequate dose (that will achieve a good peak concentration) to be administered.

Aminoglycoside concentration monitoring. Because of toxicity and pharmacokinetic variability in patients with infection and CKD, monitoring is essential to guide aminoglycoside dosing, particularly when therapy is initiated or significant changes occur in kidney function or clinical condition. Routine monitoring is not required for short treatment (<48 hours). Graphic methods using a single-point concentration 6 to 14 hours after administration are valid only with relatively normal GFR. They do not provide information on attainment of peak concentrations (for efficacy) and are not recommended in patients with CKD. Trough concentrations can be measured but must be interpreted in the context of the time after the dose when the sample was drawn. Trough monitoring does not provide information on the attainment of peak concentrations. Some patients, especially those with severe sepsis and CKD, may have altered (usually higher) V_D, which results in lower peak concentrations. Measuring peak concentrations (30 minutes after dosing) is the only certain way to determine dose adequacy. Combining peak and trough monitoring (approximately two half-lives after dosing) provides information on both V_D and clearance and can therefore be used to determine both the size of individual doses and the administration interval. Provided the relationship between the time of administration and blood sampling is known, simple dose modifications are made on first principle estimates (see Chapter 77). Peak and trough target levels for aminoglycosides are shown in Table 77.6.

Carbapenems. Doripenem, imipenem, and meropenem are significantly excreted in urine but with appropriate dose modification can be used safely. Imipenem can cause significant neurotoxicity (myoclonic activity, seizures, and confusion), especially in high doses in those with underlying CNS disorders or CKD. Imipenem is inactivated by dehydropeptidase 1 in the kidney and is combined with cilastatin to prevent this.

Cephalosporins. Although most cephalosporins are predominantly removed by the kidney, their relative safety means that normal doses are used for most short-course therapies even in dialysis patients (e.g., ceftriaxone, cefaclor, and cephalexin). High-dose parenteral therapy and prolonged courses of some agents require dose reduction in severe impairment (e.g., cefepime, cefotaxime, ceftazidime, cefoxitin, and cefazolin). Therapeutic concentrations of cefazolin are maintained after doses of 20 mg/kg after dialysis three times weekly.[15] Some cephalosporins (e.g., cefoxitin) interact with colorimetric assays for creatinine, resulting in falsely elevated serum creatinine values.[16]

Fluoroquinolones. Kidney excretion is significant with ciprofloxacin, norfloxacin, and gatifloxacin, and doses should be reduced if GFR is less than 30 mL/min/1.73 m^2.[17] Moxifloxacin is less dependent on kidney excretion, and dose reduction is not required. Norfloxacin plasma concentrations are too low for treating bloodborne infections, but urinary concentrations are adequate for treating UTIs. Quinolones are generally well tolerated but can cause CNS effects (headache, dizziness, insomnia, depression, restlessness, and tremors), interstitial nephritis, musculoskeletal effects (tendonitis and arthralgias), aortic aneurysms, and crystalluria. If use is essential, quinolones should be administered at least 1 hour before or 2 hours after meals and metallic phosphate binders, which may reduce absorption.

Glycopeptides. Vancomycin is a glycopeptide that is extensively removed by the kidney. Because of nephrotoxicity and ototoxicity, dose modification is essential even in mild to moderate impairment. Nephrotoxicity is more likely in those with preexisting CKD, with prolonged therapy, high plasma concentrations, and when concomitant nephrotoxins are prescribed. Ototoxicity may involve sensorineural deafness and tinnitus and is more likely with previous auditory compromise or impaired GFR. Rapid infusion also can cause an erythematous anaphylactoid-like reaction involving the upper body (red man syndrome) that usually resolves with slowing of the infusion rate and antihistamines. If vancomycin use is essential, duration of therapy should be minimized with regular monitoring of serum concentrations and GFR. Vancomycin should be administered once plasma serum concentrations have fallen below target values that are related to the MIC. Vancomycin distributes into body tissues, and clearance from the bloodstream after initial doses can appear greater than expected from estimates of GFR or CrCl. Once these tissues are saturated, clearance is purely via kidney clearance and is relatively predictable. In dialysis patients, single doses (e.g., 1 g of vancomycin) can maintain therapeutic concentrations (>15 μg/mL) for 3 to 5 days.[18] Vancomycin is removed more extensively with modern high-flux than with older low-flux dialysis membranes. For teicoplanin, dose reduction is necessary when CrCl is less than 50 to 60 mL/min.

Lincosamides. Clindamycin and lincomycin are relatively safe and are not significantly excreted by the kidneys.

Macrolides. Macrolides are mostly hepatically cleared, and dose modifications are usually not required even in patients with advanced kidney failure. Dose reduction is required with high-dose or intravenous erythromycin, which may prolong QT interval and cause ototoxicity. Various macrolides are potent inhibitors of cytochrome P450 CYP3A4, 1A2, and P-glycoprotein, so there may be major interactions with and increased exposure to coadministered drugs that rely on CYP3A4, 1A2, or P-glycoprotein–mediated absorption and metabolism (including cyclosporine, tacrolimus, sirolimus, everolimus, and statins). Erythromycin and clarithromycin are the most potent inhibitors. Roxithromycin and azithromycin are much weaker inhibitors, causing few or no significant interactions (see Table 78.2).

Penicillins. Most penicillins have a short half-life and are rapidly eliminated by glomerular filtration and tubular secretion. Most have a relatively wide therapeutic window and are used at normal doses for short courses of oral therapy (e.g., amoxicillin) regardless of kidney function. High-dose parenteral therapy or prolonged high-dose oral therapy may require dose reduction to prevent electrolyte disturbances and neurotoxicity in kidney failure. Because the bactericidal effect of penicillins is not dependent on antibiotic concentration and exerts little or no postantibiotic effect, the amount of time above the MIC is more important than the maximum concentration. This translates into the frequency of dosing being more important than the size of each dose. For patients with UTIs who also have CrCl less than 40 to 50 mL/min, penicillins are a good choice (if the pathogen is sensitive) because urinary concentrations are higher than with agents that are merely filtered (e.g., trimethoprim). Dose reduction of benzyl penicillin, ticarcillin-clavulanate, and piperacillin-tazobactam are advised in patients with CrCl less than 40 to 50 mL/min.

Rifamycins. Rifamycins are mainly hepatically metabolized and used at normal doses. Orange-red coloration of body fluids (e.g., urine and peritoneal dialysis [PD] fluid) is common. These agents cause hepatotoxicity and blood dyscrasias. Rifampin is a potent CYP450 enzyme inducer and significantly increases metabolism of drugs, including immunosuppressants and oral contraceptives. Rifabutin does not induce CYP450 enzymes to the same extent.

Tetracyclines. Tetracycline was the originator of this class but has largely been replaced by newer derivatives due to the need for frequent administration, adverse effects (including Fanconi-like syndrome from outdated tetracycline), and resistance among pathogens. In CKD, tetracycline should be avoided because it is catabolic, causing uremia, hyperphosphatemia, and metabolic acidosis; it also may aggravate preexisting kidney failure.[19] Doxycycline, minocycline, and tigecycline are newer derivatives that are not significantly dependent on kidney clearance and may be used as usual.

Sulfonamides and trimethoprim. Many sulfonamides are eliminated by acetylation followed by kidney excretion. Acetylated metabolites may cause crystalluria and tubular damage. Sulfamethoxazole and trimethoprim display similar kidney excretion except at extremes of urine pH. Alkaline urine promotes sulfamethoxazole excretion, whereas acidic urine promotes trimethoprim excretion. Both accumulate in CKD, and dose reduction is advisable except perhaps in the treatment of UTIs when higher plasma concentrations might be required to facilitate adequate urinary concentrations. Trimethoprim inhibits tubular secretion of creatinine, resulting in an increase in serum creatinine[20] that does not reflect a true change in GFR and can be misinterpreted as nephrotoxicity.

Other antibiotics. Linezolid is used at a normal dose. Metronidazole has a partially active metabolite, although only 15% of the parent drug is removed by the kidney. It is usually given in usual doses or reduced to twice-daily doses with dialysis.

Antimycobacterials

Ethambutol is extensively removed by the kidney, and dose reduction is required when CrCl is less than 30 mL/min to avoid visual toxicity.[21] Isoniazid, pyrazinamide, and rifampin-rifabutin can be given in usual doses. Rifampin causes induction of hepatic enzymes and severe drug interactions with transplant immunosuppressants. Amikacin, kanamycin, streptomycin, capreomycin, and gatifloxacin have extensive kidney clearance, are nephrotoxic, and require significant dose reduction.

Antifungals

Amphotericin. Amphotericin use is limited by nephrotoxicity (see Chapter 55). Nephrotoxicity with crystalline amphotericin may be minimized with prehydration and administration by continuous infusion. Liposomal formulations have fewer infusion-related problems and are less nephrotoxic but more expensive. Oral amphotericin (used for its enteric effect and lozenges for oral thrush) is not absorbed and does not contribute to nephrotoxicity.

Azole antifungals. Most azole antifungals (ketoconazole, itraconazole, posaconazole, and voriconazole) are extensively metabolized and do not require dose reduction. Fluconazole is excreted by the kidney; after a loading dose, maintenance doses should be reduced in moderate to severe CKD, and it should be given after dialysis. Fluconazole is significantly excreted in urine and hence is often useful for fungal UTIs. The manufacturer recommends avoiding intravenous voriconazole in severe CKD because of possible accumulation of the intravenous vehicle (sulfobutyl betadex sodium). Voriconazole, ketoconazole, and itraconazole are potent inhibitors of CYP3A4 and P-glycoprotein that are involved in the metabolism and absorption of a variety of drugs, including cyclosporine, tacrolimus, sirolimus, everolimus, and statins. A twofold to 10-fold reduction of the concomitant drug may be required (guided by drug monitoring; see Table 78.2). Interactions between ketoconazole and calcineurin inhibitors (CNIs) or mammalian target of rapamycin (mTOR) inhibitors have been exploited as a cost-reducing immunosuppressant-sparing strategy. Increased exposure to statins (except pravastatin) caused by CYP3A4 inhibition increases the risk for rhabdomyolysis-induced CKD. Fluconazole is a weak enzyme inhibitor, and although caution should be exercised, the need for preemptive dose reduction of concomitant drugs is less certain. Topical azoles, including bifonazole, clotrimazole, econazole, ketoconazole, tinidazole, and miconazole, are minimally absorbed and do not cause interactions.

Other antifungals. Absorption of nystatin from topical and oral preparations is minimal and safe in CKD. Terbinafine is hepatotoxic, and a 50% dose reduction is suggested in moderate to severe CKD. Griseofulvin, anidulafungin, and caspofungin can be given in usual doses. Flucytosine has extensive kidney clearance and requires significant dose reduction.

ANTIVIRALS

Many antivirals (or their active metabolites) have extensive kidney excretion and can cause nephrotoxicity (see also Chapter 70).

Guanine Analogs

Acyclovir, its prodrug valacyclovir, and famciclovir (a prodrug of penciclovir) have extensive kidney clearance, and doses must be reduced in proportion to the severity of CKD. These agents can also crystallize in tubules, causing obstructive nephropathy, especially when given intravenously. Where possible they should not be administered in low volumes of fluid, and the patient should be well hydrated. High concentrations cause severe CNS toxicity (cerebral irritation, ataxia, and myoclonus). Ganciclovir and its prodrug valganciclovir have extensive

kidney clearance,[22] and accumulation leads to severe bone marrow toxicity. Dose reduction based on kidney function is essential. These agents are freely dialyzed and should be given after hemodialysis (HD).

Hepatitis B and C

Pegylated interferon alfa-2a has a larger metabolic clearance than pegylated interferon alfa-2b, which has higher kidney clearance and requires dose reduction in CKD. Interferons can upregulate cell surface expression of class II histocompatibility antigens, which increases the potential for transplant rejection. Ribavirin and its metabolites rely on kidney excretion; accumulation causes severe anemia, making it contraindicated if GFR is below 50 mL/min; significantly reduced doses are sometimes used in lower levels of GFR. Newer direct-acting antivirals for hepatitis C (boceprevir, daclatasvir, ledipasvir, sofosbuvir, ombitasvir, paritaprevir, ritonavir, dasabuvir, simeprevir, telaprevir) are less dependent on kidney excretion and may be preferable in patients with CKD. Adefovir, entecavir, lamivudine, and telbivudine have extensive kidney excretion, and significant dose reduction is essential.

Neuraminidase Inhibitors

Oseltamivir is converted by hepatic esterases to its active metabolite, oseltamivir carboxylate, which is extensively (99%) removed through glomerular filtration and tubular secretion.[23] The area under the curve (AUC) is increased 10-fold in severe CKD, and, although the drug is well tolerated, dose reduction is recommended. Oseltamivir carboxylate is cleared by hemodialysis, but in anuric patients plasma concentrations remain virtually unchanged in between hemodialysis sessions. Patients on hemodialysis who have even small amounts of residual kidney function can clear oseltamivir carboxylate significantly faster than those who are anuric. Ideally, dosing in CKD would be guided by therapeutic drug monitoring, but this is not routinely available. Reducing the dose of oseltamivir in CKD used to be achieved by giving the same dose (75 mg) less frequently, but more recently it has been suggested it should be achieved by giving a lower dose (30-mg capsule) once or twice a day, depending on the degree of CKD. Giving a smaller dose from the outset delays the attainment of critical "therapeutic concentrations" because it takes approximately four times the prolonged half-life to achieve concentrations to maximize benefit. The initial dose should be 75 mg, and subsequent doses can be reduced either by reducing the dose size or prolonging the interval between doses.[24] It may be wiser to use zanamivir whenever CrCl falls below 20 mL/min. Zanamivir is also removed by the kidney, but dose modification is not necessary because absorption from the inhaled formulation is very low (~2%).

Other Antivirals

Cidofovir and foscarnet have extensive kidney clearance and require dose reduction in CKD. Both are nephrotoxic, require close monitoring of kidney function, and should be administered with hydration. Cidofovir is recommended to be administered with probenecid to slow kidney secretion and minimize nephrotoxicity. Tenofovir doses should also be reduced in moderate chronic kidney failure and avoided below 30 mL/min/1.73 m^2 and in combination with other nephrotoxins, such as adefovir. Agents active against HIV infection are also discussed in Chapter 58.

IMMUNOSUPPRESSANTS

Dosing of immunosuppressive agents used in kidney transplantation, as well as adverse effects, are discussed in Chapter 106. Initial and maintenance doses in individuals are highly variable and depend on local protocol, concomitant therapy, rejection risk, drug concentrations, and response. Immunosuppression is required for the life of the transplant and should never be withheld except in exceptional circumstances (life-threatening infection or malignancy). Regimens should preferably be convenient (e.g., twice daily) to enhance compliance. In practice, the precise timing of doses or intake relative to time and food is not as important as consistency in relation to time and food because doses can be titrated to levels and response. Most immunosuppressants are hepatically metabolized and do not require dose modification based on altered excretion in CKD.

Immunosuppressants are prone to a range of significant drug interactions, which should be considered whenever a patient receiving these agents has a change in drug regimen. Significant interactions also can occur with "natural" or "herbal" medicines (e.g., St. John's wort; see also Chapter 77 and Table 78.1). If these products are deemed essential, it is advisable to monitor response, kidney function, blood counts, and serum drug concentrations regularly but especially during initiation, dose alterations, and stopping the "natural" product. Therapeutic monitoring is recommended for several immunosuppressants[25] (tacrolimus, cyclosporine, everolimus, sirolimus, and mycophenolate). The target range may differ from center to center due to assay differences and may change with time posttransplant and immunosuppressive regimen. Reported concentrations should always be interpreted in the context of patient response and adverse effects.[26]

Calcineurin Inhibitors

CNIs are extensively metabolized to inactive metabolites. A major adverse effect of CNIs is nephrotoxicity (acute and chronic),[27] and regular assessment of kidney function is essential. Nephrotoxicity may increase with concurrent use of mTOR inhibitors. Early detection of CNI nephrotoxicity on biopsy assists in planning maintenance therapy (see Chapters 106 and 109). Lower doses or temporary withdrawal may be used when CNIs have caused or are likely to cause nephrotoxicity (e.g., delayed graft function). Calcium channel blockers (CCBs) and blockers of the renin-angiotensin system may both reduce CNI nephrotoxicity. CNIs are substrates of P-glycoprotein and CYP3A4. Drugs that inhibit or compete as substrates for these can increase absorption and reduce metabolism of CNIs, causing increased serum concentrations and adverse effects. Drugs that induce these can reduce absorption and increase metabolism of CNIs, causing reduced serum concentrations, and increase the risk for rejection (Table 78.2). Tacrolimus trough concentrations (C_0) show good correlation with drug effect/toxicity and are used to monitor therapy. Clinically, a combination of C_0 (trough), C_2 (concentration 2 hours after dose), and $AUC_{0\text{-}4}$ (multipoint AUC, 0–4 hours) has been used to measure cyclosporin. Different assay methodologies (high-performance liquid chromatography [HPLC] and immunoassays) have differing abilities to differentiate parent compound from inactive metabolites. Specific HPLC methods are preferred, and physicians should be aware that results from different laboratories may differ due to assay specificity.

Corticosteroids

Corticosteroids are predominantly cleared by hepatic metabolism to inactive metabolites. Dose modification based on kidney function is not required.

Antiproliferative and Cytotoxic Agents

Various antiproliferative and cytotoxic agents are used to prevent transplant rejection (azathioprine and mycophenolate) and to suppress the immune system in patients with autoimmune and inflammatory kidney disorders (azathioprine, cyclophosphamide, chlorambucil, methotrexate, and mycophenolate). Their primary dose-limiting toxicity is bone marrow

TABLE 78.1 Common Drug Dosing Recommendations in Chronic Kidney Disease Including Kidney Transplantation and Dialysis

	PREDOMINANT ELIMINATION PATHWAY			
Drugs	**Hepatic**	**Kidney**	**Dosing Recommendations**	**Comments**
Analgesics				
Simple analgesics	Acetaminophen		Normal dosing	
Opioids		Morphine	Avoid/dose reduction	Metabolite kidney clearance
		Pethidine (meperidine)	Avoid	Metabolite kidney clearance
	Fentanyl		Cautious normal doses	
	Hydromorphone		Cautious normal doses	
	Methadone		Cautious normal doses	
	Oxycodone		Cautious normal doses	
	Tramadol		Cautious normal doses	
NSAIDs			Avoid if possible	Potential nephrotoxicity
Neuropathic pain		Gabapentin	Significant dose reduction	CNS adverse effects
		Pregabalin	Significant dose reduction	CNS adverse effects
	Carbamazepine		Normal dose	
	Low-dose TCAs		Normal dose	
	Valproate		Normal dose	
Antiinfectives				
Aminoglycosides		Amikacin	Avoid/dose reduction	Nephrotoxicity
		Gentamicin	Avoid/dose reduction	Nephrotoxicity
		Tobramycin	Avoid/dose reduction	Nephrotoxicity
Carbapenems		Ertapenem	Reduce in severe impairment	
		Doripenem	Dose reduction	
		Imipenem	Dose reduction	
Cephalosporins		Cefotaxime	Dose reduction	
		Ceftazidime	Dose reduction	
		Cephalexin	Normal dose	
	Ceftriaxone		Normal dose	
Fluoroquinolones		Ciprofloxacin	Reduce in severe impairment	PO_4 binders may impair absorption
		Norfloxacin	Reduce in severe impairment	PO_4 binders may impair absorption
	Moxifloxacin		Normal dose	
Glycopeptides		Teicoplanin	Avoid/dose reduction	Nephrotoxicity and ototoxicity
		Vancomycin	Avoid/dose reduction	Nephrotoxicity and ototoxicity
Macrolides	Azithromycin		Normal dose	
	Clarithromycin		Normal dose	CYP3A4 interactions
	Roxithromycin		Normal dose	
		Erythromycin	Dose reduction	CYP3A4 interactions
Penicillins		Amoxycillin	Normal dose	
		Benzylpenicillin	Dose reduction	
		Piperacillin	Dose reduction	
		Ticarcillin/clavulanic acid	Dose reduction	
Sulfonamides and trimethoprim			Reduce high doses	Falsely elevates creatinine
Tetracyclines		Tetracycline	Avoid	
	Doxycycline		Normal dose	
	Minocycline		Normal dose	
Antimycobacterials		Ethambutol	Dose reduction	
	Isoniazid		Normal dose	
	Pyrazinamide		Normal dose	
	Rifampicin		Normal dose	CYP3A4 interactions
Azole antifungals		Fluconazole	Reduce maintenance doses	
	Ketoconazole		Normal dose	CYP3A4 interactions

suppression, which is exacerbated by combined use with other bone marrow suppressants (e.g., ganciclovir, cotrimoxazole, and mTOR inhibitors). Regular blood monitoring is needed to guide dosage. Methotrexate relies on kidney clearance and should be avoided or used cautiously at a reduced dose in people with a low GFR. Kidney clearance is significant with cyclophosphamide, which can cause hemorrhagic cystitis via an active metabolite (acrolein) if it is allowed to dwell in the bladder for lengthy periods (hence it should not be administered prior to bedtime), and chlorambucil, and dose modifications are required. Allopurinol and febuxostat significantly interfere with metabolism of the active metabolite of azathioprine (6-mercaptopurine), and coprescription can lead to life-threatening bone marrow suppression. The combination should be avoided by exchanging azathioprine with mycophenolate or by significant (75%) dose reduction of azathioprine or mercaptopurine.

mTOR Inhibitors

Although not nephrotoxic when used alone, mTOR inhibitors (sirolimus, everolimus) can potentiate the nephrotoxicity of CNIs. mTOR inhibitors are almost entirely hepatically metabolized to essentially inactive metabolites. Dosage is independent of kidney function and based on response, serum drug levels, and specific toxicities (especially hematologic and lipids). mTOR inhibitors are substrates of CYP3A4 and P-glycoprotein and susceptible to the same drug interactions as CNIs (Table 78.2). Bone marrow toxicity (neutropenia, anemia, and thrombocytopenia) is increased when they are used in combination with other myelosuppressants (azathioprine, mycophenolate, ganciclovir, and cotrimoxazole). Trough levels show good correlation with drug efficacy/toxicity and are used to monitor therapy. Different assay methodologies (HPLC vs. immunoassays) vary in their ability to detect parent drug from metabolites. Specific HPLC methods are recommended, and results from different laboratories or methods may not be interchangeable.

Immunosuppressant Antibodies

Antibodies used for immunosuppression include T cell–depleting antibodies (antithymocyte globulin, anti–interleukin-2 receptor (CD25) antibodies (basiliximab and daclizumab), and B cell–depleting antibodies (rituximab) (see Chapter 106). Dosage is independent of kidney function, and these agents should be administered after plasma exchange[28] to avoid drug removal. They are not removed by HD.

CHEMOTHERAPY AND CYTOTOXIC AGENTS

Kidney function affects the outcomes of patients with cancer due to the impact on the anticancer drug selection and dosing.[29] Alternative use of the second- or third-line agent may lead to reduced effectiveness; underestimation of kidney function may lead to inappropriate agent selection, dose reductions, underdosing, reduced effectiveness, and failure of therapy. Conversely, overestimation of kidney function may lead to overdosing and toxicity from anticancer drugs cleared by the kidney. Cytotoxic agents are drugs with a narrow therapeutic index, hence a small change in plasma concentrations can lead to toxicity or loss of efficacy. Many anticancer drugs are excreted predominantly as unchanged drug or active metabolite in the urine and therefore require dose adjustment for kidney function (e.g., bleomycin, capecitabine, carboplatin, cisplatin, cyclophosphamide, erlotinib, etoposide, fludarabine, imatinib, methotrexate, mitomycin, pemetrexed).

Carboplatin dose is calculated based on the Culvert equation, which takes into consideration the target AUC and the patient's kidney function:

$$\text{Dose (mg)} = \text{Target AUC} \times (\text{GFR} + 25)$$

Carboplatin dosing varies significantly on the estimate of GFR. The dose depends on the method used for estimation of GFR and whether a body surface area (BSA) indexed eGFR or absolute eGFR is used in the Culvert formula.

Tyrosine Kinase Inhibitors

Tyrosine kinase inhibitors are novel small molecule targeted therapies administered orally and associated with improved outcomes and reduced toxicity compared with the conventional chemotherapy. Most of these agents do not require dose adjustment in mild and moderate CKD.[30] The pharmacokinetics for some of these agents have not been studied in patients with severe CKD, and therefore their use has not been recommended in this patient population (e.g., alectinib, cabozantinib) or may be administered with caution (e.g., ceritinib, dabrafenib, trametinib).

Some of these agents require dose adjustment in patients with severe CKD (e.g., afatinib, brigatinib, crizotinib, vandetanib). Crizotinib is an anaplastic lymphoma kinase 1 (ALK-1) inhibitor. It may act as a

TABLE 78.2 Common CYP3A4/P-gp–Mediated Interactions With Transplant Immunosuppressants (Cyclosporine, Tacrolimus, Sirolimus, Everolimus)

Drug Class	Examples	Relative Potency
Drugs That Inhibit CYP3A4 and P-gp		
Macrolide antibiotics	Azithromycin	–
	Clarithromycin	+++
	Erythromycin	+++
	Roxithromycin	+
Azole antifungals	Fluconazole	+/–

	Phenytoin	+++
	Phenobarbitone	++
Antibiotics	Rifampin	+++
Herbals, foods	St. John's wort	+++

CCB, Calcium channel blocker; *P-gp,* P-glycoprotein.

competitive inhibitor of CrCl by the organic cation transporter 2 (OCT2) in the proximal tubule. This effect is similar to other drugs (e.g., trimethoprim, cimetidine), leading to the increase in serum creatinine that is not associated with true AKI (i.e., pseudo-AKI).

ANTICOAGULANTS, ANTIPLATELET AGENTS, THROMBOLYTICS, AND HEMOSTATICS

Bleeding risk with anticoagulants, antiplatelet agents, and thrombolytics is generally increased in patients with CKD.[31]

Unfractionated Heparin

Unfractionated heparin (UFH) is cleared via a saturable mechanism of the endothelium and reticuloendothelial system and a nonsaturable mechanism through the kidneys. Half-life is slightly prolonged (1.5-fold) in CKD, especially at higher doses. However, UFH is used at normal dose with titration based on activated partial thromboplastin time monitoring. In some centers, UFH is preferred in severe CKD because its duration of effect is shorter and more easily measured and reversed.

Low-Molecular-Weight Heparins

Low-molecular-weight heparins (LMWHs) (enoxaparin, dalteparin) rely more on kidney clearance than UFH and in moderate to severe CKD can accumulate, increasing the risk for serious bleeding, especially following surgery. Consideration should be given to using UFH in this setting. In situations where LMWHs are preferred and there is doubt about clearance (or other kinetic issues), dosing should be guided by anti-Xa activity assay. Tinzaparin does not accumulate in patients with CrCl greater than 20 mL/min after at least 10 days of dosing and may be a useful option for bridging anticoagulation.

Other Parenteral Anticoagulants

Other parenteral anticoagulants that accumulate in CKD and that should be avoided or used with significant dose reduction include bivalirudin, danaparoid, fondaparinux, lepirudin, ximelagatran, and melagatran. Argatroban may be used at normal dose. Prostacyclin, used to prevent platelet aggregation in HD circuits, is rapidly hydrolyzed and not affected by CKD.

Oral Anticoagulants

The liver extensively metabolizes warfarin, and in CKD it is usually commenced at normal dose and titrated according to the international normalized ratio. Warfarin is highly protein bound, and with hypoalbuminemia there may be increased sensitivity to warfarin. Similarly, hepatic metabolism may be altered with CKD that results in increasing sensitivity. Warfarin may promote vascular calcification and should be avoided in advanced CKD unless absolutely necessary (e.g., those with a mechanical heart valve). Newer, direct-acting oral anticoagulants (DOACs) (rivaroxaban and apixaban) are partially dependent on kidney clearance. Dabigatran is very dependent on kidney clearance. Because these agents are difficult to monitor (assays not routinely available), they are dose reduced according to estimates of CrCl and are contraindicated (rivaroxaban <15 mL/min, apixaban <25 mL/min, and dabigatran <30 mL/min) in advanced CKD.

Antiplatelet Drugs

Commonly prescribed doses of oral antiplatelets (aspirin, clopidogrel, and dipyridamole) do not require adjustment, although patients with CKD are more prone to bleeding. Despite their efficacy in reduced kidney function, eptifibatide and tirofiban are excreted by the kidney and have been associated with bleeding in this setting. Abciximab is cleared by platelet binding and is not associated with increased bleeding risk in patients with CKD.

Thrombolytics

Streptokinase, anistreplase, and alteplase are used as normal, but the high risk for hemorrhage should be considered. Urokinase and alteplase are also used to unclot dialysis catheters and occasionally to prevent catheter dysfunction.

Hemostatics

Tranexamic acid is highly (90%) dependent on clearance via the kidneys and requires dose reduction in moderate to severe CKD. Protamine and vitamin K are used as normal, as are fresh-frozen plasma and whole blood with critical bleeding.

DIURETICS

Diuretics must reach the tubular lumen of the kidney in unbound form to exert an effect.[32] Pharmacokinetic and pharmacodynamic properties of diuretics can change with proteinuria or CKD, usually causing a resistance to their effect. Diuretics in the immediate post-transplant setting may increase urine flow in native kidneys, giving a false impression of transplant function.

Thiazide Diuretics

Thiazide diuretics (chlorthalidone, hydrochlorothiazide, and indapamide) become less effective as diuretics when GFR is less than 30 mL/min/1.73 m^2, although they may augment the effectiveness of a loop diuretic and retain their antihypertensive effects. Metolazone can maintain efficacy at a lower GFR.

Loop Diuretics

Loop diuretics (furosemide, bumetanide, torsemide, and ethacrynic acid) remain effective at low GFR and are generally preferred in patients with CKD, although higher doses are usually required because less reaches the site of action in the lumen as GFR falls.

Potassium-Sparing Diuretics

Potassium-sparing diuretics are the least effective diuretics and should be used cautiously in moderate to severe CKD because of the risk for hyperkalemia.

ANTIHYPERTENSIVES

Antihypertensives should be used cautiously to avoid kidney hypoperfusion.[33] Hypotension during HD may require that doses be withheld or delayed on dialysis days.

ACE Inhibitors and ARBs

Although various ARBs and the active metabolites of ACE inhibitors are excreted by the kidney, they can be used effectively in CKD if initiated at moderate doses and titrated to response, kidney function, and serum potassium level. An increase in serum creatinine (up to 30% in the first 2 months) may be associated with blood pressure response. All ACE inhibitors and ARBs can cause AKI by inhibiting angiotensin II–mediated homeostatic vasoconstriction of the efferent renal arteriole during kidney hypoperfusion (e.g., with dehydration, hypotension, blood loss, and infection) or preexisting CKD (see also Chapter 70). Nephrotoxicity is more likely with coadministration of drugs that reduce kidney perfusion, including diuretics, antihypertensives, and NSAIDs.[34] Hyperkalemia is more likely in those with CKD and those

taking potassium-sparing diuretics or supplements. ACE inhibitors or ARBs also can worsen anemia by reducing erythropoietin production.

β-Blockers

Most β-blockers (carvedilol, labetalol, metoprolol, pindolol, and propranolol) are hepatically metabolized and used at normal doses. Sotalol and atenolol are 90% removed and bisoprolol 50% removed by the kidney, and so dose reductions are often but not always required as they can be dosed to clinical effect. Atenolol can sometimes be given three times weekly after dialysis. β-Blockers may slightly elevate serum potassium.

Calcium Channel Blockers

Pharmacokinetics of CCBs are generally unaltered in CKD. These drugs are usually well tolerated and used in normal doses. Dihydropyridine CCBs (especially amlodipine) can cause edema in the lower limbs that is more likely due to "capillary leakage" than fluid retention, and it is less responsive to diuretics. This can aggravate the edema of CKD. To varying extents, CCBs inhibit CYP3A4 and P-glycoprotein, causing increased absorption and reduced elimination of various substrate drugs, including CNIs and mTORs. Verapamil and diltiazem are moderately potent inhibitors, and dose modification of the affected drug is required. This interaction has been exploited so that diltiazem and other, more potent CYP3A4 and P-glycoprotein inhibitors are used as immunosuppressant-sparing agents.[35,36] Other CCBs do not usually cause clinically significant interactions.

Other Antihypertensives

Methyldopa, clonidine, prazosin, terazosin, doxazosin, and minoxidil can be initiated and titrated at conventional dosage but may be associated with a higher incidence of adverse effects in patients with CKD. In particular, minoxidil is relatively contraindicated in CKD because it can lead to volume expansion with the development of pericardial and pleural effusions; when used, additional diuretic therapy may be required. α-Blockers cause profound orthostatic hypotension. Nitroprusside must be used cautiously because the toxic metabolite thiocyanate may accumulate with CKD but can be removed by hemodialysis.

ANTIANGINAL AGENTS

Most antianginals (nitrates, CCBs, nicorandil, and perhexiline) can be used as normal.

ANTIARRHYTHMICS

Various antiarrhythmics (digoxin, flecainide, disopyramide, procainamide, and sotalol) rely on kidney excretion and require dose modification. Digoxin has significant kidney excretion and a narrow therapeutic window, so dose reduction is essential even in mild CKD. Because of reduced tissue protein binding and V_D, some physicians use a smaller loading dose of digoxin than in patients with normal kidney function. Cautious monitoring and titration can prevent accumulation and toxicity. When possible, monitoring of antiarrhythmic drug concentrations and the electrocardiogram is recommended. Other agents (amiodarone, flecainide, metoprolol, mexiletine, and verapamil) are used at normal doses.

LIPID-LOWERING AGENTS

Bile Acid–Binding Resins

Bile acid–binding resins are now rarely used, and the large fluid volumes required to administer them limit their use in fluid-restricted kidney patients. They can interfere with absorption and enterohepatic recirculation of various drugs, including mycophenolate.

Statins

Most statins (hydroxymethylglutaryl–acetyl CoA [HMG-CoA] reductase inhibitors) are extensively metabolized and can be used effectively at normal doses in CKD and those who have undergone transplantation.[37] Pravastatin is partially cleared via the kidneys. Rhabdomyolysis with AKI can occur, although the risk does not appear to be greatly increased with CKD. The risk increases with concomitant use of fibrates and drugs that inhibit the CYP3A4 metabolism of most statins. Patients commencing therapy should have kidney function and creatine kinase monitored regularly.

Fibrates

Fenofibrate but not gemfibrozil has extensive kidney clearance, and dose reduction is required. Combination of statins and fibrates significantly increases the risk for rhabdomyolysis and should be used only when benefits outweigh risks and with monitoring for muscle symptoms, creatine kinase, and alanine aminotransferase.

DIABETES

In addition to diabetes being a cause of CKD, the kidney also plays an important role in insulin metabolism, and thus kidney function influences glycemic control. Diabetes is common after transplantation because of resumed insulin metabolism by the functioning transplant and also the effect of tacrolimus and corticosteroids. Patients with CKD are at increased risk for hypoglycemia, and drugs should be initiated and titrated cautiously.[38] Various antidiabetic drugs depend on kidney excretion, and accumulation in CKD can cause adverse effects.[39] Management of diabetes in CKD is discussed in Chapter 33.

Diabetes Management in Peritoneal Dialysis

Patients receiving PD may have higher antihyperglycemic requirements because of the glucose load in PD fluid. If insulin is administered intraperitoneally, dosages may differ from intravenous requirements. Icodextrin solutions can significantly interfere with blood glucose monitoring because of metabolites (maltose, maltotriose, or maltotetrose) that falsely elevate blood glucose readings when monitors that use the enzyme glucose dehydrogenase pyrroloquinoline quinone reaction are used. This may lead to administration of insulin and the development of life-threatening hypoglycemia. A glucose-specific test strip is required to avoid interference.

Biguanides

Metformin is excreted almost entirely unchanged in urine, and accumulation can contribute to severe or fatal lactic acidosis (see Chapter 33),[40] although the association is inconsistent. Metformin should be temporarily discontinued in situations known to increase the risk for lactic acidosis or reduce kidney function (e.g., acute tissue hypoxia, dehydration, serious infection, or trauma) and 24 to 48 hours before anticipated surgery or use of iodinated radiocontrast media. Current Kidney Disease: Improving Global Outcomes guidelines recommend metformin as first-line therapy in CKD but to discontinue it where GFR is less than 30 mL/min/1.73 m^2. Even with low-dose use in patients with GFR less than 30 mL/min/1.73 m^2, there is still a risk for lactic acidosis, and an acute deterioration in kidney function can reduce drug clearance at any time. Patients on this regimen should be advised to seek early medical advice in any cases of acute deterioration in health.

Insulins

As GFR decreases, insulin clearance decreases in parallel, and so hypoglycemia may ensue if kidney function deteriorates and insulin regimens are not adjusted accordingly. Uremia, however, can cause peripheral resistance to insulin, requiring increased doses. Most insulin regimens can be used in patients with CKD or transplantation with cautious titration and monitoring.

Meglitinides

The nonsulfonylurea insulin secretagogues repaglinide and nateglinide can be used in patients with kidney failure without dose adjustment.

Sulfonylureas

Sulfonylureas are metabolized, and some (glibenclamide and glimepiride) have active metabolites that are excreted by the kidney. In moderate to severe CKD, the risk of hypoglycemia is increased.[41] These agents should be initiated at a low dose and titrated to response. Gliclazide and glipizide are preferable because they do not have active metabolites. Regardless of which agent is used, the effect of sulfonylureas still may be increased because the insulin they release will itself have a prolonged action in CKD.

Sodium-Glucose Cotransporter-2 Inhibitors

Sodium-glucose cotransporter-2 inhibitors (e.g., dapagliflozin, canagliflozin, empagliflozin) depend on adequate kidney function to lower blood glucose levels and may be less effective at achieving this outcome in moderate or severe CKD. Nevertheless, trials suggest their independent renoprotective benefits by reducing proteinuria and delaying diabetic kidney disease.[42,43] Dapagliflozin, empagliflozin, and ertugliflozin are currently not licensed for eGFR less than 45 mL/min/1.73 m^2.

Dipeptidyl Peptidase-4 Inhibitors

Many dipeptidyl peptidase-4 inhibitors (saxagliptin, sitagliptin, vildagliptin) rely on kidney excretion and require significant dose reduction in CKD. No dose adjustment is required for linagliptin.

Glucagon-Like Peptide-1 Receptor Agonists

Several glucagon-like peptide 1 analogs (dulaglutide, liraglutide, semaglutide) may be used without dose adjustment even in severe CKD. However, exenatide should be used with caution when eGFR is less than 45 mL/min/1.73 m^2 and is not recommended when eGFR is less than 30 mL/min/1.73 m^2.

Thiazolidinediones

Thiazolidinediones are extensively metabolized and excreted in bile. Their pharmacokinetics are not significantly altered by CKD and in fact show reduced exposure, possibly because of reduced protein binding. However, they can cause fluid retention and edema, exacerbating the difficulties of fluid management and heart failure and are generally best avoided in CKD. Thiazolidinediones have been associated with dilutional anemia because of an increase in plasma volume, which may complicate management of the anemia associated with CKD.

DRUGS FOR THYROID DISORDERS

Thyroid hormones generally do not require dose alteration in CKD.[44] Doses should be initiated and titrated to thyroid-stimulating hormone levels and clinical effect. In circulation, thyroxine (T_4) is 99.98% protein bound (0.02% free), and triiodothyronine (T_3) is 99.8% bound (0.2% free). T_3 and T_4 bind partially, in slightly different proportions, to three different plasma proteins: thyroid-binding globulin, thyroid-binding prealbumin, and albumin. In protein-deficient states (e.g., nephrotic syndrome), there is the possibility of transient or permanent changes in thyroid hormone protein binding that may alter the free fraction of T_3 and T_4, leading to transient toxicity. Uremic toxins can inhibit enzymes associated with conversion of T_4 to T_3. Oral absorption of thyroid hormones is affected by coadministration with metallic phosphate binders and iron. Euthyroid patients with CKD may have abnormal thyroid function test results, possibly because of decreased peripheral conversion of T_4 to T_3, decreased clearance of reverse T_3 generated from T_4, or decreased binding of thyroid hormones to proteins. Antithyroid (carbimazole and propylthiouracil) can be used at usual doses.

MINERAL AND BONE DISORDERS

Prescribing for these disorders is further discussed in Chapter 88.

Phosphate Binders

Phosphate binders should be taken with meals for maximal efficacy. Patients can be educated to adjust phosphate binder dose to the phosphate content in each meal. Doses are not affected by kidney function, except that the requirement for phosphate binders tends to increase as GFR declines. Dosage is based on plasma phosphate concentration and the need to avoid biochemical abnormalities. Acid suppression may reduce the effectiveness of some phosphate binders but not sucroferric oxyhydroxide. Phosphate binders also may reduce gastrointestinal absorption of drugs, including thyroid hormones, fluoroquinolones, tetracyclines, digoxin, and immunosuppressants.

Vitamin D

In patients with CKD, inability of the kidneys to convert 25-hydroxycholecalciferol to the active 1,25 dihydroxycholecalciferol (calcitriol) may produce relative vitamin D deficiency and hypocalcemia, which requires treatment with the active vitamin D preparations calcitriol, paricalcitol, or alfacalcidol.

Calcimimetics

Cinacalcet dosage is independent of kidney function. When possible, cinacalcet should be administered with the evening meal to improve absorption and minimize side effects. Similarly, morning blood samples for parathyroid hormone levels should be drawn at least 12 hours after administration. Cinacalcet and etelcalcetide (a calcimimetic for parenteral use), are further discussed in Chapter 90.

DYSPEPSIA, GASTROESOPHAGEAL REFLUX DISEASE, AND PEPTIC ULCERS

Proton pump inhibitors, histamine-2 (H_2) receptor blockers, and antacids are commonly used in patients with CKD (see Chapter 90).

Antacids

Alginates, magnesium trisilicate, and sodium bicarbonate are useful for symptom control, but the latter has high sodium content, which exacerbates hypertension and fluid status. Magnesium and aluminum salts can reduce the absorption of mycophenolate. Aluminum salts were widely used in the past as phosphate binders but are now often avoided in patients with advanced CKD due to the toxicity from absorbed aluminium (especially encephalopathy and bone toxicity).

H_2 Antagonists

Most H_2 antagonists are removed by the kidney but are relatively safe, so dose reduction is usually not required.[45] Protein binding and V_D are unaltered; however, the bioavailability of nizatidine is reduced in CKD. Cimetidine should be avoided because accumulation produces CNS effects, and it causes significant interactions through the CYP450 system and falsely elevates serum creatinine levels.

Proton Pump Inhibitors

Proton pump inhibitors (PPIs) are generally safe and well tolerated even at normal doses, although they have been associated with interstitial nephritis as well as with increased risk for CKD. As such, subjects with CKD should be evaluated for their need of PPIs or switched to H_2 antagonists if possible.

ANTIEMETICS

Dopamine Antagonists

Domperidone, metoclopramide, and prochlorperazine are not significantly removed by the kidney; however, extrapyramidal and CNS effects may occur in CKD as well as QT prolongation, especially at high doses. Domperidone does not cross the blood-brain barrier and may be preferable for long-term management. Metoclopramide and domperidone increase gastric emptying, which may alter drug pharmacokinetics.

5-HT_3 Antagonists

Most 5-HT_3 antagonists are minimally excreted in urine and have a wide therapeutic window. Dolasetron, granisetron, ondansetron, and tropisetron are safe, and dose modification is not required.

APERIENTS AND LAXATIVES

Adequate fluid intake is important for normal bowel function, and fluid restrictions required in many end-stage kidney disease (ESKD) and dialysis patients are frequently accompanied by constipation as a consequence. Common low-potency agents, including docusate, bisacodyl, glycerin, lactulose, liquid paraffin, senna, and sorbitol, may be used for acute or chronic constipation. Normal doses should be titrated to effect while avoiding significant dehydration, fluid shifts, or electrolyte disturbances. High-potency laxatives and bowel preparations should be used cautiously, as they may cause significant fluid and electrolyte disturbances. Preparations containing high amounts of phosphate should be avoided. Despite the large fluid volumes required for administration, isoosmotic laxatives may be used for bowel preparation in patients with CKD and dialysis.

ANTIDIARRHEALS

Opioids or their derivatives should be used with the same caution as when they are used as analgesics. Loperamide and diphenoxylate-atropine can be given in usual doses.

DRUGS FOR ERECTILE DYSFUNCTION

Phosphodiesterase-5 Inhibitors

The AUCs of sildenafil (2-fold), tadalafil (4-fold), and vardenafil (20%–30%) are increased in patients with severe CKD despite minimal dependence on kidney excretion. However, provided that relevant CV and drug contraindications are excluded, they can be used safely. They should be initiated at low doses and titrated to response. Shorter-acting agents (sildenafil and vardenafil) may be preferable. Vardenafil can prolong the QT interval.

Intracavernosal Therapy

Drugs given directly by intracavernosal injection do not achieve significant concentrations in the systemic circulation and can be used in patients with CKD.

MUSCULOSKELETAL DRUGS

Nonsteroidal Antiinflammatory Drugs

NSAIDs can cause significant nephrotoxicity and should be avoided or used with extreme caution in patients with CKD.

Miscellaneous Arthritis Drugs

Gold salts and penicillamine are now rarely used for rheumatoid arthritis. Both were associated with nephrotic syndrome caused by membranous nephropathy. Glucosamine and fish oil can be used safely.

Gout and Hyperuricemia

Gout is common in CKD due to the impaired ability to remove urate. In acute therapy, short courses of oral corticosteroids are safe and preferable to NSAIDs. Colchicine accumulation in CKD may cause diarrhea and hypoperfusion-induced CKD, as well as myelosuppression, and dosing should be reduced. In maintenance therapy, allopurinol is effective but should be initiated in low doses (50-100 mg/day) and then slowly increased over weeks, as initiation with higher disease has been associated with the allopurinol hypersensitivity syndrome (a Stevens-Johnson–like syndrome). The toxicity is greater in subjects who carry the HLA-B*58-01 allele, which is more common in Chinese (Han) and Korean peoples. Oxypurinol (the active metabolite) can also accumulate in patients with low GFR.[46] Despite this, some patients with ESKD require and tolerate normal doses. Febuxostat is another xanthine oxidase inhibitor that is not affected by decreased kidney function but was associated with a higher risk for CV mortality than allopurinol in the CARES trial, although more recent studies did not confirm this finding. Allopurinol and febuxostat significantly interacts with azathioprine with a risk for severe myelosuppression. If the combination is unavoidable, the azathioprine dose should be reduced by 75% and blood counts monitored carefully. Uricosuric agents (e.g., probenecid) inhibit secretion of acids in the proximal tubule and prevent reabsorption of uric acid from the tubular lumen. They often become ineffective with diminishing kidney function and are best avoided if GFR is less than 40 mL/min/1.73 m^2. Probenecid also interferes with the tubular secretion of many drugs, thereby increasing plasma concentrations.

Bisphosphonates

Bisphosphonates are extensively excreted in urine. The fraction not excreted is incorporated into bone, from which it slowly dissociates. In CKD, impaired clearance of the absorbed drug may increase the fraction available for incorporation into bone. The long terminal elimination half-life of these agents reflects rate-limiting dissociation from bone and may not be significantly altered in patients with CKD. Oral bisphosphonates appear to be safe in CKD stages 2 and 3. Their safety in CKD stages 4 and 5 is less well established, and they are contraindicated in adynamic bone disease. Rapid administration of intravenous bisphosphonates (pamidronate and zoledronic acid) without hydration has been associated with acute nephrotoxicity. Intravenous preparations should be administered slowly with hydration and kidney function assessed regularly. Oral bisphosphonate administration may be complicated by the volumes of fluid recommended. In addition, many patients with CKD are taking calcium-based phosphate binders or supplements that impair the absorption of oral bisphosphonates.

ANTIEPILEPTICS

Patients with CKD may be more prone to seizures (e.g., uremic encephalopathy and dialysis disequilibrium syndrome) and to the CNS effects of antiepileptics. Some antiepileptics (especially gabapentin and

levetiracetam) are primarily cleared via the kidneys, and dose modification is essential. Some antiepileptics (barbiturates, phenytoin, and carbamazepine) are strong inducers of drug-metabolizing enzymes. Coadministration with drugs reliant on hepatic metabolism (e.g., immunosuppressants) can reduce exposure and efficacy of the concomitant drug. Therapeutic drug monitoring is available for many antiepileptics and should be used to guide dosage.

Benzodiazepines

See the "Psychotropic Drugs" section.

Carbamazepine

Carbamazepine is administered as normal and titrated to response and blood concentrations. It is a potent enzyme inducer, and care must be taken to account for important drug interactions.

Phenytoin

Caution should be exercised with phenytoin in CKD because of its erratic absorption, saturable metabolism, nonlinear pharmacokinetics, reduced protein binding, and increased V_D. The concentration of free drug may be higher than in normal kidney function due to displacement from protein binding sites by uremic toxins. Ideally, the unbound (active) concentration of phenytoin should be assayed. A low total serum phenytoin level in CKD should not be mistaken as subtherapeutic and a reason to increase the dose. Nystagmus, cerebellar ataxia, and seizures can occur in overdose. Cautious titration based on effect and monitoring of free concentration is advised. Phenytoin is a potent enzyme-inducing agent, and care must be taken to account for drug interactions.

Other Antiepileptics

Levetiracetam, topiramate, and vigabatrin undergo significant kidney excretion, and dose modification is required. Valproate and lamotrigine are not significantly excreted by the kidney and do not cause enzyme induction or inhibition. Protein binding changes can increase the free fraction of valproic acid, predisposing to increased responsiveness.

ANTIPARKINSONIAN DRUGS

In addition to their use for Parkinson disease and hyperprolactinemia disorders, dopaminergic drugs are used to treat restless legs and other limb movement disorders in patients with CKD. Most are hepatically cleared and safe, although dopaminergic agents may exacerbate postural hypotension. Amantadine is highly dependent on kidney excretion, and dose modification is essential.

ANTIMIGRAINE DRUGS

Simple analgesics (acetaminophen) are used as normal, although aspirin should be avoided at analgesic doses and opioids used cautiously (see discussion of analgesics). NSAIDs are best avoided because of potential nephrotoxicity. 5-HT_1 agonists are effective in patients with CKD and transplantation. Naratriptan relies the most on kidney excretion (50%), and a lower maximum dose is recommended. Sumatriptan and zolmitriptan are preferred because they are less dependent on kidney excretion.

PSYCHOTROPIC DRUGS

Most psychotropics are fat soluble and nondialyzable, undergo significant hepatic metabolism, and are excreted as inactive compounds. Even so, kidney patients are often more susceptible to common adverse effects (especially CNS effects).[47] Slow titration and dose modifications are required. Adverse effects are not easily distinguished from symptoms of uremia. Despite being metabolized extensively by CYP450 enzymes, very few psychotropics cause clinically significant inhibition or induction of CYP3A4.

Selective Serotonin Reuptake Inhibitors

Most selective serotonin reuptake inhibitors (SSRIs) are extensively metabolized to compounds without significant SSRI activity.[48] Normal doses of citalopram, fluvoxamine, paroxetine, and sertraline can be used with cautious dose titration. Fluoxetine is metabolized to an active metabolite (norfluoxetine), but single- and multiple-dose studies have shown little change in pharmacokinetics, even in dialysis patients. Patients with CKD may be more prone to the CNS toxicity of SSRIs and serotonin syndrome. SSRIs can cause the syndrome of inappropriate antidiuretic hormone secretion and platelet aggregation or hemorrhagic complications, which may increase the risk for bleeding in uremic patients who are already prone to bleeding complications. Although most SSRIs have some inhibitory effect on CYP3A4, this is usually not significant. Fluoxetine and fluvoxamine are more likely to interact than citalopram and sertraline, but all can be used in patients taking immunosuppressants. Cinacalcet can cause significant inhibition of CYP2D6-mediated metabolism of SSRIs and perhexiline. This may increase the possibility of serotonin syndrome or perhexiline toxicity, though this risk can be mitigated by extra monitoring.

Tricyclic Antidepressants

Tricyclic antidepressants (TCAs) are now infrequently used for depression but more for neuropathic pain and sleep, and their anticholinergic properties in urinary tract disorders. They are predominantly metabolized to metabolites with varying activity. Patients with CKD may be more prone to the common anticholinergic adverse effects, particularly urinary retention, orthostatic hypotension, confusion, and sedation.[49] Some including amitriptyline can also prolong QT interval. Obstructive uropathy can occur from the anticholinergic properties. Cautious initial doses and titration of TCAs are recommended. Depending on response, many agents can be used at up to normal or maximal doses.

Monoamine Oxidase Inhibitors

Monoamine oxidase inhibitors (MAOIs) are extensively metabolized by the liver. Although they are now rarely used, normal doses of reversible MAOIs (moclobemide) are preferred and can be titrated cautiously to full doses. MAOIs can cause peripheral edema, which is not usually associated with fluid retention and is unresponsive to diuretics. Prostatic hypertrophy and urinary retention also may occur.

Other Antidepressants

Venlafaxine dose should be initially reduced in patients with severe CKD because of reduced clearance of the active metabolite *O*-desmethylvenlafaxine and the potential for hypertension. Nefazodone is used at a normal dose.

Antipsychotics

Conventional antipsychotics cause a variety of side effects to which patients with CKD may be susceptible (sedation, confusion, and postural hypotension). Caution is advised for atypical antipsychotics that prolong the QT interval (e.g., pimozide, thioridazine, mesoridazine, droperidol, and ziprasidone). Newer atypical agents are more commonly used and better tolerated. Clozapine, olanzapine, quetiapine, and aripiprazole are commenced at normal doses and titrated to response. The clearances of risperidone and its active metabolite 9-hydroxyrisperidone are reduced by 60% in severe CKD. Lithium is

filtered and reabsorbed mainly in the proximal tubule. It has extensive kidney clearance and accumulates even in mild CKD, causing toxicity, and should be used with increased plasma monitoring if required. Lithium is handled by the body like sodium, and any drug that affects plasma sodium concentration will likely affect plasma lithium concentration. Such drugs include diuretics that increase sodium loss, and the kidney "compensates" by retaining lithium and NSAIDs. HD is efficient in removal of lithium and can be used in overdose; however, multiple dialysis treatments are usually required because plasma concentrations rebound soon after HD. Chronic lithium nephrotoxicity is discussed further in Chapter 65.

Benzodiazepines

Benzodiazepines are extensively metabolized by the liver to a range of active and inactive metabolites. Enhanced CNS toxicity, especially sedation, is the main concern in kidney patients. Because of the potential for accumulation, chronic use should be discouraged. Shorter-acting benzodiazepines are preferred, and the dose should be titrated cautiously according to response. The dose of midazolam should be reduced because of changes in plasma protein binding. Hemoperfusion and dialysis are not useful in patients with benzodiazepine intoxication. Flumazenil may be used as an antidote in patients with overdose, at doses similar to those with normal kidney function.

ANEMIA DRUGS

Erythropoiesis-Stimulating Proteins

The pharmacokinetics of erythropoiesis-stimulating agents (ESAs) are not affected by kidney function per se. However, as kidney function decreases, dose requirements may increase to account for reduced endogenous erythropoietin production. Use of ESAs is discussed in detail in Chapter 86.

Iron Therapy

Oral supplements may be sufficient in early-stage CKD or PD patients who do not have the same degree of regular blood loss as HD patients. The most iron that can be absorbed from the gut is likely approximately 20 mg/day, and many iron tablets contain much more than this (generally 80–100 mg). Patients with severe iron deficiency including those on HD often require intravenous supplementation (see Chapter 86).

ANTIHISTAMINES

Normal doses of sedating antihistamines generally can be used. They should be used cautiously in patients with bladder outflow obstruction because of their anticholinergic adverse effects that may cause or aggravate urinary frequency or retention. Newer, less sedating antihistamines are better tolerated and have a wider therapeutic window, and accumulation rarely causes significant complications. Cetirizine relies more on kidney clearance, and dose reduction is suggested. Loratadine and desloratadine have active metabolites but are safe. Fexofenadine is safe; however, terfenadine should be avoided because of the risk for arrhythmias.

VACCINES

Live vaccines (BCG [bacillus Calmette-Guérin], oral poliovirus, rubella, typhoid, yellow fever, and varicella) in immunosuppressed patients are contraindicated because of the potential for causing disease. Attenuated vaccines (diphtheria-tetanus, hepatitis B, influenza, meningococcal, and pneumococcal) may be used, but impaired response in immunocompromised individuals may lead to inadequate protection. Hepatitis B may need more doses for seroconversion to be achieved in patients on HD. Immunization should preferably occur at least 1 month before initiation of immunosuppression. After transplantation, the immune response may be inadequate for at least 6 to 8 months, meaning that vaccination should be withheld until then.[50]

VITAMIN SUPPLEMENTATION

Patients with CKD may become vitamin deficient as a result of poor dietary intake and the effect of dialysis on removal of water-soluble vitamins. Administration of vitamin supplements (B, C, and folic acid) is recommended after dialysis. In contrast, liposoluble vitamin A (retinol, beta-carotene) may accumulate in patients on dialysis, causing hypervitaminosis A, and supplementation is not required.[51]

SELF-ASSESSMENT QUESTIONS

1. Which of the following drugs require(s) clinically significant dose modification in patients with significantly reduced kidney function?
   A. Enoxaparin
   B. Gabapentin
   C. Amoxicillin
   D. Amlodipine
   E. Famciclovir
2. Which of the following drugs is/are the most likely to cause clinically significant drug interactions with calcineurin inhibitors?
   A. Fluconazole
   B. Clarithromycin
   C. Vancomycin
   D. Acyclovir
   E. Roxithromycin
3. Which of the following drugs require(s) dose modifications in chronic kidney disease because of a metabolite that is substantially removed by the kidney?
   A. Olanzapine
   B. Allopurinol
   C. Atenolol
   D. Amlodipine
   E. Pethidine (meperidine)
4. Which of the following drugs is/are likely to be removed by hemodialysis and should therefore be dosed after dialysis?
   A. Pregabalin
   B. Amiodarone
   C. Levetiracetam
   D. Pantoprazole
   E. Acyclovir

Herbal and Over-the-Counter Medicines and the Kidney

Mark S. Segal, Xueqing Yu

The use of herbal medicines and dietary supplements continues to increase globally. An estimated one-third of adults in wealthy countries and more than 80% of the population in many low- and middle-income countries use herbal and folk medicines to promote health and manage a number of common maladies, such as colds, hay fever, indigestion, and constipation, as well as liver cirrhosis, cancer, heart disease, acquired immunodeficiency syndrome (AIDS), and diabetes.[1] With the expanding legalization of medicinal and recreational marijuana, this use is poised to increase even further. In Africa, up to 80% of the population depends on traditional medicine for primary health care; in China, herbal preparations account for up to 50% of the total consumption of pharmaceutical agents; and there has been a surge in the popularity of herbal medicine in the West. For instance, the U.S. herbal medicine market increased from $1.6 billion in 1994 to $9.6 billion in 2019[1,2]; complementary and alternative medicines, including Chinese herbal medicines and herbal plants, have been used by about 50% of Australians.[1]

Germany and France are the leaders in sales of over-the-counter (OTC) herbal medicines in Europe and also have large markets for prescription herbal preparations (Fig. 79.1).[3] The European Union has taken steps to regulate herbal remedies with the Traditional Herbal Medicinal Products Directive (also known as Directive 2004/24/EC), which was implemented in May of 2011. This mandates that all herbal medicinal products must obtain an authorization to market within the European Union and that herbal medicines must be manufactured under Good Manufacturing Practice.

There are at least 11,000 species of plants for medicinal use, and about 500 of them are commonly used by various ethnic groups.[1,4] These herbal plants may be used either in their primary forms or in mixtures. However, the source and composition of botanical medicines vary depending on the prevalent local practices. Herbal remedies are not tested for efficacy and safety, their ingredients are largely unknown, and there is no standardization of dosage and route of administration. Organ toxicity caused by traditional medicines is directly related to a combination of poor education, poverty, lack of medical facilities, weak or absent legislation, and widespread belief in indigenous systems of medicine in rural areas. Problems related to herbal medicines arise as a result of intrinsic toxicity, adulteration, contamination, substitution, misidentification, mistaken labeling, and unfavorable herb-drug interactions.[1,4] Increasing evidence for both adverse drug reactions and poisoning events associated with the use of herbal medicines has been reported worldwide. Herbal medicines have been found to be adulterated with synthetic drugs and other potentially toxic compounds. On the other hand, coadministration of herbal medicines with conventional drugs raises the potential for herb-drug interactions, which may cause altered drug elimination, undertreatment, and/or toxicity.[1,4,5]

HERBAL MEDICATIONS AND THE KIDNEY

The kidneys are particularly vulnerable to toxic injury because of their high blood flow rate, large endothelial surface area, high metabolic activity, active uptake by tubular cells, medullary interstitial concentration, and low urine pH. Kidney tubules are involved in active transport and urinary concentration, and therefore the local concentration of these toxins is potentially high, leading to direct injury to tubular cells. Herbal medicines may be nephrotoxic via one or more common pathogenic mechanisms, including alterations in intraglomerular hemodynamics, tubular cell toxicity, inflammation, crystal nephropathy, rhabdomyolysis, and thrombotic microangiopathy. Furthermore, potentially nephrotoxic exogenous substances such as paint thinners, turpentine, chloroxylenol, ginger, pepper, soap, vinegar, copper sulfate, and potassium permanganate are often added to herbal compounds. Drug-related nephrotoxicity is becoming more common, as more people have comorbidities that require multiple medications and more diagnostic and therapeutic procedures, all with the potential to harm kidney function. Patient-related risk factors for drug-induced nephrotoxicity include age greater than 60 years, underlying glomerular filtration rate (GFR) less than 60 mL/min/1.73 m^2, volume depletion, diabetes, heart failure, and sepsis.[6] These same risk factors also may make individuals susceptible to kidney toxicity from herbal medicines.

An overview of the potential kidney side effects of herbal medicines is shown in Table 79.1.

ARISTOLOCHIC ACID NEPHROPATHY

Aristolochic Acids

Aristolochic acids (AAs) are a family of structurally related nitrophenanthrene carboxylic acids found in herbal medicines such as *Aristolochia* spp., including *A. fangchi, A. clematitis,* and *A. manshuriensis* (Table 79.2). The predominant AAs are AAI (8-methoxy-6-nitro-phenanthro-[3,4-*d*]-1,3-dioxolo-5-carboxylic acid) and AAII (6-nitro-phenanthro-[3,4-*d*]-1,3-dioxolo-5-carboxylic acid). AAs are activated by human NAD(P)H:quinone oxidoreductase (NQO1)[7] and react with DNA to form covalent 7-(deoxyadenosin-N6-yl)aristolactam I (dA-AA) and 7-(deoxyguanosin-N2-yl)aristolactam(dG-AA) adducts. These aristolactam adducts are mutagenic.[8] After even a single dose, AAI is stably detected in the kidneys. Human aristolochic acid nephropathy (AAN) is reproducible in rodents with AA intoxication, resulting in tubular atrophy and interstitial fibrosis, leading to kidney failure.[9] The progressive tubular atrophy is related to impaired regeneration and apoptosis of proximal tubular epithelial cells, which is considered a possible mechanism of tubular epithelial cell deletion. The resident fibroblast activation plays a critical role in the process of kidney fibrosis during AA toxicity.[10] The nephrotoxic and carcinogenic

Distribution of Over-the-Counter Herbal Medicine Use in Europe

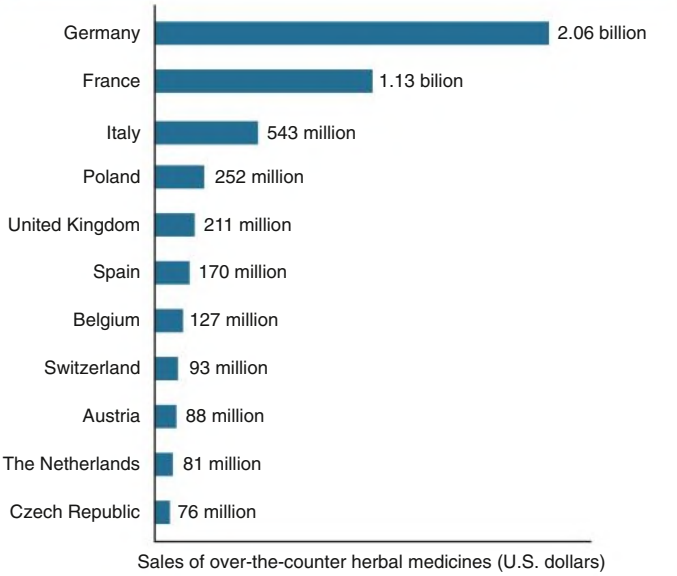

Fig. 79.1 Distribution of the $4.96 billion European market for over-the-counter herbal medicines in 2003. (Data from De Smet PA. Herbal medicine in Europe—relaxing regulatory standards. *N Engl J Med.* 2005;352:1176–1178.)

TABLE 79.1 Kidney Syndromes Induced by Herbal Medicines

Syndrome	Herbal Medicine
Hypertension	*Glycyrrhiza* spp. (Chinese herbal teas, gancao, boui-ougi-tou) *Ephedra* spp. (ma huang)
Acute tubular necrosis	Traditional African medicine: toxic plants (*Securidaca longepedunculata, Euphoria matabelensis, Callilepis laureola,* Cape aloes), or adulteration by dichromate Chinese medicine: *Taxus celebica* Morocco: *Takaout roumia* (paraphenylenediamine)
Acute interstitial nephritis	Peruvian medicine *(Uña de Gato)* Tung Shueh pills (adulterated by mefenamic acid)
Fanconi syndrome	Chinese herbs containing AAs (*Akebia* spp., boui-ougi-tou, Mokutsu) Chinese herbs adulterated by cadmium
Papillary necrosis	Chinese herbs adulterated by phenylbutazone
Chronic interstitial kidney fibrosis	Chinese herbs or Kampo containing AAs (*Aristolochia* spp., *Akebia* spp., Mu Tong, Boui, Mokutsu)
Urinary retention	*Datura* spp., *Rhododendron molle* (atropine, scopolamine)
Kidney stones	Ma huang (ephedrine) Cranberry juice (oxalate)
Urinary tract carcinoma	Chinese herbs containing AAs

AA, Aristolochic acids.

TABLE 79.2 Botanicals Known or Suspected to Contain Aristolochic Acid and Their Common Names

Botanical Name	Common or Other Names
Aristolochia spp.	Aristolochia, Guan Mu tong, Guang Mu tong
Aristolochia acuminata (syn. *A. tagala*)	Oval leaf Dutchman's pipe
Aristolochia bracteata	Ukulwe
Aristolochia clematitis	Birthwort
Aristolochia contorta	Ma Dou Ling (fruit), Bei Ma Dou Ling (root), Tian Xian Teng (herb)
Aristolochia cymbifera	Mil homens
Aristolochia debilis (syn. *A. longa, A. recurvilabra, A. sinarum*)	Ma Dou Ling (fruit), Tian Xian Teng (herb), Qing Mu Xiang (root), Sei-Mokkou (Japanese), Birthwort, Long birthwort, Slender Dutchman's pipe
Aristolochia fangchi	Guang Fang ji (root), Fang ji, Fang chi, Makuboi (Japanese), Kou-boui (Japanese), Kwangbanggi (Korean)
Aristolochia heterophylla	Han Fang Ji
Aristolochia indica	Indian birthwort (root), Yin Du Ma Dou Ling
Aristolochia kaempferi (syn. *A. chrysops, A. feddei, A. heterophylla, A. mollis, A. setchuenensis, A. shimadai, A. thibetica, Isotrema chrysops, Isotrema heterophylla, Isotrema lasiops*)	Yellowmouth Dutchman's pipe, Zhu Sha Lian
Aristolochia macrophylla (syn. *A. sipho*)	Dutchman's pipe
Aristolochia manshuriensis (syn. *Hocquartia manshuriensis, Isotrema manshuriensis*)	Manchurian birthwort, Manchurian Dutchman's pipe (stem), Guan Mutong (stem), Kan-Mokutsu (Japanese), Mokubai (Japanese), Kwangbanggi (Korean)
Aristolochia maxima (syn. *Howardia hoffmannii*)	Maxima Dutchman's pipe, Da Ma Dou Ling
Aristolochia mollissima	Wooly Dutchman's pipe, Mian Mao Ma Dou Ling
Aristolochia moupinensis	Moupin Dutchman's pipe, Huai Tong
Aristolochia sarpentaria (syn. *A. serpentaria*)	Virginia snakeroot, Serpentaria, Virginia serpentary
Aristolochia triangularis	Triangular Dutchman's pipe, San Jiao Ma Dou Ling
Aristolochia tuberosa	Tuberous Dutchman's pipe, Kuai Jing Ma Dou Ling
Aristolochia tubiflora	Tubeflower, Dutchman's pipe, Guan Hua Ma Dou Ling
Aristolochia versicolar	Versicoloraus Dutchman's pipe, Bian Se Ma Dou Ling
Asarum canodense (syn. *A. acuminatum, A. ambiguum, A. canadense, A. furcatum, A. medium, A. parvifolium, A. reflexum, A. rubrocinctum*)	Wild ginger, Indian ginger, Canada snakeroot, false coltsfoot, colic root, heart snakeroot, Vermont snakeroot, Southern snakeroot, Jia Na Da Xi Xin
Asarum himalai(y)cum	Tanyou-saishin (Japanese)
Asarum splendens	Do-saishin (Japanese)

Fig. 79.2 Traditional Chinese Pharmacy. A pharmacy selling traditional herbal remedies *(left)* including Fang Chi *(right)*. The true incidence of aristolochic acid nephropathy (AA) is largely unknown and probably underestimated because numerous ingredients known or suspected to contain AA are used in traditional medicine in India and Eastern Asia. (From Debelle FD, Vanherweghem JL, Nortier JL. Aristolochic acid nephropathy: A worldwide problem. *Kidney Int.* 2008;74:158–169.)

effects of AAs have been reported in animals; exposure to AA causes a progressive interstitial fibrosis associated with urothelial malignancy. Similar toxicities are observed in humans.

Aristolochic Acid Nephropathy

The association of kidney disease with long-term consumption of *A. fangchi* was first reported in Belgium in nine young women taking slimming preparations.[11] Since then there have been case reports and series from around the world.[12] Even though this disease may affect millions worldwide, high-quality epidemiologic data on the incidence and prevalence of AAN are lacking because of the absence of internationally agreed on diagnostic criteria and low awareness of the disease.[12] Increasing evidence supports that it is the AAs in the herbs that are responsible for their kidney toxicity (Figs. 79.2 and 79.3).[9] This syndrome was initially referred to as *Chinese herb nephropathy* and is now known by the more specific, mechanistic name of AAN.[13] The kidney toxicity of AA depends on the dosage and the duration of administration.[14] It is now clear that Balkan endemic nephropathy (BEN), a condition known for several decades without a known cause, is a form of AAN, in which there is contamination of wheat (flour) by *A. clematitis*.[9]

Definition

AAN is characterized by tubulointerstitial nephritis that progresses to fibrosis with deterioration of kidney function, ultimately leading to end-stage kidney disease (ESKD), sometimes within months after first exposure. There is a high associated risk for uroepithelial malignancy.

Epidemiology

Soon after its initial description, AAN was recognized as a global health problem.[9,11,12,14,15] Since the publication of the index cases, new cases of AAN have been reported, not only in Belgium but also worldwide.[9–16] The true incidence of AAN remains unknown and is probably underestimated because numerous ingredients known or suspected to contain AA are used in traditional medicine in China, Japan, and India (see Fig. 79.3).[9] AAN affects thousands of people living in discrete areas in Bulgaria, Bosnia, Croatia, Romania, and Serbia along the Danube River basin (Fig. 79.4), and was formerly known as BEN there.[15,17] This form of AAN typically presents in the fourth or fifth decade of life and is rarely seen in individuals younger than 20 years, presumably reflecting low-grade chronic exposure to AA.

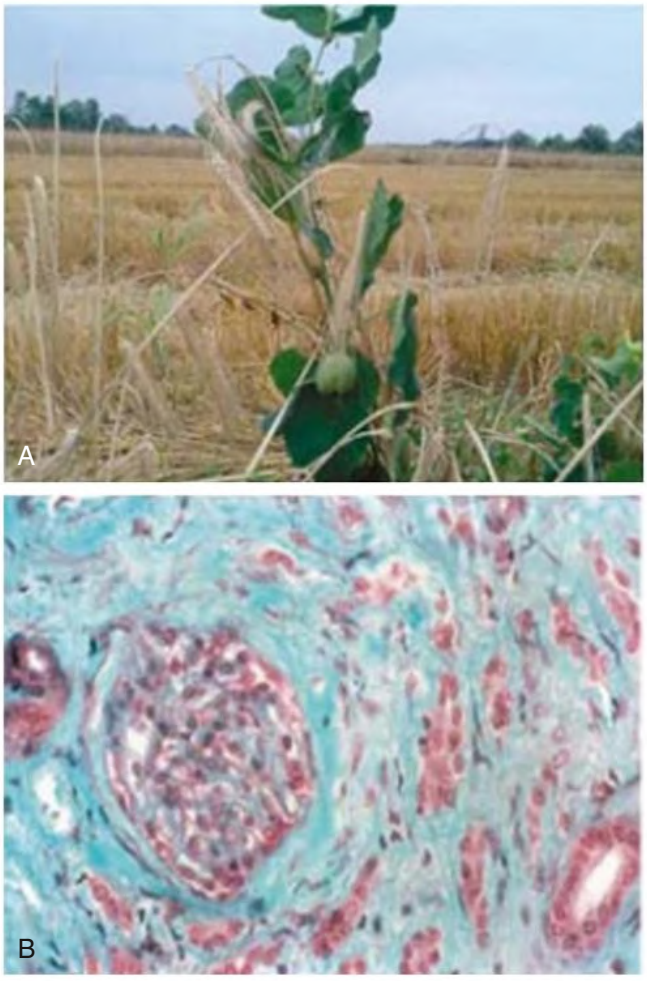

Fig. 79.3 Chinese Herb or Aristolochic Acid Nephropathy. (A) Guang Mu Tong, a Chinese herb that contains aristolochic acids. (B) Extensive paucicellular interstitial fibrosis and tubular atrophy typically found in Chinese herb or aristolochic acid nephropathy. The same pathologic appearances are seen in Balkan endemic nephropathy. (From Debelle FD, Vanherweghem JL, Nortier JL. Aristolochic acid nephropathy: a worldwide problem. *Kidney Int.* 2008;74:158–169. Courtesy Dr. Bojan Jelaković.)

Fig. 79.4 Areas Where Balkan Nephropathy is Prevalent. The endemic areas are in *red*. (From Djukanović L, Marinković J, Marić I, et al. Contribution to the definition of diagnostic criteria for Balkan endemic nephropathy. *Nephrol Dial Transplant.* 2008;23[12]:3932–3938.)

Clinical Manifestations

The initial presentation of AAN is usually silent, with the kidney disease only discovered by routine blood testing. Occasional patients present with Fanconi syndrome or with acute kidney injury (AKI) caused by acute tubular necrosis.[18] The urinary sediment is unremarkable, and the urinalysis is initially negative for albuminuria. However, urinary excretion of low molecular weight proteins (e.g., β_2-microglobulin, cystatin C) is markedly increased, and the ratio of urinary low molecular weight protein to albumin is higher than in glomerular diseases.[19] When there is prospective monitoring in endemic areas, tubular proteinuria is usually the first manifestation. Other manifestations of tubular dysfunction include impaired acidification, decreased ammonia, increased uric acid excretion, and urine-concentrating defects with salt wasting, which may precede the decrease in GFR. The disease progresses to ESKD. Other hallmarks are that the severity of the anemia is disproportionate to the degree of kidney function impairment and that the blood pressure is usually in the normal range until the development of ESKD.

The increased incidence of uroepithelial carcinomas is characteristic of AA exposure. A case series identified upper tract urothelial carcinoma as a potent risk factor for bladder urothelial carcinoma after kidney transplantation for AAN, indicating that long-term follow-up for recurrent malignancy is potentially important (see "Treatment" section).[20]

Pathology

AAN is characterized by extensive interstitial fibrosis and tubular atrophy, which generally decreases in severity from the outer to the inner cortex (see Fig. 79.3). Early in the disease, the glomeruli are relatively spared, although at later stages there is some collapse of the capillaries and wrinkling of the basement membrane. There is endothelial cell swelling with consequent thickening of interlobular and afferent arterioles.[9,21] There are no immune deposits.

Pathogenesis

The striking association between AA exposure and uroepithelial abnormalities was first noted in nephroureterectomy specimens from individuals with AAN removed at the time of transplantation, demonstrating moderate atypia and atypical hyperplasia (see Fig. 79.3).[9,22] An early and massive interstitial inflammation characterized by activated monocytes and macrophages and cytotoxic $CD8^+/CD103^+$ T lymphocytes seen in experimental AAN[23,24] suggests that the pathophysiology includes an immunologic element. The persistence of AA-DNA adducts in the kidneys of the Belgian women cohort is consistent with their postulated role of DNA adducts in urothelial cancer. Of AAN patients, 40% to 45% develop multifocal high-grade transitional cell carcinomas, mainly in the upper urinary tract.[16] There is a strong association between DNA adduct formation, mutation pattern, and tumor development. In animal models, oral ingestion of AA is followed by extensive formation of AA-DNA adducts in the forestomach, accompanied by the development of tumors.[20] A genome-wide search in a series of cancers from Taiwan (where a significant fraction of the population is prescribed herbal medicines containing AA) demonstrated the presence of AA-DNA adducts and other DNA signatures of AA exposure in cancers of the upper urinary tract. Of additional concern was the presence of AA-DNA adducts in cancers of the liver and kidney.[25] Transitional cell cancers from patients with AAN contain AA and a characteristic pattern of tumor protein 53 (TP53) mutations, 89% occurring at A:T pairs and 78% of these being A:T to T:A transversions. These types of transversions are not seen in transitional cell carcinomas of the renal pelvis in the absence of AA exposure. Molecular epidemiologic evidence relates urothelial carcinoma in patients with AAN to dietary exposure to AA.[26]

The link between AA and BEN, which confirmed that BEN is a form of AAN, came from the insight that in endemic regions, bread is a dietary staple and is traditionally prepared from flour made from locally grown wheat. The seeds of *A. clematitis,* a plant native to the region, were found interspersed with the harvested wheat grain, and dA-aristolactam and dG-aristolactam DNA adducts were found in the kidney cortex of patients with BEN but not in those with other chronic kidney diseases (CKDs).[26,27] Aristolactam-DNA adducts have been found in 70% of people in endemic areas with dietary exposure to AA and in 94% of patients with specific A:T to T:A mutations in *TP53.* Neither aristolactam-DNA adducts nor specific mutations were detected in tissues of those from nonendemic regions. Because AAN occurs only in a fraction of those individuals exposed to AA within the endemic region, it is assumed that a genetic susceptibility puts some individuals with a dietary exposure to AA at risk for AAN and urothelial carcinoma.[9,12]

Diagnosis

Diagnostic criteria for AAN are shown in Box 79.1. An analysis of 182 patients in Serbia showed that proteinuria, urine α_1-microglobulin, and kidney size are significant predictors of AAN, whereas kidney failure and several tubular disorders (urine specific gravity, increased fractional sodium excretion, and reduced tubular phosphate reabsorption) had a nonsignificant predictive value.[15,28]

Treatment

There have been no randomized trials of treatment for AAN. However, a pilot study in 35 AAN patients with CKD demonstrated a significant reduction in the number of patients reaching ESKD after 1 year of corticosteroid therapy.[29] Corticosteroid therapy was later confirmed, in a larger cohort with historical controls, to slow the progression of kidney failure.[30] It is suggested that corticosteroids, 1 mg/kg of predniso(ol)ne for 4 weeks followed by a maintenance dose of 0.1 mg/kg tapered every 2 weeks, be initiated in those with biopsy-proven AAN (including cases discovered in endemic regions) and estimated GFR (eGFR) greater than 20 mL/min per 1.73 m^2. It is recommended to discontinue steroid

BOX 79.1 Diagnostic Criteria for Aristolochic Acid Nephropathy, Including Balkan Endemic Nephropathy

- Epidemiologic pattern
- Known exposure to aristolochic acid–containing medicines or living in endemic Balkan settlements
  - Clinical features
  - Glomerular filtration rate (GFR) decrease
  - Proteinuria usually less than 1 g/24 h
  - Bland urinary sediment
  - Markers of kidney tubular damage (glycosuria, increased urinary excretion of β_2-microglobulin or α_1-microglobulin, and *N*-acetyl-β-D-glucosaminidase)
  - Typical kidney histology showing hypocellular cortical interstitial fibrosis decreasing from the outer to the inner cortex (if kidney biopsy feasible)
- Exclusion of other known kidney disease (e.g., chronic pyelonephritis [obstructive and atrophic], adult dominant polycystic kidney disease, glomerulonephritis)

Modified from Djukanović L, Marinković J, Marić I, et al. Contribution to the definition of diagnostic criteria for Balkan endemic nephropathy. *Nephrol Dial Transplant.* 2008;23(12):3932–3938; and Luciano RL, Perazella MA. Aristolochic acid nephropathy: epidemiology, clinical presentation, and treatment. *Drug Saf.* 2015;38(1):55–64.

therapy after 6 months if the eGFR continues to decrease. Although renin-angiotensin system blockade with angiotensin-converting enzyme inhibitors or angiotensin receptor blockers is important in managing CKD, there is no evidence that this strategy improves kidney function or delays progression in AAN.[12,28]

Because patients with AAN are at increased risk for uroepithelial malignancies, all patients with AAN should undergo biannual cytologic evaluation of urine. In those patients with AAN who do not yet require kidney replacement therapy (KRT), yearly surveillance is suggested with computed tomography imaging and ureteroscopy. In addition, prophylactic bilateral nephroureterectomy is strongly recommended for all patients with ESKD caused by AAN who are going to be recipients of a kidney transplant and subsequent immunosuppression.[31]

KIDNEY INJURY CAUSED BY OTHER MEDICINALS

Aside from AAs, the use of other herbal therapy may lead to kidney injury or various toxic insults, especially in patients with kidney disease. Various kidney syndromes have been reported after the use of medicinal plants, including acute tubular necrosis, acute interstitial nephritis, Fanconi syndrome, hypertension, papillary necrosis, chronic interstitial nephritis, and nephrolithiasis.[6,32] Herbal plants reported as the cause for kidney injury include *Securidaca longepedunculata* (or violet tree), *Euphorbia matabelensis, Crotalaria laburnifolia, Uncaria tomentosa* (cat's claw), *Lepidium meyenii* (common name: maca), *Tripterygium wilfordii* (Lei Gong Teng), licorice root *(Glycyrrhiza glabra),* irumban puli *(Averrhoa bilimbi),* cape aloe, *Callilepis laureola* (Impila), mushrooms, and djenkol beans *(Pithecellobium).* In addition, the medicinal grass carp *(Ctenopharyngodon idellus)* gallbladder has been noted to cause hepatitis and acute kidney failure.[1,32–36]

ACUTE KIDNEY INJURY

T. wilfordii Hook F (TWHF) is a Chinese herbal medicine that has been used for over 2000 years. When made into a cream, it is used externally for treatment of arthritis and inflammatory swelling. Extracts of TWHF have been found to have immunosuppressive effects, which could successfully treat rheumatoid arthritis, lupus, minimal change disease, and other autoimmune disorders. The adverse effects of TWHF include gastrointestinal (GI) upset, infertility, and leukopenia. In addition, it has been reported that AKI, profound hypotension, and shock may occur after ingestion of an extract of TWHF. In rats, daily intragastric ingestion of an effective compound extracted from TWHF for 16 days led to proximal tubular dysfunction.[32,33] Despite the known risks of the herbal medication, *Tripterygium* glycosides, the active compound extracted from TWHF, is being investigated for treatment of diabetic nephropathy.

Cat's claw, or *Uña de Gato,* is a Peruvian herbal preparation made from *Uncaria,* a woody vine found in the Amazon basin. It has been used for treatment of cirrhosis, gastritis, gonorrhea, cancers of the female genital tract, and rheumatism. The oxindole alkaloids from the root bark of cat's claw are thought to invoke its putative anti-inflammatory effects, but other unknown substances contribute to the overall effect of cat's claw extracts. A case of reversible acute interstitial nephritis after the use of this preparation has been reported, likely an idiosyncratic allergic reaction to the remedy.[34]

Mushrooms

Most kidney diseases associated with mushrooms are a consequence of kidney failure resulting from mushroom-induced hepatic failure. However, throughout Europe and North America, there are a variety of nephrotoxic mushrooms that can be confused with edible mushrooms and can cause AKI. The *Cortinarius* spp. (*C. callisteus, C. cinnamomeus* group, *C. gentilis, C. orellanus, C. rainierensis, C. speciosissimus, C. splendens,* and *C. semisanguineus* group) are the most notorious (Fig. 79.5). The most common nephrotoxic mushroom is probably *C. gentilis.* In 2016 there were 6421 mushroom exposures reported in the United States and its territories, with two fatalities. The type of mushroom is unknown in over 80% of cases.[35] The history of mushroom ingestion may be remote, particularly with *Cortinarius* spp. Although GI symptoms are usually noted at the time of ingestion, they may not be severe enough for patients to seek medical attention, and symptoms of kidney failure may not manifest until 1 to 3 weeks after exposure. Presentation with a shorter latent period suggests a more severe toxicity and greater risk for severe kidney failure. Improvement in kidney function may occur within several weeks to months, but patients may require chronic dialysis or kidney transplantation.

A more recently described mushroom syndrome involves *Amanita smithiana* (U.S. Pacific Northwest) or *Amanita proxima* (France, Italy, Spain). It is thought that the toxin is 2-amino-4,5-hexadienoic acid.[36] Although it causes acute tubular necrosis within hours of ingestion, the clinical outcome is usually good.

Diagnosis of Acute Kidney Injury Induced by Folk Remedies

An accurate assessment of the contribution of herbs to AKI is made difficult by failure to elicit a history by the physician unfamiliar with these risks or denial by the patients because of fear of stigmatization or social pressure. It is often difficult to discount the contribution to AKI of the original illness for which the herbal medicine was prescribed. AKI may be either the sole manifestation or part of a multisystem and metabolic involvement.

Treatment

Management of AKI is usually supportive and includes volume replacement and correction of metabolic abnormalities. KRT is offered for the usual indications. About 60% of all folk remedy related AKI cases need KRT, with 25% to 75% mortality. Charcoal hemoperfusion is effective in clearing alfa-amanitin from circulation in those with poisoning from *Amanita* mushrooms.[37]

OTHER KIDNEY COMPLICATIONS OF HERBAL REMEDIES

Hypertension

Ma huang is an ephedra-containing herbal preparation used in the treatment of bronchial asthma, cold and flu symptoms, fever and chills, headaches and other aches, edema, and lack of perspiration. In Western countries, ephedrine and herbal ephedra preparations are used to promote weight loss and enhance athletic performance. Dietary supplements that contain ephedra alkaloids have been reported to induce hypertension, palpitations, tachycardia, and stroke. Prescribed ephedrine was not associated with a substantially increased risk for adverse cardiovascular outcomes in a registry-based case-crossover study.[38,39] However, ephedra may pose a serious health risk to some users, such as patients with kidney disease who are prone to hypertension.

The dried roots of the licorice plant *(G. glabra)* have been consumed for over 6000 years and are used as flavoring and sweating agents, as demulcents and expectorants in the Western world, and as antiallergic and anti-inflammatory agents in Asian countries, including China, Japan, and Korea. Licorice contains glycyrrhizin. After oral administration of licorice preparations, glycyrrhizinic acid is hydrolyzed by intestinal bacteria into glycyrrhetic acid. Glycyrrhetic acid can inhibit distal tubule 11-β-hydroxysteroid dehydrogenase-2 (11-BOHD-2), which converts the corticosteroid hormone cortisol to cortisone. Decreased activity of 11-BOHD-2 leads to an excess of cortisol and an overstimulation of the mineralocorticoid receptor, leading to sodium and water retention and increased excretion of potassium. Large doses of glycyrrhizinic acid over a prolonged period can cause pseudoaldosteronism, with hypokalemia, hypernatremia, edema, and hypertension, as well as arrhythmia and other cardiac disorders.[1] To minimize the adverse effects, it is recommended that licorice not be ingested for longer than 4 to 6 weeks.[40]

Crystalluria and Nephrocalcinosis

Many health drinks that are well tolerated by individuals with normal kidney function can cause serious problems in patients with kidney disease. One example is star fruit (carambola) juice, which can contain as much as 800 mg of oxalate in 100 mL and can provoke oxalate crystalluria. It should be noted that star fruit should also be avoided in dialysis patients and those with advanced kidney insufficiency because caramboxin, the neurotoxin found in star fruit, is excreted by the kidney and if ingested in large enough amounts can cause paresthesias, seizures, coma, and death. Sour carambola juice is a popular beverage in Taiwan. Although preparation of commercial carambola juice, by pickling and dilution, markedly reduces oxalate content, fresh juice or only mildly diluted postpickled juice may contain high quantities of oxalate. Cranberry concentrate tablets also can lead to an increase in oxaluria. Ingestion of ma huang drinks have been reported to lead to kidney stones, and the use of ephedrine and guaifenesin individually or in combination causes more than 35% of urinary stones that are related to pharmaceutical metabolites and 0.1% of all urinary stones.[41]

Hyperkalemia

Dietary potassium restriction is often recommended for people with chronic kidney disease, especially because hyperkalemia is a side effect of many medications used to slow the progression of kidney disease. Common foods high in potassium include oranges, bananas, tomatoes, avocadoes, and potatoes. However, some health drinks are also very high in potassium. Noni juice, often taken to increase energy, contains more potassium than any other fruit juice. The legume alfalfa *(Medicago sativa)* and the plants dandelion *(Taraxacum officinale),* stinging nettle *(Urtica dioica),* and horsetail *(Equisetum arvense)* all contain significant amounts of potassium[42] and may induce hyperkalemia in persons with CKD.

Urinary Obstruction

Djenkol beans or Jering *(Pithecellobium jiringa)* are broad, round, reddish beans that grow during monsoon season in Myanmar, Indonesia, and Malaysia and are considered a delicacy. The Jering seeds are extolled for their supposed ability to prevent diabetes and high blood pressure. In addition, the seeds have bladder spasmodic properties and are used as a remedy to eliminate stones from the bladder. Jering poisoning or djenkolism is characterized by spasmodic suprapubic and/or flank pain, urinary obstruction, and AKI.[42] Chronic djenkol bean consumption is associated with a fourfold higher risk for nonglomerular hematuria. The djenkol bean contains a large amount of djenkolic acid in the range of 0.3 to 1.3 g/100 g wet weight; 93% of the acid exists in a free state. Djenkolic acid crystals may lacerate kidney tissue and cause bleeding or obstruction. Obstruction of the kidney tubules by crystals of djenkol acid is a possible mechanism of acute tubular necrosis. Mild djenkolism requires pain control and hydration. Severe djenkolism, manifested by anuria and AKI, is usually managed with analgesia, aggressive hydration, and alkalinization of the urine with sodium bicarbonate to increase the solubility of djenkolic acid. Some cases of severe djenkolism with anuria do not respond to conservative therapy and require surgical intervention.[43]

Kidney Toxicity From Contaminants in Herbal Medicines

Herbal medicines may be contaminated with excessive or banned pesticides, microbial products, heavy metals, or chemical toxins or adulterated with orthodox drugs. These contaminants are related to the source of these herbal materials, whether grown in a contaminated environment, contaminated during collection, or contaminated during storage, sometimes intentionally. The presence of orthodox drugs is often a result of the intentional adulteration of the herbal remedy by the manufacturers.[44] A report found undeclared pharmaceuticals or heavy metals in 32% of Asian medicines sold in California. These included ephedrine, chlorpheniramine, methyltestosterone, phenacetin, sildenafil, corticosteroids, and fenfluramine; 10% to 15% contained lead, mercury, or arsenic. Of more than 500 Chinese drugs, approximately 10% contained undeclared drugs or heavy metals.[4]

Several case reports link these adulterations with kidney injury. The first report was a 73-year-old Malaysian woman who presented with kidney failure and bilateral papillary necrosis after having consumed 2 tablets daily of a traditional herbal preparation, freely available from Chinese medical halls, for 10 years for osteoarthritis. She denied the consumption of any other analgesics, but the analysis of the herbal preparation showed 120 mg of phenylbutazone in each tablet. The second report concerned a 34-year-old housewife taking a mixture of Chinese herbs who presented with Fanconi syndrome and nephrogenic diabetes insipidus. She had a urinary excretion of cadmium 50 times greater than normal. In another report, a patient presented with AKI with marked albuminuria, pyuria, and hematuria after a 4-week treatment with Tung Shueh pills for arthralgias. The cause was acute interstitial nephritis, and the Tung Shueh pills were found to contain both diazepam and mefenamic acid. In Morocco, the traditional *el badia,* a powder made of the seeds of *Tamarix orientalis,* is used as hair dye; however, in times when the *T. orientalis* seeds are scarce, they are replaced with *Takaout roumia,* which contains paraphenylenediamine. Inadvertent ingestion of paraphenylenediamine is an issue in a number of African countries; for example, in Morocco it is responsible for about 10% of all cases of AKI, 50% of all cases of rhabdomyolysis, 25% of intensive care unit admissions for poisonings, and two-thirds of poisoning-related deaths.[4,6]

In Thailand and other parts of Southeast Asia and India, there are reports of contamination of herbal remedies with cadmium and/or mercury. In South Africa, about 15% of herbal remedies are contaminated with uranium. In the United States, ginseng dietary supplements have been shown to contain the pesticides quintozene and hexachlorobenzene or to exceed the standard for lead content.

Herb-Drug Interactions Resulting in Adverse Kidney-Related Effects

Herbs with potential for pharmacokinetic and/or pharmacodynamic herb-drug interactions are often taken concomitantly with therapeutic drugs, without the prescribing physician's knowledge. Pharmacokinetic herb-drug interactions are caused by altered absorption, metabolism, distribution, and excretion of drugs. A frequent underlying mechanism of altered drug concentrations by concomitant herbal medicines is the induction or inhibition of hepatic and intestinal cytochrome P-450 enzymes (CYPs). There are reports of 32 drugs interacting with herbal medicines in humans. These drugs include anticoagulants (warfarin, aspirin, and phenprocoumon), sedatives and antidepressants (midazolam, alprazolam, and amitriptyline), oral contraceptives, antiretroviral agents (indinavir, ritonavir, and saquinavir), immunosuppressants (cyclosporine and tacrolimus), anticancer drugs (imatinib and irinotecan), and digoxin. Most of them are substrates for CYPs and/or P-glycoprotein, and many have narrow therapeutic indices. Toxicity arising from drug-herb interactions may be minor, moderate, or even fatal, depending on a number of factors associated with the patients, herbs, and drugs.[1]

St. John's wort, derived from the plant *Hypericum perforatum,* has been used since ancient times for depression and anxiety. It is the most common antidepressant used in Germany. St. John's wort induces a hepatic enzyme through activation of the CYP system, leading to decreased serum levels of a wide range of prescribed drugs, with possible clinically serious consequences. For example, St. John's wort ingested for 10 days by a group of healthy volunteers reduced the bioavailability of digoxin by an average of 25%. St. John's wort ingested for 2 weeks reduced the total absorption of indinavir by 50%, which is large enough to cause treatment failure. Other reports indicated significant increases in the metabolism of warfarin, theophylline, oral contraceptives, and cyclosporine. Use of St. John's wort in transplant recipients is associated with both toxicity and underdosage of calcineurin inhibitors as a result of phytochemically triggered activity changes of isoenzyme CYP3A4 metabolism and drug transport proteins.[45,46]

Gingko biloba is one of the most popular plant extracts in Europe and is approved in Germany for the treatment of dementia. *G. biloba* is composed of several flavonoids, terpenoids (e.g., ginkgolides), and organic acids believed to act synergistically as free radical scavengers. *G. biloba* should not be administered with concomitant anticoagulation or in patients with bleeding disorders. Concomitant use of aspirin or nonsteroidal antiinflammatory drugs (NSAIDs), as well as anticoagulants such as warfarin and heparin, should be avoided. Spontaneous hyphema and spontaneous bilateral subdural hematomas have been observed in patients taking *G. biloba* and are attributed to ginkgolide B, a potent inhibitor of platelet-activating factor needed to induce arachidonate-independent platelet aggregation. Hemorrhagic complications were observed often in patients administered concomitant anti-aggregate or anticoagulant therapy. However, the exact mechanism of the interaction of *G. biloba* with aspirin, warfarin, and NSAIDs remains unclear. Experimental data from rats suggest that a *G. biloba* diet markedly increased the content of CYP and activity of glutathione-*S*-transferase and markedly induced the level of CYP2B1/2, CYP3A1, and CYP3A2 messenger RNA in the liver.[47]

Most information about the toxicity of herbal medicines is found only in case reports, and precise identities of the culprit substances, toxicologic characteristics, and pathogenic mechanisms of herbal

medicines remain largely unknown. Although many herbs have been used for centuries without evidence of acute kidney damage, insidious damage caused by long-term use is a concern because many herbs have not been rigorously tested for toxicity.

OVER-THE-COUNTER MEDICINES AND THE KIDNEY

In addition to the increasing popularity of OTC health foods, nutritional supplements, and medicinal products from plants or other natural sources, there is increasing consumption in many countries of pharmaceutical products bought OTC, particularly analgesics and agents for treatment of dyspepsia.

Analgesics

OTC analgesics used for fever and minor musculoskeletal symptoms are one of the most widely used classes of drugs in the developed world. NSAIDs are also used to treat inflammatory conditions; and aspirin is used prophylactically as an anticoagulant in thrombosis-related disorders. Acetaminophen (paracetamol), aspirin, ibuprofen, and naproxen are available OTC in many countries, sometimes in combinations. Although studies on the association between the long-term use of aspirin, NSAIDs, and other analgesics and ESKD have given conflicting results, many studies suggest an association between chronic ingestion of analgesics and kidney disease.

Because analgesic use is widespread, even a small percentage of increased risk for kidney disease may have major public health implications. NSAIDs inhibit cyclooxygenase and may inhibit lipoxygenase, decreasing the production of prostaglandins and leukotrienes, which account for many NSAID-induced effects on the kidney. In patients with volume depletion, renal perfusion depends on circulating prostaglandins to vasodilate the afferent arterioles, allowing more blood flow through the glomerulus. So the contribution of prostaglandins to renal homeostasis is most critical in elderly patients and those with circulatory disturbances, such as kidney or liver dysfunction, congestive heart failure, or volume depletion.[48]

Patients who warrant chronic therapy with analgesics and NSAIDs should be monitored by regular screening with dipstick urinalysis and serum creatinine for early evidence of kidney injury. Specifically, low-risk patients should be monitored within 3 months and have studies repeated every 6 to 12 months and high-risk patients should be monitored within 1 to 3 weeks and have studies repeated every 3 to 6 months. Early detection and removal of the offending agent could halt or even reverse analgesic-induced kidney injury. There is a pressing need for multicenter prospective studies to assess the true incidence of this problem and study the effects of various analgesic agents (alone and in combination) in at-risk populations.

Analgesic Nephropathy

Analgesic nephropathy, resulting from the habitual consumption over several years of compound analgesics, is characterized by renal papillary necrosis and chronic interstitial nephritis. It is an increasingly rare condition because phenacetin (the analgesic most implicated as a causative agent) is banned in many countries. Phenacetin alone was not the cause of analgesic nephropathy (in fact, phenacetin was never marketed as a single agent); it was the use of phenacetin in combination analgesics that caused the problem. A retrospective cohort study using data from the Australia and New Zealand Dialysis and Transplant Registry showed that among 31,654 patients receiving KRT over the previous 35 years, 10.2% had analgesic nephropathy, but the incidence was less than 3.5% in 2005.[49] Analgesic nephropathy is discussed further in Chapter 65.

Proton Pump Inhibitors

Proton pump inhibitors (PPIs), such as omeprazole, are now available OTC in many countries and can be associated with granulomatous allergic interstitial nephritis (see Chapter 64). Use of PPIs has been linked epidemiologically to an increased risk for CKD in the general population.

Cannabis and Synthetic Cannabinoids

With the legalization of cannabis in Canada in 2018 and the decriminalization and legalization of recreational and/or medicinal use of cannabis in some states in the United States, cannabis is now the most commonly used psychotropic drug in the United States, second only to alcohol. In herbal cannabis, the dried flowers, fruits, leaves, and stems from the female hemp plant *Cannabis sativa,* and its subspecies, there are over 100 phytocannabinoids. The major active phytocannabinoids are cannabidiol (CBD), a nonpsychoactive phytocannabinoid, and delta 9-tetrahydrocannabinol (THC), a psychoactive phyotcannaminoid.[50] Phytocannabinoids, synthetic cannabinoid analogs, and endocannabinoids, such as anandamide and 2-arachidonoylglycerol, are all ligands of the cannabinoid receptor type 1 and 2 (CB1 and CB2, respectively). The principal location of CB1 is in the central nervous system, where they have an inhibitory effect on γ-aminobutyric acid (GABA). Activation of CB1 results in the neuropsychiatric effects of synthetic cannabinoids, such as elation, irritability, and anxiety. The principal location of CB2 is in tissues related to the immune system, and these receptors are suggested to have a role in the control of emesis and pain. Both CB1 and CB2 are also expressed in human podocytes and other cells of the glomerulus. Endocannabinoids, such as anandamide, activate the CB1 receptor and increase the GFR and renal blood flow in rodents, independent of changes in blood pressure. In addition, anandamide stimulates nitric oxide production and leads to inhibition of sodium transport in the thick ascending limbs of the loop of Henle.[51]

CBD is metabolized by cytochrome P450 (CYP)3A4 and CYP2C19 and is suspected to be a potent inhibitor of these pathways. All drugs metabolized by this system (Table 79.3; including tacrolimus) would have a prolonged half-life in the presence of CBD, and there have been case reports of CBD oil affecting tacrolimus levels.

Synthetic cannabinoids, like many herbal supplements, are manufactured in unregulated laboratories and accidental or purposeful contamination may occur by the manufacturers and/or distributors. The synthetic cannabinoids are solubilized, applied to dried, plant material, and sold as "synthetic marijuana," "herbal incense," "spice," and potpourri. Some synthetic cannabinoids are more powerful than THC and a number of cases of AKI have been attributed to smoking synthetic cannabinoids.[52] Although AKI may be secondary to a contaminant or nephrotoxin present in a single batch of drug, a number of the reported AKI patients used a product that was known to contain a novel fluorinated synthetic cannabinoid (XLR-11) or its metabolites were found in clinical samples of the patients.[52]

Many of the touted therapeutic benefits of CBD are for symptoms that are common in people with advanced CKD, such as pain, nausea, anxiety, and insomnia. At this time, the evidence supporting using nonsynthetic cannabinoids for symptom management is limited to the treatment of chronic neuropathic pain, with a potential to treat uremic pruritus. However, nonsynthetic cannabinoids, particularly smoked cannabis, can pose significant health risks; thus the limited substantiated therapeutic benefit of cannabis must be weighed against these risks.[53]

TABLE 79.3 Metabolism of Medications Affected by CBD

Cytochrome P450 Isoenzyme	Drugs Metabolized
CYP2C19	Amitriptyline, carisoprodol, citalopram, cyclophosphamide, diazepam, hexobarbital, imipramine, indomethacin, clomipramine, lansoprazole, mephenytoin, mephobarbital, moclobemide, nelfinavir, nilutamide, omeprazole, pantoprazole, phenobarbital, phenytoin, primidone, progesterone, proguanil, propranolol, rabeprazole, temazepam, teniposide, valproic acid, (R)-warfarin, zidovudine
CYP3A4	Acetaminophen, codeine, ciclosporin (cyclosporin), diazepam, and erythromycin, alfentanil, alprazolam, amiodarone, amlodipine, amitryptyline, aprepitant, aripiprazole, astemizole, atorvastatin, buspirone, carbamazepine, cerivastatin, chlorpheniramine, cilostazol, cisapride, clarithromycin, codeine cyclosporine A, dapsone, dexamethasone, dextromethorphan, diazepam, digoxin, diltiazem, docetaxel, domperidone, eplerenone, ergotamine, erythromycin, estradiol, etoposide, ethynylestradiol, felodipine, fentanyl, finasteride, fluoxetine, gleevec, haloperidol, halothane, hydrocortisone, indinavir, irinotecan, ivabradine, ketoconazole, lercanidipine, levonorgestrel, lidocaine, loratadine, lovastatin, methadone, metronidazole, midazolam, mifepristone, nateglinide, nelfinavir, nifedipine, nisoldipine, nitrendipine, ondansetron, omeprazole, paracetamol, pimozide, propranolol, progesterone, quetiapine, quinidine, quinine, risperidone, ritonavir, saquinavir, salmeterol, sildenafil, simvastatin, sufentanyl, tacrolimus (FK506), taxol, tamoxifen, terfenadine, testosterone, theophylline, trazodone, triazolam, valproate, warfarin, venlafaxine, verapamil, vincristine, zaleplon, ziprasidone, zolpidem

CBD, Cannabidiol.

SELF-ASSESSMENT QUESTIONS

1. A very slender 25-year-old international fashion model presented with kidney failure, minimal hypertension, and mild albuminuria. Kidney function deteriorated, and the patient received a kidney transplant. Six months later, she developed bilateral urogenital tract tumors. What was the most likely cause of her kidney disease?
   A. Analgesic nephropathy
   B. Aristolochic acid nephropathy
   C. Anorexia nervosa
   D. Heavy metal intoxication
2. A 30-year-old recent emigrant from Romania presents with a 3-month history of fatigue, dyspnea on exertion, anorexia, and nausea. On physical examination, she is thin and appears chronically unwell. Blood pressure is 160/100 mm Hg, with otherwise normal physical examination findings. Laboratory workup is significant for hematocrit 22, serum potassium 5.7 mmol/L, serum bicarbonate 19 mmol/L, serum glucose 90 mg/dL, blood urea nitrogen 80 mg/dL, and serum creatinine 4 mg/dL. Urinalysis shows 1+ glucose, 2+ protein, 20 to 30 leukocytes per high-power field. Urine culture is negative for bacteria and acid-fast bacilli. Urine protein was 500 mg/24 h; kidney ultrasound, right kidney, 9.8 cm; left kidney, 9.6 cm; and no hydronephrosis. What is the most likely cause of her impaired kidney function?
   A. Acute kidney failure from tubular necrosis
   B. Chronic glomerulonephritis
   C. Chronic tubulointerstitial nephritis (Balkan endemic nephropathy)
   D. Occult diabetic nephropathy
3. A previously noncompliant patient with stage 4 chronic kidney disease secondary to hypertension comes into your office saying he has changed his ways. He has lost weight, is taking all of his medications, and is drinking homemade star fruit (carambola) juice for its antioxidant properties. His serum creatinine is 5.1 mg/dL (previously 2.4 mg/dL). In the figure, which picture are you most likely to see on urinalysis?
   A. Cystine crystal
   B. Urate crystal
   C. Triple phosphate
   D. Oxalate crystal
4. A 52-year-old woman 5 years after kidney transplantation is taking mycophenolate mofetil and cyclosporine with stable transplant function. She reports that she just came back from a health spa and that she feels wonderful. She said she was diagnosed with depression and was started on St. John's wort by the herbalist. Which of the following transplant-related problems are you are most concerned about?
   A. Acute rejection
   B. Crystal formation in the graft
   C. Cyclosporine toxicity
   D. Hypertension

Epidemiology of Chronic Kidney Disease and Dialysis

Morgan E. Grams, Stephen P. McDonald

The global average life expectancy is now 73.4 years—an enormous increase from 61.7 years in 1980, due in part to declining mortality from communicable, maternal, neonatal, and nutritional disease.[1,2] On the other hand, with the aging of the population, chronic kidney disease (CKD) has become one of the most common noncommunicable diseases in the world, as well as a leading cause of mortality. Half of the people in the United States are expected to develop CKD during their lifetime.[3] Associated with huge health system costs, particularly with kidney failure, CKD has come into focus as a common, morbid, and often preventable disease.[4]

DEFINING CHRONIC KIDNEY DISEASE

Chronic Kidney Disease Staging

Over the past decade, the definition of CKD has evolved to incorporate advances in knowledge about prognosis.[5] The National Kidney Foundation's Kidney Disease Outcomes Quality Initiative guidelines published in 2002 classified CKD into five stages on the basis of glomerular filtration rate (GFR) and signs of kidney damage (pathologic abnormalities or markers of damage in blood, urine, or imaging studies).[6] This staging system was modified in the 2012 Kidney Disease: Improving Global Outcomes (KDIGO) clinical practice guidelines to reflect the independent contributions of GFR, albuminuria, and cause of CKD.[7] The two-dimensional "heat map" that classifies CKD in GFR categories (G stages) and albuminuria categories (A stages) has been widely accepted and robustly validated, but less is known about the third dimension, as routine reporting on the cause of CKD is relatively uncommon (Fig. 80.1).[8]

Classification Based on Estimated Glomerular Filtration Rate

Serum creatinine is the most commonly used filtration marker for the estimation of GFR, and GFR estimating equations incorporating serum creatinine, as well as age and sex, generate precise and accurate assessments of kidney function in the vast majority of both CKD and non-CKD populations.[9,9a] In North America, the best available GFR estimating equation is that developed by the Chronic Kidney Disease Epidemiology Collaboration (CKD-EPI).[10] The accuracy of GFR estimation also has benefited from universal standardization of the creatinine laboratory assay (see Chapter 3).[11] Serum cystatin C is an additional filtration marker used in the estimation of GFR, with an equation that uses both cystatin C and serum creatinine recognized as being the most accurate.[9a]

Classification Based on Albuminuria

Multiple techniques exist to estimate urine albumin excretion. The semiquantitative dipstick method is most common, followed by spot and 24-hour urine protein or albumin excretion assessments. All are subject to limitations. Dipstick testing is inexpensive, but the diagnostic accuracy can be low,[12,13] particularly for moderately increased levels of albuminuria. Although a full day's collection of urine albumin is the gold standard for albuminuria estimation, the process is tedious and imposes substantial burden on the patient. Thus, the KDIGO guideline recommends a spot collection of urine, with early morning timing preferred, as the initial screening test.[7] Urine albumin is recommended over urine protein assessment given the superiority of the laboratory assay and standardization, as well as the relative importance in prognosis. Spot samples are standardized to urine creatinine to normalize to 24-hour excretion and account for any differences in concentration (e.g., albumin-to-creatinine ratio [ACR]). Abnormalities in GFR or albuminuria must persist for more than 3 months to meet the definition of CKD (see Chapter 3).

Classification Based on Chronic Kidney Disease Cause

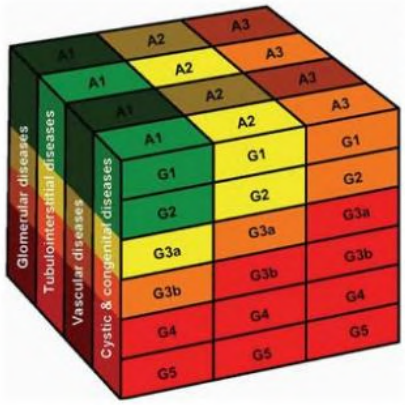
The cause of kidney disease (the "C" in the KDIGO CGA staging) is the least studied aspect of the CKD definition. The proposed KDIGO classification categorizes disease by the presence of underlying systemic disease and the location of the abnormality (see Fig. 80.1). For example, diabetic nephropathy might be classified as a systemic disease affecting the glomerulus, and obstructive nephropathy as a primary kidney disease affecting the tubulointerstitium. Limitations of this approach include the infrequent use of kidney biopsy, the gold standard for assessment of pathologic location of kidney abnormalities. On the other hand, decisions not to perform kidney biopsies are often driven by the uncertain benefit of precise localization of pathologic abnormalities in terms of prognostic implications—a vicious circle begetting sparse evidence.

Rationale for the Chronic Kidney Disease Definition

Associations With Adverse Outcomes

The cut-points of GFR and albuminuria used to define CKD (<60 mL/min/1.73 m^2 and ≥30 mg/g, respectively) have been rigorously

Chronic Kidney Disease Classification According to Glomerular Filtration Rate and Albuminuria



GFR categories (mL/min/1.73 m²) description and range		
G1	Normal or high	≥90
G2	Mildly decreased	60-89
G3a	Mildly to moderately decreased	45-59
G3b	Moderately to severely decreased	30-44
G4	Severely decreased	15-29
G5	Kidney failure	<15

Persistent albuminuria categories description and range		
A1	A2	A3
Normal to mildly increased	Moderately increased	Severely increased
<30 mg/g <3 mg/mmol	30-300 mg/g 3-30 mg/mmol	>300 mg/g >30 mg/mmol

Classification of CKD based on presence or absence of systemic disease and location within the kidney	
Presence of systemic disease affecting the kidney	Primary kidney diseases
Glomerular diseases	
Tubulointerstitial diseases	
Vascular diseases	
Cystic and congenital diseases	

Fig. 80.1 Depiction of Chronic Kidney Disease (CKD) Classification: G Stages and A Stages. The cube denotes how the three components of the CKD classification scheme (glomerular filtration rate [G], albuminuria [A], and underlying kidney disease) interact to influence the risk of progression to kidney failure. This risk is represented in qualitative terms (lowest to highest) by *green, yellow, orange,* and *red* colors.

Odds of Laboratory Abnormalities by Estimated Glomerular Filtration Rate

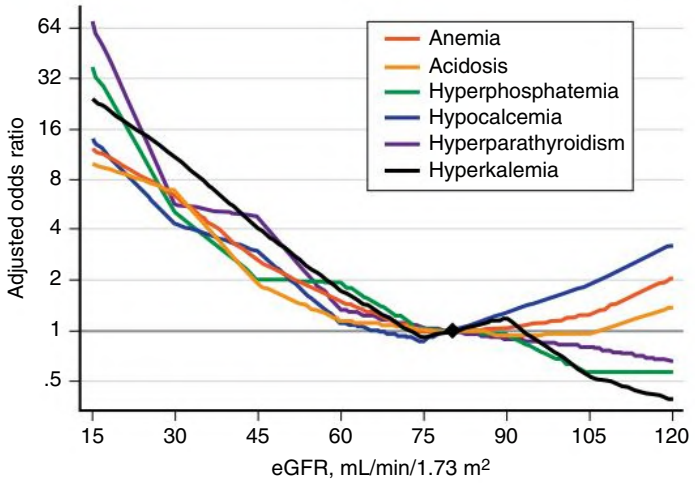


Fig. 80.2 Odds of laboratory abnormalities according to estimated glomerular filtration rate (eGFR) among people from the general US population. (From the continuous National Health and Nutrition Examination Survey [1999–2010].)

examined. Each represents a higher risk state compared with normal levels for a variety of outcomes. For example, the relationship between GFR and the prevalence of anemia, acidosis, hyperphosphatemia, hypoalbuminemia, and hyperparathyroidism demonstrates a continuous increase in risk with GFR less than 60 mL/min/1.73 m² (Fig. 80.2).[14] Furthermore, the risk for future kidney outcomes, including acute kidney injury (AKI), CKD progression, and kidney failure, all exhibit graded associations with lower GFR.[15] Although relationships with progression to kidney failure with kidney replacement therapy (KRT) are strongest, both lower eGFR and more severe albuminuria are independently associated with cardiovascular mortality and all-cause mortality as well (Fig. 80.3).[8] For example, for a given value of GFR, more severe albuminuria is associated with higher risk for adverse events compared with albuminuria levels less than 30 mg/g.[4]

Persistent Relationships Within Subgroups

Although there remains some controversy about the use of different thresholds for different groups of people,[16] the risk relationships between eGFR and ACR with adverse outcomes are remarkably robust in different subgroups, including older and younger adults and men and women. For example, while reduced GFR is more common among older individuals compared to younger individuals, it remains a strong

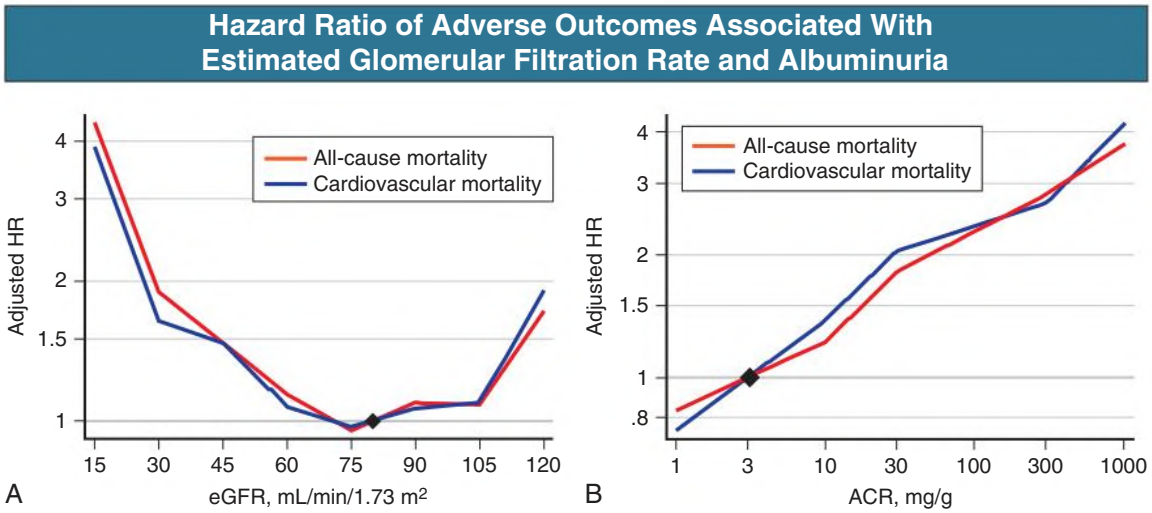

Fig. 80.3 Hazard ratios (HRs) of adverse outcomes associated with estimated glomerular filtration rate (eGFR) (A) and albuminuria (B) among people from the general US population. *ACR,* Albumin-to-creatinine ratio. (From the National Health and Nutrition Examination Survey III [1988–1994] and the continuous National Health and Nutrition Examination Survey [1999–2010].)

risk factor for KRT compared with higher levels of GFR.[17] Similarly, the risk relationships between ACR and adverse outcomes appear fairly consistent in women compared with men, counter to the proposed sex-specific definitions that assign a higher ACR threshold in women (Fig. 80.4).[18]

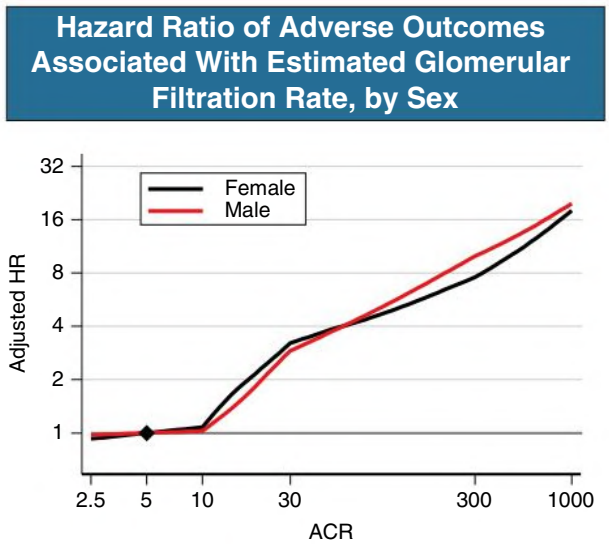

Fig. 80.4 Hazard ratios (HR) of adverse outcomes associated with albuminuria, by sex. *ACR,* Albumin-to-creatinine ratio. (From Nitsch D, Grams M, Sang Y, et al. Associations of estimated glomerular filtration rate and albuminuria with mortality and renal failure by sex: a meta-analysis. *BMJ.* 2013;346:f324.)

GLOBAL BURDEN OF CHRONIC KIDNEY DISEASE

Accurate estimations of CKD prevalence are difficult because tests for filtration markers and albuminuria are not uniformly performed; however, many believe the global burden of CKD to be large and increasing.[19] The best estimates are derived from nationally representative samples, such as the National Health and Nutrition Examination Survey (NHANES) in the United States; estimates based on populations receiving health care may overestimate (or, in some cases, underestimate) disease prevalence.[20] In the United States, estimates of CKD prevalence based on a one-time measurement of serum creatinine recently placed the proportion of the population with stage G3 or G4 CKD at 6.9%; using a definition of ACR greater than 30 mg/g or eGFR less than 60 mL/min/1.73 m^2, the prevalence of any CKD was 14.2%.[21] This definition likely overestimates prevalence because the persistence of albuminuria was not taken into account. Publications from countries in Europe show wide variation in CKD prevalence, from 3.3% in Norway to 17.3% in northwest Germany, but this may reflect differences in sampling strategy rather than true population-level differences.[22] Estimates in lower-income countries are less available, but most place the global population burden between 8% and 16%, affecting nearly 500 million adults worldwide in 2010.[23]

RISK FACTORS FOR CHRONIC KIDNEY DISEASE

Age

Many risk factors have been implicated in the development of CKD. Age is a strong risk factor for GFR less than 60 mL/min/1.73 m^2, and so population aging is almost inevitably associated with an increase in CKD burden. Interestingly, although incidence rates of KRT tend to be highest among persons older than 65 years, older age is often associated with a lower risk for developing KRT in multivariable-adjusted analyses.[4,24] In other words, for the same level of kidney function, a younger person is at higher risk for progression to end-stage kidney disease (ESKD) than an older person. This observation may be due in part to the fact that mortality is lower in younger persons and that younger persons may be more likely to accept or be prescribed a replacement therapy (dialysis or transplantation) compared with older persons.

Sex and Race/Ethnicity

Risk for CKD differs by other demographic factors as well. Women are generally at higher risk for incident CKD but lower risk for incident KRT than men.[2] In the United States, Black individuals have a higher prevalence of KRT than White individuals. Much of the difference in CKD burden stems from long-standing and pervasive structural racism resulting in differences in socioeconomic status and access to health care.

Differences in the frequency of specific genetic variants also partially underlie this disparity. Sickle cell trait and the *APOL1* high-risk genotype, present in 7% and 13% of persons of African descent, respectively, confer higher risk for CKD and KRT.[25,26] The presence of sickle cell trait may confer risk via subclinical sickling in the oxygen-poor medulla, leading to impairments in concentrating ability and hematuria over time. The mechanism of the *APOL1* high-risk genotype is as yet uncertain, but it appears to be mediated through the development of albuminuria. Other racial/ethnic groups also have higher risk of KRT, including persons of Hispanic ethnicity and Indigenous Americans/Alaskan Natives in the United States, as well as indigenous people in many other countries.[27]

Social Determinants

Socioeconomic factors play an important role in CKD risk. People with lower socioeconomic status face greater burden of CKD and rapid GFR decline in the United States, and this finding has been replicated in many other developed countries.[4,7] Socioeconomic status is often lower in racial and ethnic minorities, and several studies have demonstrated attenuation or elimination of racial disparities in kidney outcomes with accounting for differences in income and the presence of health insurance, including risk for AKI, eGFR decline, and delay in transplantation in children.[28]

Comorbid Conditions

Diabetes mellitus and hypertension are often cited as the major attributable causes of CKD in the developed world, and recent studies suggest similarities in the developing world.[4] Nearly half of the population with kidney failure has diabetes. Persons with diabetes and CKD merit concern, not only for the risk for albuminuria and CKD progression, but also for heightened risk for many other adverse outcomes, particularly cardiovascular disease. Risk for CKD among those with diabetes mellitus may be managed through tight control of blood glucose and blood pressure and the use of specific therapies such as angiotensin-converting enzyme inhibitors, angiotensin receptor blockers, and sodium-glucose cotransporter-2 inhibitors. Hypertension also has shown a graded association with the risk for KRT in observational studies, although the relationship with kidney disease is more complex than that of diabetes and CKD because hypertension is thought to be both a cause and a consequence of CKD. Obesity may confer increased risk for CKD over the long term, possibly mediated through the development of diabetes and hypertension, and smoking has also been linked to higher KRT risk.[29]

ISSUES WITH IDENTIFYING CHRONIC KIDNEY DISEASE

Lack of Awareness

Generally, a silent disease until the most advanced stages, CKD is largely underrecognized by providers and patients. Fewer than 10% of people with laboratory-confirmed CKD in the NHANES survey reported being aware that they had kidney disease, a finding corroborated in other regions.[4] Provider awareness may not be much higher; only 12% of patients with CKD had an associated diagnostic code in Stockholm health care.[30] Low awareness of disease may lead to low testing and referrals, with only 27% of patients with eGFR less than 60 mL/min/1.73 m^2 tested for albuminuria and 23% referred to a nephrologist. Albuminuria testing is also low in persons with diabetes. In the Stockholm cohort, 38% of patients with diabetes were evaluated for albuminuria, very similar to the testing frequency among US Medicare patients with diabetes.[4]

Imperfect Biomarkers

Another issue in CKD identification is the occasional fallibility of existing biomarkers. Serum creatinine, the most widely used filtration marker to estimate GFR, has non-GFR determinants, including diet and muscle mass. As a consequence, amputees and persons with reduced muscle mass may have a falsely elevated eGFR when creatinine is used. Thus, the KDIGO guidelines recommend a confirmatory measurement performed for persons in whom measuring creatinine may be less accurate.[7] To confirm diagnosis, KDIGO recommends obtaining a cystatin C–based eGFR or clearance measurement, or measuring GFR with an exogenous filtration marker when treatment decisions are at stake. Of note, cystatin C has its own non-GFR determinants, including body mass index and inflammation. For this reason, for the general population the most accurate estimating equation uses both creatinine and cystatin (see Chapter 3).[31]

Errors in Urine Albumin Assessment

Variability in albumin excretion and measurement can confound CKD identification. In clinical practice, spot samples are usually assessed and standardized to urine creatinine to correct for error induced by differences in hydration status. However, urine albumin and creatinine excretion are thought to follow a circadian rhythm, additionally varying with posture, exercise, and diet.[32] Moreover, many providers instead quantify urine protein, a less sensitive and specific marker of glomerular permeability. Urine protein measurement is hampered by interlaboratory variation in methods and calibration and the lack of a reference measurement protocol.[7] For these reasons, urine albumin assessment is generally preferred over urine protein assessment, and repeated 24-hour collections offer the most accurate estimation of true albuminuria.

OUTCOMES OF CHRONIC KIDNEY DISEASE

Associations With Adverse Outcomes

The public health implications of CKD are enormous because of the strong associations with adverse outcomes—in particular, cardiovascular disease, kidney failure, and mortality. Some have argued that CKD should be considered a coronary heart disease risk equivalent, much like diabetes, and some guidelines recommend preventive statin use for all patients with CKD older than 50 years.[33] The independent associations of GFR and albuminuria with adverse outcomes has been demonstrated in general, high-risk, and CKD populations, as well as in separate geographic regions.[8,34]

Variation in Absolute Risk for Adverse Outcomes

Increasingly, risk scores are used to inform patient counseling and treatment decisions. Guidelines encourage the incorporation of kidney failure risk prediction in kidney replacement therapy planning, and several risk scores now exist.[7] The kidney failure risk equation is the most widely used and has been globally validated.[24] The absolute risk for progression to kidney failure was observed to be slightly lower in non–North American countries, a difference that was not explained by differences in demographic or clinical characteristics. Variation in absolute risk for KRT thus might suggest differences in treatment availability, patient or provider acceptance, or differences in the competing risk for death.

DIALYSIS EPIDEMIOLOGY

The number of people receiving chronic KRT (dialysis or kidney transplantation) worldwide has progressively increased over the 50 years since these treatments became available, and this increase continues. Initially available only to selected patients in restricted centers in some countries, both long-term dialysis and kidney transplantation

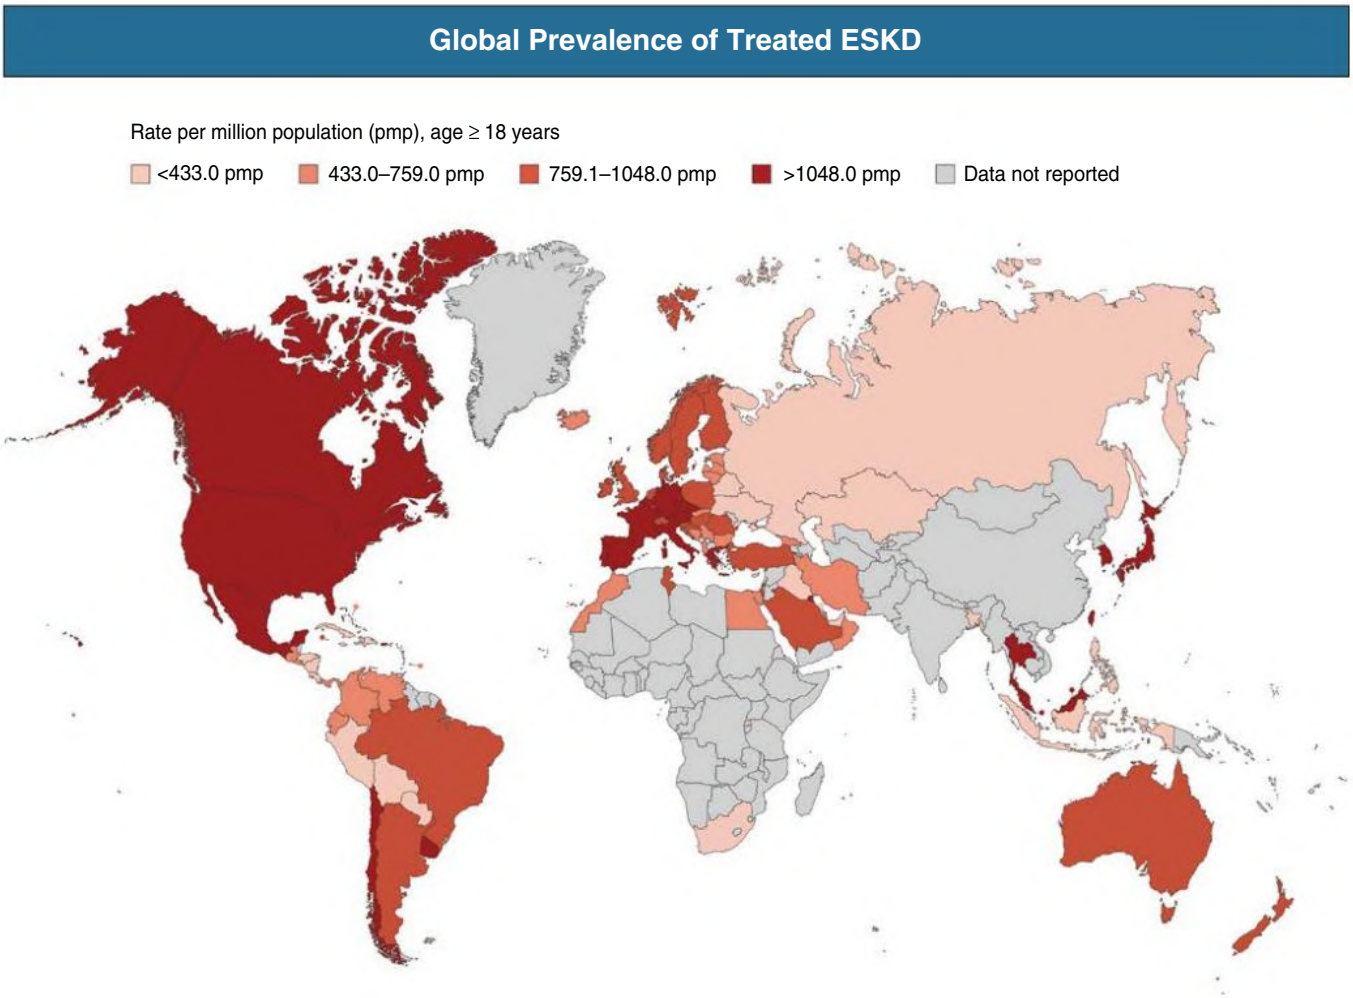

Fig. 80.5 Patients receiving kidney replacement therapy in 2010. *ESKD,* End-stage kidney disease. (From Bello A, et al. *Global Kidney Health Atlas: A Report by the International Society of Nephrology on the Global Burden of End-Stage Kidney Disease and Capacity for Kidney Replacement Therapy and Conservative Care Across Countries and Regions*. International Society of Nephrology; 2019.)

have become progressively more available not just in high-income countries but also in many low-income countries. Approximately 2.5 million people were estimated to be receiving chronic KRT in 2010[35]; absolute rates are high in North America, but the highest prevalent rates (people currently receiving KRT) per million population are in Taiwan and Japan (Fig. 80.5), where the vast majority of people receive long-term dialysis. Good data are available throughout the developed world because of the existence of regional and national dialysis registries; conversely, information such as this is less commonly available in lower-income countries.[36] These registries typically report rates, outcomes, and practice patterns of dialysis at a national level; many also have a major role in provision of hospital-specific information and other safety and quality reporting, as well as providing a substantial resource for clinical research.

Incidence and Prevalence of Chronic Dialysis

Incidence rates (the number of new KRT patients) comprise patients starting chronic or long-term dialysis and a small number of people receiving preemptive kidney transplants. Incidence rates are highest in Taiwan, Mexico, and the United States, followed by various other Asian countries. There is substantial variation among countries in every region around the world (Fig. 80.6). Diabetic kidney disease (DKD) has been the main factor in the increase in incidence rates in almost all countries. In most countries, DKD is attributed as the cause for kidney failure in 40% to 60% of cases.

The trends in incidence rates vary across different regions. In many Asian countries (e.g., Korea, Singapore, Malaysia, Thailand), rates continue to increase. However, in the United States, Canada, Western Europe, Australia, and New Zealand, incidence rates have generally stabilized over the last 5 to 10 years. Nevertheless, in these countries the *prevalent* numbers and rates of dialysis continue to increase because the number of people leaving dialysis programs (deaths and transplant recipients) is smaller than the incident number.

Not every person with kidney failure receives dialysis or transplantation. In some situations (particularly those with substantial comorbidities or limited life expectancy), dialysis may not be clinically appropriate, or a decision is made for a conservative (nondialysis) approach to treatment (see Chapter 95). Registries typically report rates of KRT, which is synonymous with ESKD, a US administrative term meaning treatment with dialysis or kidney transplantation for chronic kidney failure. Estimating the "total burden" of kidney failure requires incorporation of both the number of people commencing KRT and the number of people dying of kidney failure without treatment. This has been examined using data linkage (of registry data with death certificates) in Australia[37] and in cohort studies, most notably in Alberta, Canada.[37] These studies suggest that among older age groups (over 75 years), dialysis therapy is used in

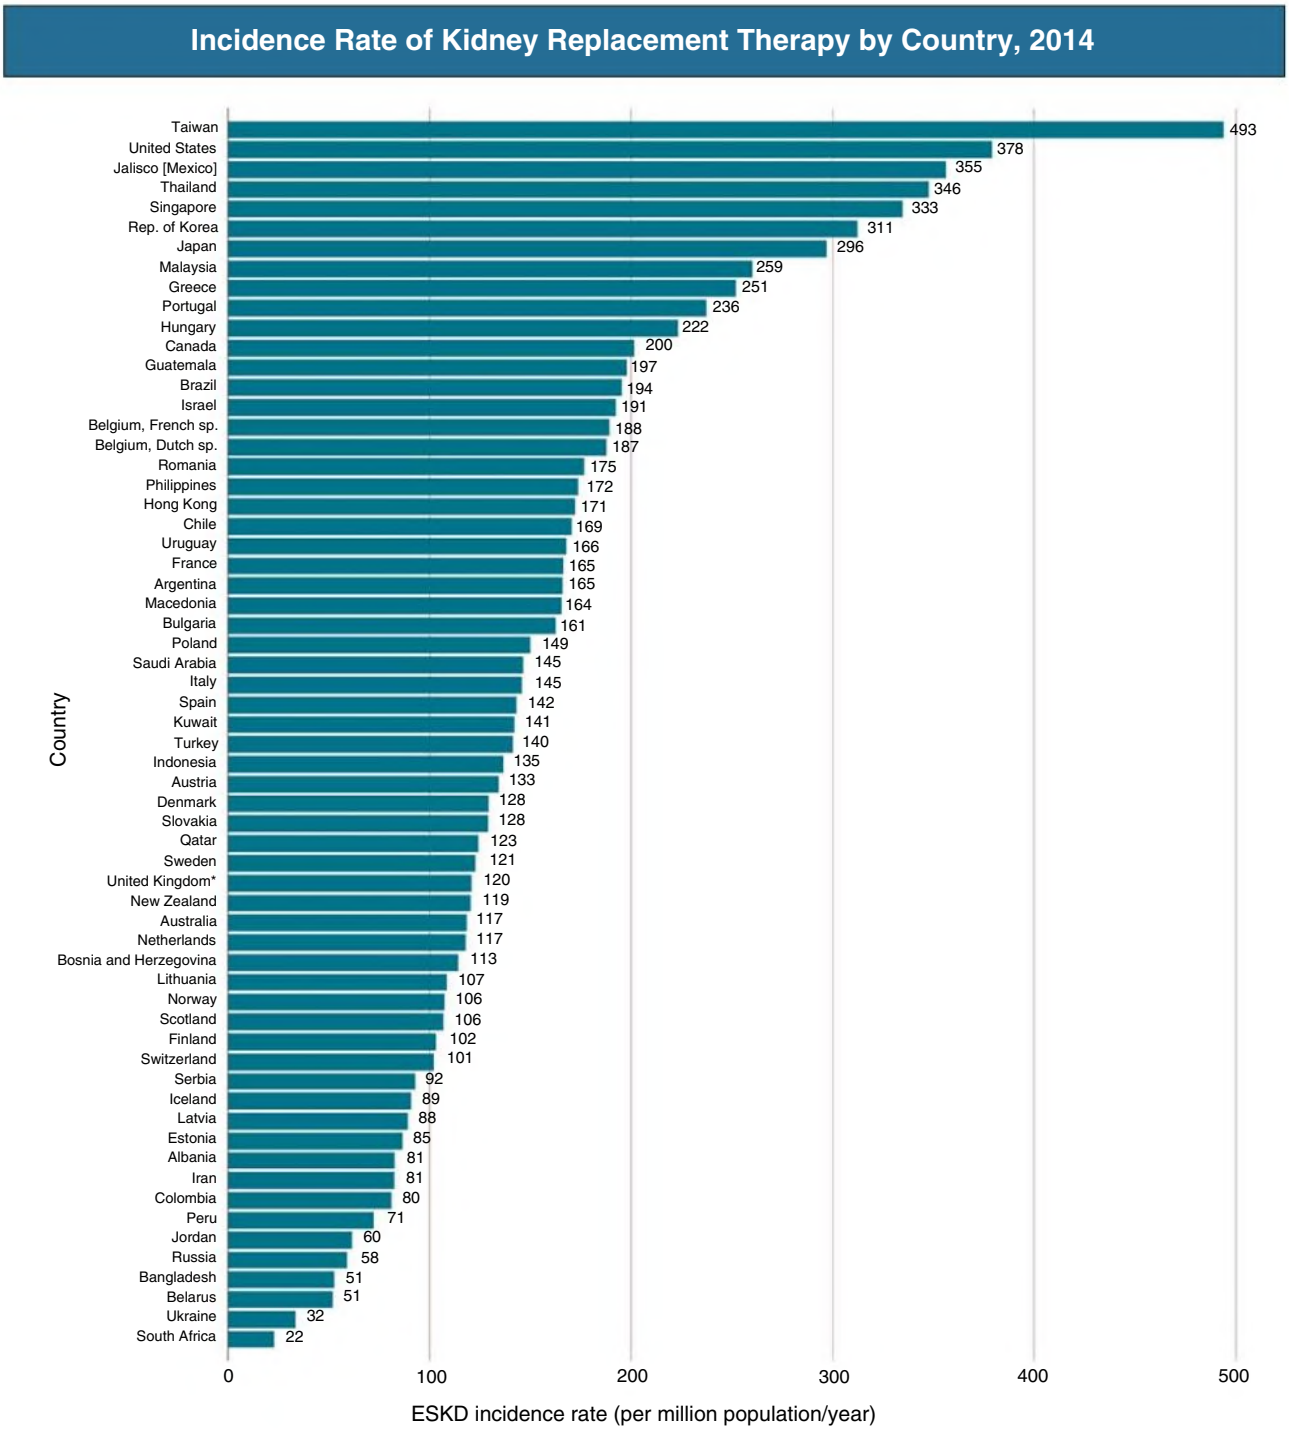

Fig. 80.6 Incidence rate of kidney replacement therapy (per million population per year), by country for 2014. *Includes England, Wales, and Northern Ireland. *ESKD,* End-stage kidney disease. (From US Renal Data System. *International Comparisons. USRDS 2018 Annual Data Report. Vol. 2. Atlas of End-Stage Renal Disease in the United States.* National Institutes of Health, National Institute of Diabetes and Digestive and Kidney Diseases; 2018.)

fewer than 50% of people with kidney failure. Consistent with this is evidence suggesting that among older patients with comorbidities, there is little or no survival advantage of dialysis therapy.[38]

Dialysis is a resource-intensive therapy, and there is a relationship between the provision of (and access to) dialysis and the overall economic development of a country (Fig. 80.7). As with other chronic diseases, there is also a gradation seen within many societies in rates of incident kidney failure, with higher rates seen among those at the lower end of the socioeconomic spectrum.[39,40] Gradients with income and education are also seen among predialysis patients.[41]

Incidence rates vary with sex, with rates generally lower among women than men.[42] Incidence rates increase with older age, up to 75 to 80 years old. There have been progressive changes differing across age-specific incidence rates over many years, with increasing incidence

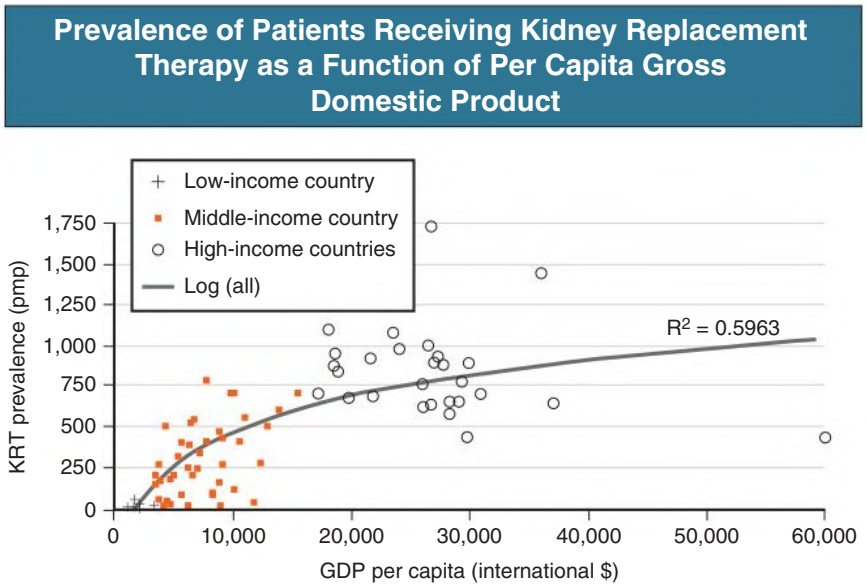

Fig. 80.7 Prevalence of patients receiving kidney replacement therapy (KRT) as of December 31, 2002, and gross domestic product (GDP) per capita. *PMP,* Per million population. (From White SL, Chadban SJ, Jan S, et al. How can we achieve global equity in provision of renal replacement therapy? *Bull World Health Organ.* 2008;86:229–237.)

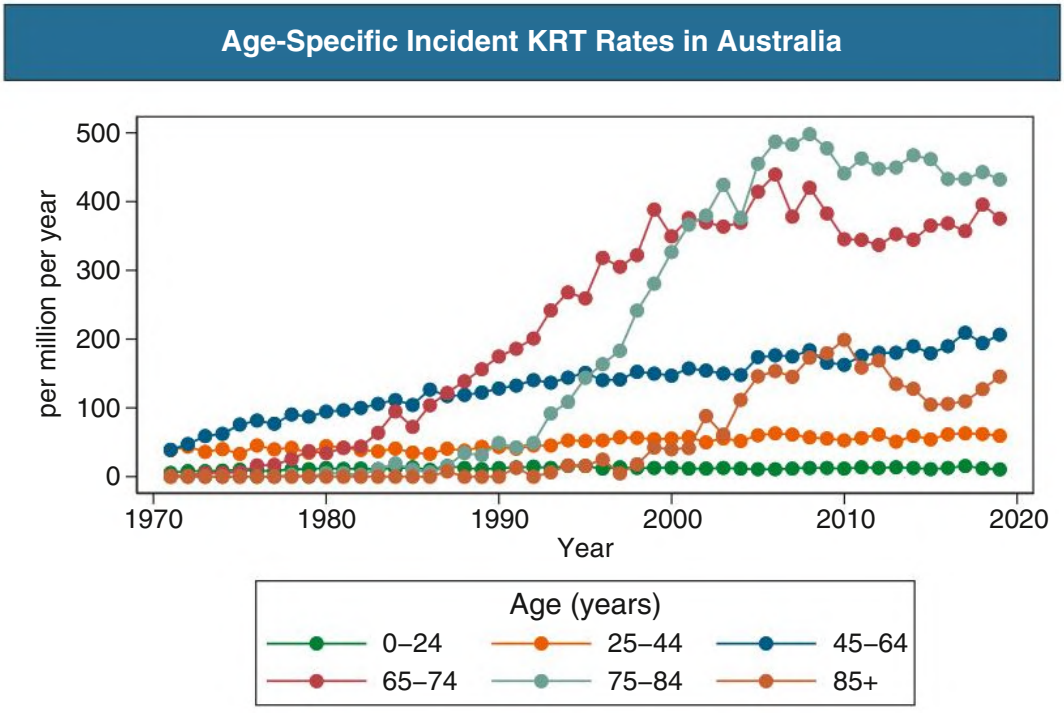

Fig. 80.8 Age-specific kidney replacement therapy (KRT) incidence rates in Australia. (From *ANZDATA Registry: 43rd Annual Report,* 2020.)

rates of progressively older age groups over a long period followed by stabilization in more recent years. An example of this (from Australia, but typical of that seen in high-income countries) is shown in Fig. 80.8.

Some ethnic groups experience particularly high rates of kidney failure and dialysis. Indigenous peoples in Australia, New Zealand, Canada, and the United States have very high rates of kidney disease, poorer outcomes, and less access to transplantation.[43] The causes underlying this are complex, but common elements appear to include very high rates of diabetes, metabolic syndrome, and hypertension driving high rates of CKD.

Dialysis Practice Patterns

Dialysis practice patterns vary widely across countries, with different usage of PD, HD, and home HD. For prevalent patients, the regions with the highest proportion of PD are Hong Kong (72% of prevalent patients) and the Jalisco region of Mexico (47% of prevalent patients).[44]

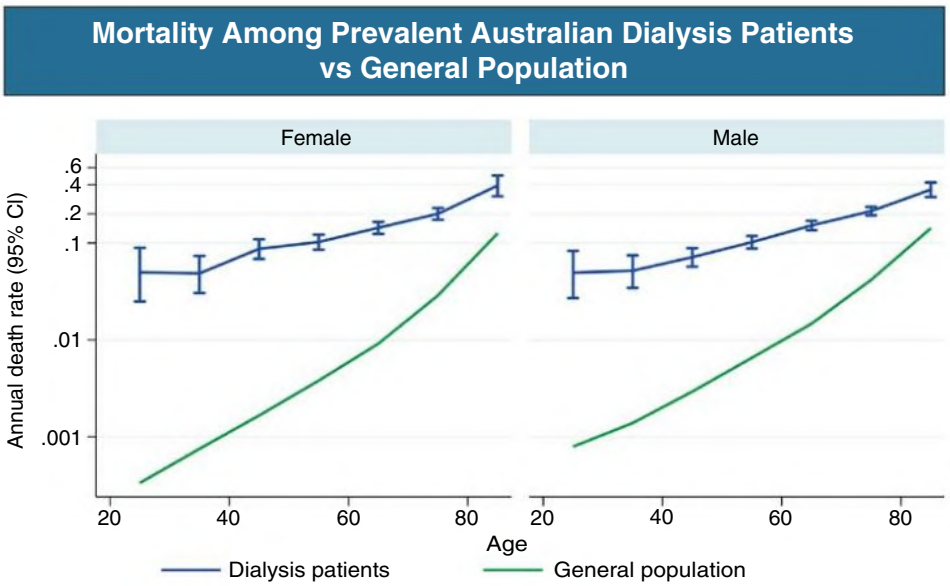

Fig. 80.9 Death rates of prevalent dialysis patients versus general population. *CI,* Confidence interval. (From *ANZDATA Registry: 43rd Annual Report,* 2020.)

Home HD is most commonly used in New Zealand and Australia, where 18% and 9%, respectively, of prevalent KRT patients are treated with this modality. Practice patterns also vary in the application of various techniques of HD; for example, dialysis sessions are generally longer in Japan, with slower blood flow rates.

Outcomes

The rationale for dialysis is to prevent death from uremia, and hence the outcome for dialysis treatment is usually reported as mortality rate. Other important outcomes commonly reported include cause-specific mortality rates, hospitalizations, and technique failure. Patient-reported outcomes (including measures of quality of life and functional ability) are also extremely important.

Crude mortality rates vary widely; a multinational observational study (Dialysis Outcomes and Practice Patterns Study) reported rates from 6.6% per year in Japan to 21.7% in the United States.[45] Mortality rates among dialysis patients are substantially higher than in the general population, a differential particularly marked among younger age groups (Fig. 80.9). The excess mortality is primarily driven by cardiovascular and infectious causes. There is also a modest (approximately 3-fold) excess risk for cancer among dialysis patients, even after exclusion of cancers directly related to the cause of kidney disease (see Chapter 92).[46] An issue unique to categorization of deaths among the dialysis cohort is assignment of deaths as a result of withdrawal from therapy. There is a wide range in reported frequency of withdrawal, from less than 5% to more than 20% of all deaths.[47] These differences may in part reflect different coding mechanisms but are also likely to reflect differences in practice patterns in the commencement of therapy among older patients with higher levels of comorbidity.

There is variation in mortality over time, with the highest rates seen in the first 3 months after commencing dialysis, particularly among older age groups (Fig. 80.10). After this period, mortality rates approximate the longer-term rates. There are a number of possible contributors to this, including the risk associated with commencement of dialysis (such as the placement of central venous catheters) and increased severity of comorbidities associated (or causing) the deterioration of kidney function.

Multiple observational studies have compared mortality between PD and HD, but no definitive randomized controlled trials (RCTs) have been completed despite several attempts. Results from observational studies have varied across countries; common elements are the presence of multiple interactions such that the comparison depends on comorbidities and patient age, the length of follow-up, and selection biases and local/regional outcomes of each technique.

For PD (and to a lesser extent home HD), "technique survival" is a common metric. This refers to the proportion of people continuing on PD at various time points. It is a combined end point, with patient death and transfer to HD considered failures. Typically, 30 days of HD is considered to be a permanent transfer to HD. It is important to ensure consistency of definitions in comparisons of technique survival; alternative duration definitions have substantial effects on the calculated technique survival.

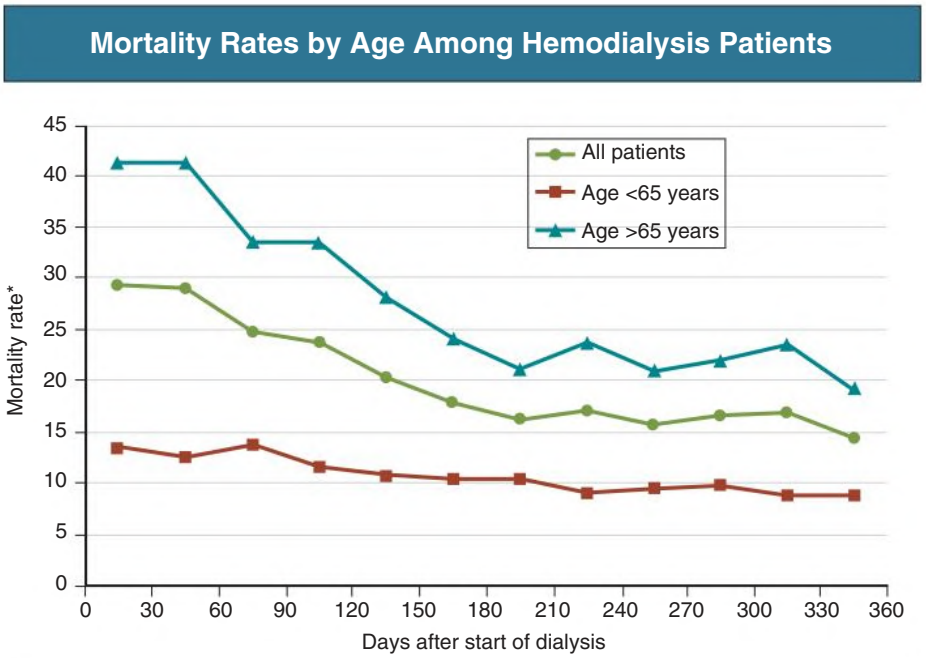
The use of patient-reported outcomes (PROMs) is growing, supported by evidence that patient priorities around dialysis treatment differ from those of clinicians.[48] However, there are significant limitations to the uptake of PROMs. First, the resources required for implementation of PROMs in routine practice can be a substantial barrier.[49] Second, despite the conceptual simplicity, there is limited evidence to date about how measuring PROMs may affect quality of life.

EPIDEMIOLOGIC CONCEPTS

Epidemiologic factors influence the reported rates of KRT; understanding the potential biases is a necessary part of interpretation of these data.

The *prevalent* number of KRT patients at any point in time receiving a form of KRT reflects both the rate of people starting treatment (for overall KRT numbers, the *incidence* rate) and the rate of people ceasing treatment (the *mortality* rate). These rates can be considered *transition probabilities* among various states. This concept can be applied to the overall number of people receiving KRT, the number receiving dialysis or transplantation, and other subgroups. For example, the determinants of the prevalent number of people receiving dialysis at any point in time can be determined from the existing population plus the number of new patients (incidence rate plus the number of people who have lost graft function) less the number of deaths (mortality rates during dialysis) and kidney transplants.

This form of multistate model is often known as a Markov model. Use of these models to estimate future trends can be used by health



Mortality rate during the first 360 days of HD treatment

	0-30	31-60	61-90	91-120	121-150	151-180	181-210	211-240	241-270	271-300	301-330	331-360
All patients	29.3	28.9	24.9	23.8	20.4	17.9	16.2	17.0	15.7	16.5	16.8	14.4
Age <65 years	13.3	12.6	13.5	11.6	10.7	10.4	10.2	9.1	9.3	9.7	8.9	8.7
Age >65 years	41.2	41.2	33.7	33.5	28.2	24.0	21.1	23.6	21.0	21.9	23.5	19.2

Fig. 80.10 Overall mortality rates among hemodialysis patients by age. ∗Number of deaths per 100 patient-years. *HD,* Hemodialysis. (From Robinson BM, Zhang J, Morgenstern H, et al. Worldwide, mortality risk is high soon after initiation of hemodialysis. *Kidney Int.* 2014;85:158–165.)

services and others in predicting the future number of people receiving KRT. This can be done under existing conditions and under various hypothetical scenarios to model the effects of various interventions.

The *incidence* rates reported for ESKD typically exclude dialysis for AKI. Definitions of the start point of KRT vary across registries and data collections. In many cases, an "intent" definition is used (i.e., dialysis is commenced with the intention of long-term treatment, underpinned by a diagnosis of irreversible kidney failure). The other approach (used by the US registry and some other registries) is to use day 90 after dialysis start as the point at which patients are deemed to require "chronic" dialysis. Although this approach eliminates uncertainty around people with prolonged acute (or acute on chronic) kidney injury who may or may not recover, it does prevent analysis of early mortality.

Selection bias affects incidence rates. There may be constrained provision of dialysis services that affects ability to access dialysis services. There have also been changes in clinical practice over time affecting the propensity to treat in certain situations (especially among older and more frail patients). These factors will influence observed rates; differences in these selection biases will be relevant to comparisons of disease incidence among groups and also to the same group between different times. This is likely to have contributed to the increasing dialysis rates among progressively older people observed in the 1970s to late 1990s.

Lead time bias occurs when the time point of observation differs between groups. One example of this is the comparison of PD and HD cohorts. Patients commencing KRT with PD typically do so at a higher eGFR than those commencing with HD; current UK data suggest this mean difference is around 0.5 mL/min/1.73 m^2.[50] Although small, this may amount to 2 to 3 months of difference in starting point of analyses.

Competing risks arise when an illness may lead to multiple possible outcomes, but the occurrence of one precludes another. For example, changes in cardiovascular mortality may affect the incidence rate of KRT because patients who survive despite significant heart disease may avoid premature death that would preclude dialysis treatment. Another example is the influence of kidney transplantation in evaluation of survival of a dialysis cohort: increased occurrence of transplantation may lead to higher mortality in a dialysis cohort.

Immortal time bias arises when an inappropriate time point is chosen for comparators. An example of this might be comparison of mortality after coronary angiography performed as a pretransplant assessment between those transplanted and not transplanted; the transplanted group will accumulate "immortal" follow-up time between angiography and transplantation, in contrast to the nontransplanted group.

EVIDENCE QUALITY

There is a relative dearth of RCTs supporting practice in the area of dialysis compared with other disciplines. Most large-scale trials examining dialysis-specific interventions have yielded negative or inconclusive results; for example, the use of non–calcium-containing phosphate binders,[51] increased dialysis dose,[52] use of statins in dialysis patients,[53] and hemodiafiltration.[54] In response to this, clinical trials networks with a focus on nephrology have been established in several countries to catalyze the conduct of trials (particularly where there is limited commercial interest). Examples of this approach currently underway are multicenter randomized trials examining issues such as dialysate sodium concentration and the effect of differing phosphate targets.

The outcomes examined in trials also have been critically examined. Due to the time delay and multiple contributing factors to mortality, many trials have used surrogate outcomes. Given the association of many biochemical abnormalities with increased mortality, their use

appears logical. However, as in other areas of medicine, use of surrogate outcomes in trials and evidence generation in nephrology has been problematic, with changes in surrogates not reflected by reduction in mortality or other hard endpoints. An example of this is the use of phosphate (and parathyroid hormone) as a surrogate to assess the effectiveness of cinacalcet. Partly as a response to this, initiatives have been instituted to develop and standardize the outcomes for trials.[55] An important element of this is also the inclusion of input from patients and consumers of services in setting research priorities.

SELF-ASSESSMENT QUESTIONS

1. The KDIGO CKD classification includes all of the following in the staging of CKD *except:*
   - **A.** the severity of hypertension.
   - **B.** the severity of albuminuria.
   - **C.** the level of GFR.
   - **D.** the cause of disease.
2. Which statement is *true?*
   - **A.** Low GFR is unimportant in older adults.
   - **B.** Higher albuminuria is worse for men than women.
   - **C.** Higher albuminuria is associated with acute kidney injury.
   - **D.** Assays for proteinuria are more accurate than assays for albuminuria.
3. Racial disparities in kidney failure incidence are in part attributable to:
   - **A.** the higher prevalence of *APOL1* genetic risk variants in those of European descent.
   - **B.** lower socioeconomic status and poorer access to health care among Black individuals.
   - **C.** greater rates of smoking among Black individuals.
   - **D.** lipoxins.
4. Which statement is *most true* about rates of new dialysis patients?
   - **A.** They are highest in Eastern European countries.
   - **B.** An increase in rates of glomerulonephritis is the major driver.
   - **C.** Rates are highest among young people.
   - **D.** Rates are higher among men than women.
   - **E.** Rates are generally lower among groups with lower socioeconomic status.
5. Which statement is *true* regarding competing risks in comparison of rates of new dialysis patients between groups?
   - **A.** Competing risks refers to higher rates seen among health systems in which funding is allocated on a competitive grants basis.
   - **B.** Men more than women are affected because testosterone leads to greater competitive drive.
   - **C.** Competing risks from transplantation will not be a factor if measured covariates are included and adjustment is made for them.
   - **D.** Incident dialysis rates might be higher if vascular mortality associated with CKD were lower.
   - **E.** Propensity score matching can largely address the problems raised by competing risks.

Pathophysiology of Disease Progression in Proteinuric and Nonproteinuric Kidney Disease

Ariela Benigni, Norberto Perico, Giuseppe Remuzzi

Chronic kidney disease (CKD) is a worldwide threat to public health and has a risk-multiplier effect on major noncommunicable diseases, including cardiovascular diseases.[1] More than 697 million individuals are currently affected by CKD worldwide,[2] and the number of patients with end-stage kidney disease (ESKD) treated with renal replacement therapy with dialysis or transplantation globally exceeds 2.6 million people.[3] Independent of the initial insult, progression to ESKD is relatively common in chronic nephropathies. Many forms of progressive noncystic kidney disease are glomerular in origin, and yet it is the intensity of the accompanying or evolving injury of the tubulointerstitial compartment, rather than the extent of glomerular changes, that predicts the overall decline in kidney function.[4] Although genetic factors contribute to susceptibility and progression of kidney disease, increased glomerular capillary flow and pressure consistently leading to increased urinary protein traffic have been claimed as independent factors of progression and poor kidney outcomes in nondiabetic and diabetic kidney disease.[5,6] The Ramipril Efficacy in Nephrology (REIN) study was the first trial to formally test the role of proteinuria in the progression of kidney disease.[7-9] The trial showed that in 352 patients with proteinuric nephropathies from different etiologies, higher proteinuria at inclusion was associated with faster glomerular filtration rate (GFR) decline and progression of ESKD on follow-up.[5,10] Notably, in the REIN trial, larger proteinuria reduction and less residual proteinuria at follow-up were both associated with slower GFR decline and more effective protection against progression to ESKD, independent of treatment allocation.[11] Greater proteinuria reduction predicted slower progression, as in the patients with type 2 diabetes with overt nephropathy included in the Reduction of Endpoints in NIDDM with the Angiotensin II Antagonist Losartan (RENAAL)[6] study and Irbesartan Diabetic Nephropathy Trial (IDNT).[12] The predictive pathogenic role of proteinuria was confirmed by a pooled analysis of 2387 CKD patients included in 11 trials, which showed that, irrespective of treatment, short-term changes in proteinuria were strongly consistent with long-term outcomes, whereas no effect on proteinuria predicted no long-term benefit.[13] Thus, efforts to dissect the mechanisms and mediators underlying disease progression in proteinuric nephropathies are of utmost importance to help design novel medications to further improve the efficacy of current renoprotective interventions.

FROM GLOMERULAR HEMODYNAMIC CHANGES TO LOSS OF CHARGE- AND SIZE-SELECTIVE PROPERTIES

Under normal conditions, the kidney filtration barrier prevents the passage of macromolecules from the blood into the urinary space. The ability to retain proteins in the glomerular capillary is influenced by the intrinsic permeability and selectivity properties of the three distinct but interacting layers: fenestrated glomerular endothelial cells, the glomerular basement membrane (GBM), and podocytes with their foot processes and slit diaphragms.[14-16] The glomerular barrier properties allow for high filtration rate of water and nonrestricted passage of small and middle-size molecules while maintaining charge and size selectivity for serum albumin and larger proteins.

The luminal surface of glomerular endothelial cells is covered by the glycocalyx, a thin, negatively charged layer of membrane-bound glycoproteins, proteoglycans, and glycosaminoglycans.[17] The negative charges prevent the transmural passage of anionic circulating proteins, such as albumin, by acting as an electrostatic barrier. Therefore, although endothelial fenestrae are much larger than albumin (about 60 nm in diameter compared with the albumin's radius of only 3.6 nm), negatively charged circulating macromolecules stay away from the endothelial surface due to electrical repulsion and remain within the circulation. It is now evident that the first restriction to albumin filtration across the glomerular capillary wall consists in the endothelial surface layer, and its role is to substantially decrease protein concentration in the fluid that enters the GBM layer.[17] The thickness of the glycocalyx layer appears to be importantly affected by shear stress. In particular, increased fluid shear stress is associated with glycocalyx formation and reorganization on the cell surface in contact with fluid flow.[18] Thus, pathologic conditions in which changes in glomerular capillary flow (i.e., reduced flow) may occur are expected to decrease glycocalyx formation, thereby reducing the retention of anionic proteins within the bloodstream. It has been demonstrated that disruption of the endothelial glycocalyx increases glomerular albumin filtration even in the presence of only minor changes in both the GBM and glomerular epithelial cells.

The epithelial filtration slit of podocytes is a major component of the glomerular barrier that also contributes to restrict protein transport. As shown from animal models in the early 1980s, a variety of insults ultimately lead to a common pathway of glomerular capillary hyperperfusion and hypertension, followed by increased permeability with excess passage of proteins across the glomerular capillary wall and progressive glomerular injury.[19] Enhanced intraglomerular capillary pressure stretches the glomerular wall, which, in addition to directly injuring glomerular cells,[20] impairs the selective function of the glomerular capillary, an effect explained by the appearance of very large pores that exceed the sizes observed in normal conditions and allow increased filtration of plasma proteins (Fig. 81.1).[21] Mechanical strain also increases angiotensin II (Ang II) production and expression of Ang II type 1 (AT_1) receptors in podocytes.[22] Independent of its hemodynamic effects, Ang II may directly impair the glomerular barrier sieving function, possibly through inhibition of podocyte expression of nephrin, the essential protein component of the glomerular slit diaphragm (Fig. 81.2).[23] This observation has been confirmed in studies in diabetic animals showing that blockade of Ang II synthesis/activity preserved the expression of nephrin in the glomeruli and prevented

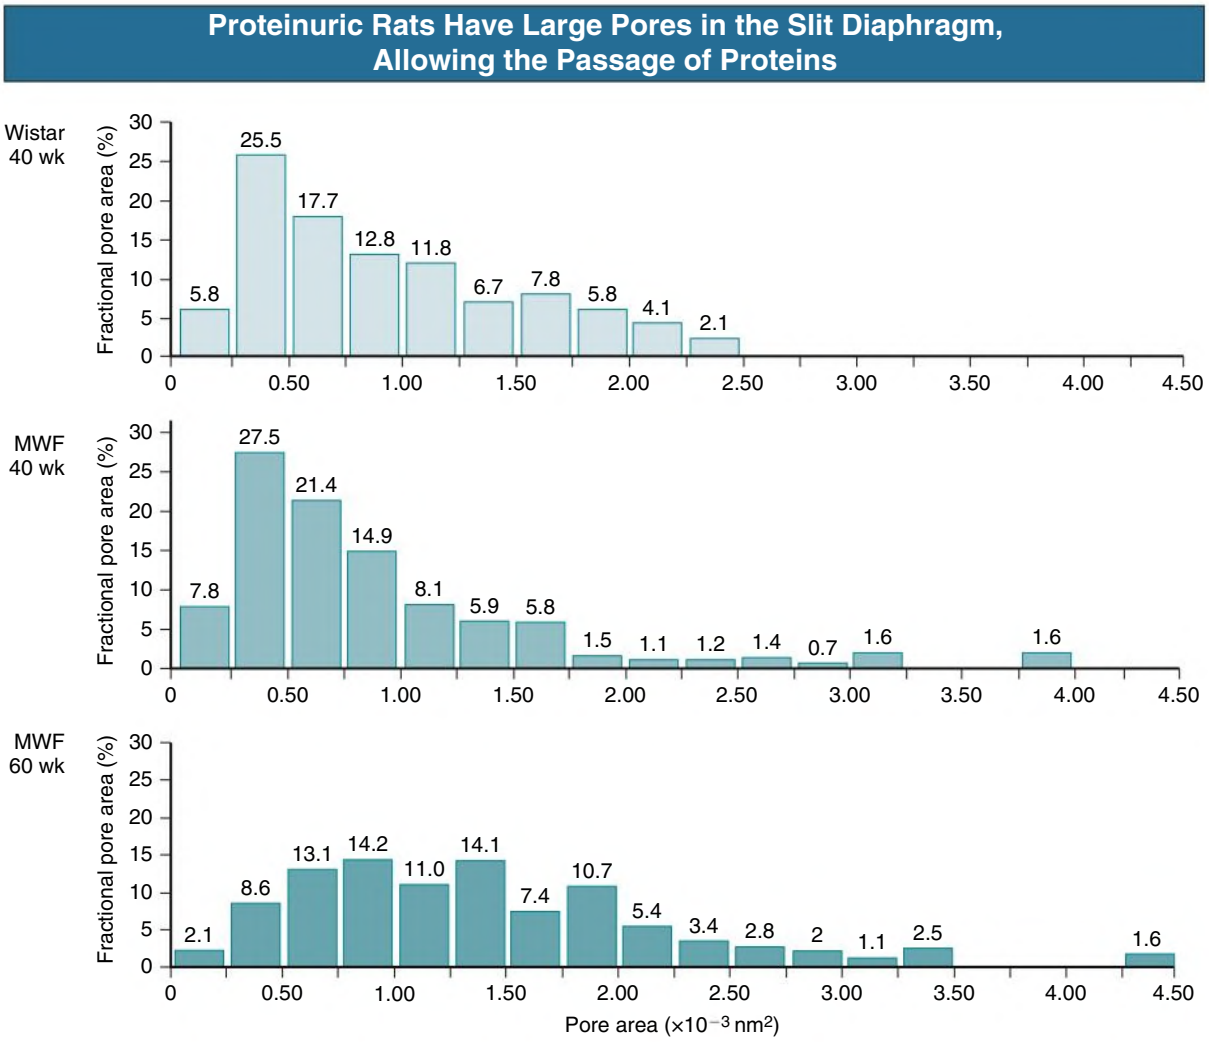

Fig. 81.1 Proteinuric Munich Wistar Frömter (MWF) Rats Have Large Pores in the Glomerular Capillary Slit Diaphragm That Exceed the Size Observed in Normal Animals. Distribution of fractional pore area (the fraction of the total pore area for given pore area interval) calculated for slit pores in 40-week-old normal Wistar rats and in 40- or 60-week-old proteinuric MWF rats. (From Gagliardini E, Conti S, Benigni A, Remuzzi G, Remuzzi A. Imaging of the porous ultrastructure of the glomerular epithelial filtration slit. *J Am Soc Nephrol.* 2010;21[12]:2081–2089.)

overt proteinuria.[24] Thus, in the setting of diabetes, after the initial insult of hyperglycemia and intraglomerular hypertension, Ang II plays a relevant role in sustaining glomerular injury via persistent activation of Notch1 and Snail signaling in the podocyte, eventually resulting in persistent downregulation of nephrin expression.[25] The consistency of the findings in Zucker diabetic fatty rats with overt nephropathy and in patients with type 2 diabetes and established nephropathy provides a robust reason to infer an important role for the Ang II Notch1/Snail axis in perpetuating loss of glomerular size–selective properties. A recent experimental study points to protective actions of mitochondrial glycerol 3-phosphate dehydrogenase (mGPDH), a protein located on the inner mitochondrial membrane, against podocyte injury and progression of diabetic kidney disease.[26] In particular, mGPDH expression was found to be downregulated in podocytes of mice and patients with diabetic nephropathy. Podocyte-specific mGPDH knockout mice showed exacerbated diabetes-induced proteinuria, podocyte damage and glomerulosclerosis. Inhibition of the receptor for the advanced glycation end-product (RAGE) abrogated mGPDH-induced podocyte injury and glomerular disease, suggesting that the effects of this mitochondrial protein were exerted through the regulation of the RAGE signaling pathway. Restoration of mGPDH expression in mice with established glomerular injury resulted in renoprotection, making mGPDH a potential therapeutic target for ameliorating diabetic kidney disease.[26]

Given the abundant evidence that podocyte injury underlies most, if not all, proteinuric kidney diseases, new technologies, including ultrahigh-resolution imaging and genetically engineered models of human disease, were used to develop a biophysical theoretical model of glomerular ultrafiltration.[27,28] According to this model, remarkable intraluminal hydrostatic pressure exerts physical forces on the capillary wall that are counteracted by the GBM and by podocytes. When podocytes are injured, they take on a simplified, effaced phenotype, and the slit diaphragm length is much reduced. Concomitantly, the capacity of podocyte foot processes to provide compressive forces to counteract a transmembrane pressure of 40 mm Hg is decreased, thereby reducing the compression of GBM, with eventual increase in the permeability to albumin.[27,28] However, this hypothesis does not account for the role played by the subpodocyte space (SPS) which surrounds the filtration membrane and increases under pathologic conditions.[29,30] Indeed, evidence from studies that used Munich Wistar Frömter (MWF) rats, an

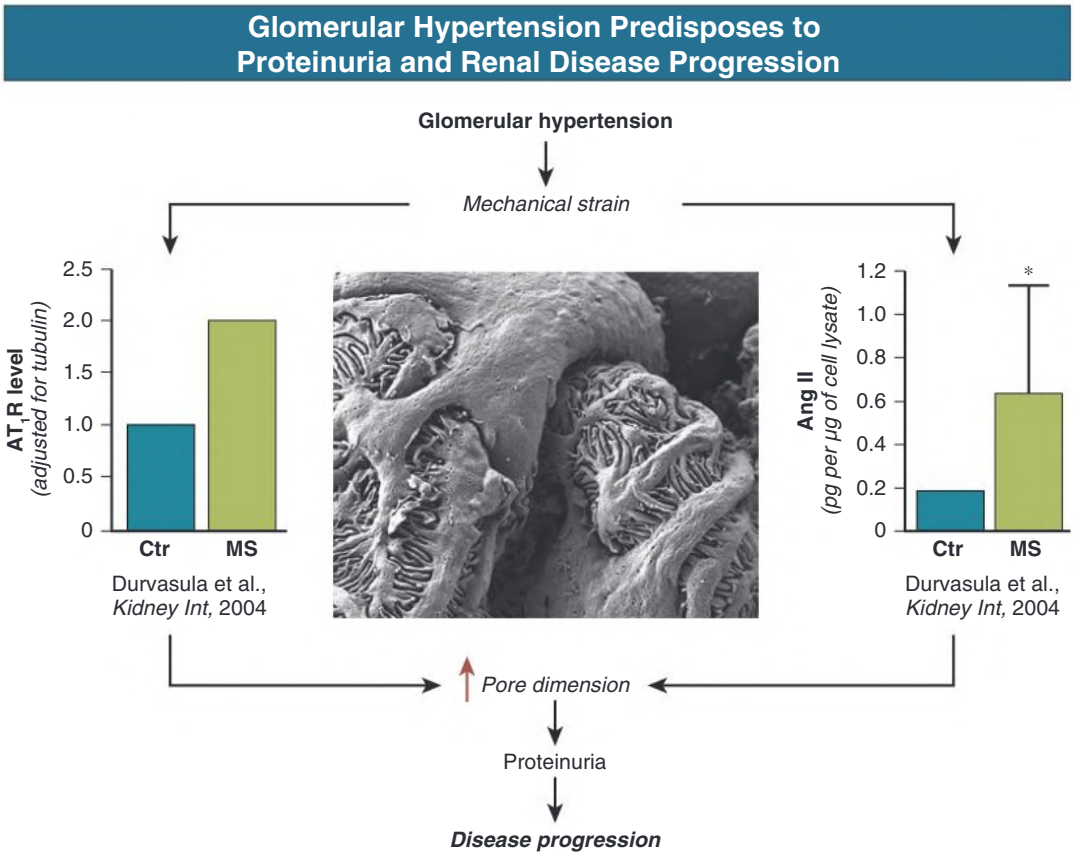

Fig. 81.2 Schematic Process Linking Glomerular Capillary Hypertension to Proteinuria and Kidney Disease Progression. After the original disease process causes an initial loss of nephron units, enhanced intraglomerular capillary pressure stretches the glomerular wall, impairing its size-selective function. Mechanical strain also increases angiotensin II (Ang II) production and expression of Ang II type 1 receptors (AT_1R) in podocytes, eventually directly contributing to loss of the glomerular barrier sieving function through inhibition of podocyte slit diaphragm nephrin expression. $*P < .05$ vs control. *Ctr,* Control; *MS,* mechanical strain. (From Durvasula RV, Petermann AT, Hiromura K, et al. Activation of a local tissue angiotensin system in podocytes by mechanical strain. *Kidney Int.* 2004;65[1]:30–39.)

experimental model of spontaneous proteinuria and glomerulosclerosis,[31] indicates that loss of glomerular filtration function depends strongly on abnormal rearrangement of podocytes, which causes an expansion of the SPS, an increase in its hydraulic resistance to filtered water, and an increased force acting within the SPS, which tends to detach podocytes from the capillary membrane.[32] This evidence is further corroborated by the finding that angiotensin-converting enzyme (ACE) inhibition preserves podocyte structure, reducing the spatial extension of SPS and restoring the hydrodynamic detaching forces which act on podocytes, eventually normalizing water filtration and glomerular barrier function.[32]

Podocyte Response to Protein Trafficking

Besides being affected by mechanical stress, podocytes are also damaged by excessive protein load resulting from alteration of glomerular permeability to macromolecules.[33]

Protein uptake by podocytes may occur through binding to megalin, a receptor for albumin and immunoglobulin light chains that is endocytosed after ligand binding, as shown in cultured murine podocytes.[34] Excessive protein uptake by podocytes also induces transforming growth factor-β (TGF-β) production, which contributes to cell apoptosis, an additional cause of podocyte loss in proteinuric glomerulopathies.[35]

Finally, podocytes possess a fully functional endothelin (ET) system, and evidence has highlighted the role of ET-1 in promoting structural and functional alteration of these cells in kidney disease.[36] This possibility is supported by the beneficial effects of ET receptor antagonists on the development of proteinuria and glomerular injury in type 1 diabetic animals, partially attributed to attenuation of podocyte loss.[24] Although the mechanism of podocyte preservation by ET receptor antagonism remains ill defined, recent observations indicate that ET-1 induces an epithelial-to-mesenchymal transition-like event associated with increased podocyte motility.[37] This is dependent on the activation of ET_A receptor, which recruits β-arrestin 1, leading to epithelial growth factor receptor translocation and β-catenin phosphorylation, in turn promoting the expression of migratory genes.[37]

Furthermore, the preservation of podocyte structure under ET receptor antagonism could be secondary to a reduction in the protein load reaching the cells, as suggested by recent findings in diabetic apoE knockout mice.[38] In this model, the ET_A receptor antagonist atrasentan restored the structural integrity of glomerular endothelial glycocalyx normalizing the barrier against the excessive traffic of albumin through the capillary wall up to podocytes.[38]

Crosstalk of Podocytes With Mesangial and Endothelial Cells

The mesangial cells are a critical part of the glomerular functional unit, interacting closely with podocytes.[39] Alterations in one cell type can produce changes in the others. Whether cytokines generated by podocytes influence mesangial cells has yet to be clearly defined, but

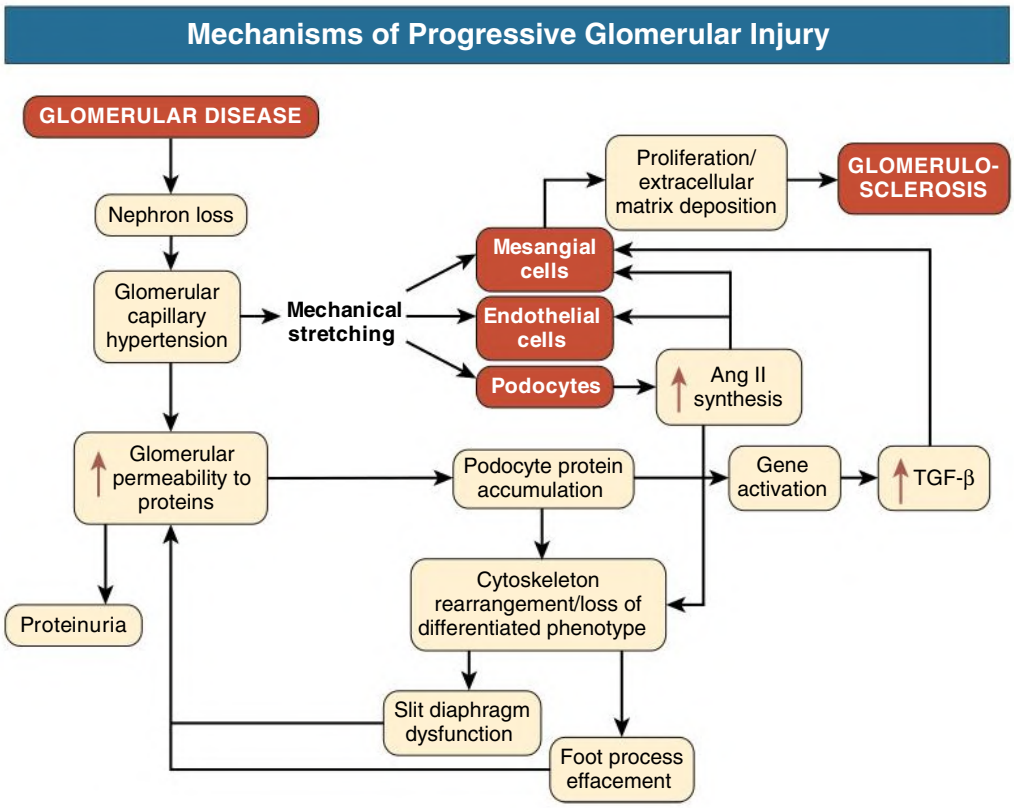

Fig. 81.3 Mechanisms of Progressive Glomerular Injury. A reduction in the number of nephrons as a consequence of various glomerular diseases results in compensatory glomerular hemodynamic changes that are ultimately detrimental. By mechanical stretching, the increased glomerular capillary pressure directly injures glomerular cells. Glomerular hypertension also impairs the glomerular capillary size-selective function, which causes excessive protein ultrafiltration and, eventually, podocyte injury and proteinuria. *Ang II,* Angiotensin II; *TGF-β,* transforming growth factor-β.

the observation that podocyte injury frequently results in mesangial cell proliferation supports the existence of such cytokine crosstalk.[39] Moreover, podocyte abnormalities are accompanied by upregulation of TGF-β messenger RNA and enhanced production of the related protein,[40] which ultimately induces differentiation of mesangial cells into myofibroblasts, abnormal extracellular matrix (ECM) deposition, and glomerulosclerosis.[41,42]

Loss of podocytes secondary to protein-induced cell injury may lead to reduced production of vascular endothelial growth factor (VEGF), a molecule constitutively expressed and secreted by podocytes,[43] influencing the formation of glomerular endothelial fenestrae and eventually promoting endothelial cell apoptosis.[44] How VEGF reaches endothelial cells against the urine flow is not yet known, however. Conversely, in vitro evidence has shown that blockade of VEGF in glomerular endothelial cells enhanced the release of ET-1, which induced nephrin shedding from podocytes,[45] leading to further dysfunction of glomerular protein permeability (Fig. 81.3).

Activation of Parietal Epithelial Cells

Changes in glomerular perm-selective function, as it occurs in proteinuric glomerulopathies, elevate the filtered load of plasma albumin and consequently its concentration in Bowman's space (Fig. 81.4).[46] Evidence shows that the abnormally filtered albumin impairs the mechanism underlying regeneration of damaged podocytes.[47] Indeed, although podocytes have limited capacity to divide, they are potentially replaced by differentiation of a population of kidney progenitor cells localized within Bowman's capsule.[48] In vitro, albumin overload blocked the differentiation of human kidney progenitor cells into podocytes expressing podocin and other functional molecules. The albumin-dependent block of relevant gene transcription and of progenitor differentiation was explained by specific binding and sequestration of retinoic acid, which is endogenously synthesized by the cells from retinol (see Fig. 81.4).[47]

The abnormal concentration of proteins in the ultrafiltrate also can lead to activation and accumulation of parietal epithelial cells (PECs) within Bowman's space as a common response to glomerular injury,[49] as shown in several human proliferative glomerulonephritides. This possibility is supported by findings in MWF rats, which are genetically programmed to undergo kidney damage characterized by excessive migration and proliferation of parietal progenitor cells, leading to their accumulation into cellular lesions and glomerulosclerosis.[50] Along Bowman's capsule in the adult MWF rats, a population of PECs expressing the neural cell adhesion molecule (NCAM), a marker of metanephric mesenchyme,[51] together with CD24, a mouse and human kidney stemness marker, has been identified.[50] Double-staining of NCAM with the podocyte marker WT1 identified three cell populations lining Bowman's capsule: immature progenitor cells expressing NCAM, transitional cells expressing markers from progenitor cells and podocytes ($NCAM^+WT1^+$), and more differentiated epithelial cells, the parietal podocytes ($NCAM^-WT1^+$). $NCAM^+$ PECs in vitro differentiate into podocytes, confirming their progenitor nature.[50] We investigated the behavior and role of $NCAM^+$ PECs in the evolution of glomerular lesions in MWF rats that showed early lesions consisting of bridges between the parietal and visceral epithelium, followed by hyperplastic lesions that eventually evolve to sclerosis.[50] The majority of cells in glomerular lesions were $claudin^+$ PECs of Bowman's capsule, whereas there were few podocytes. In old MWF animals, the

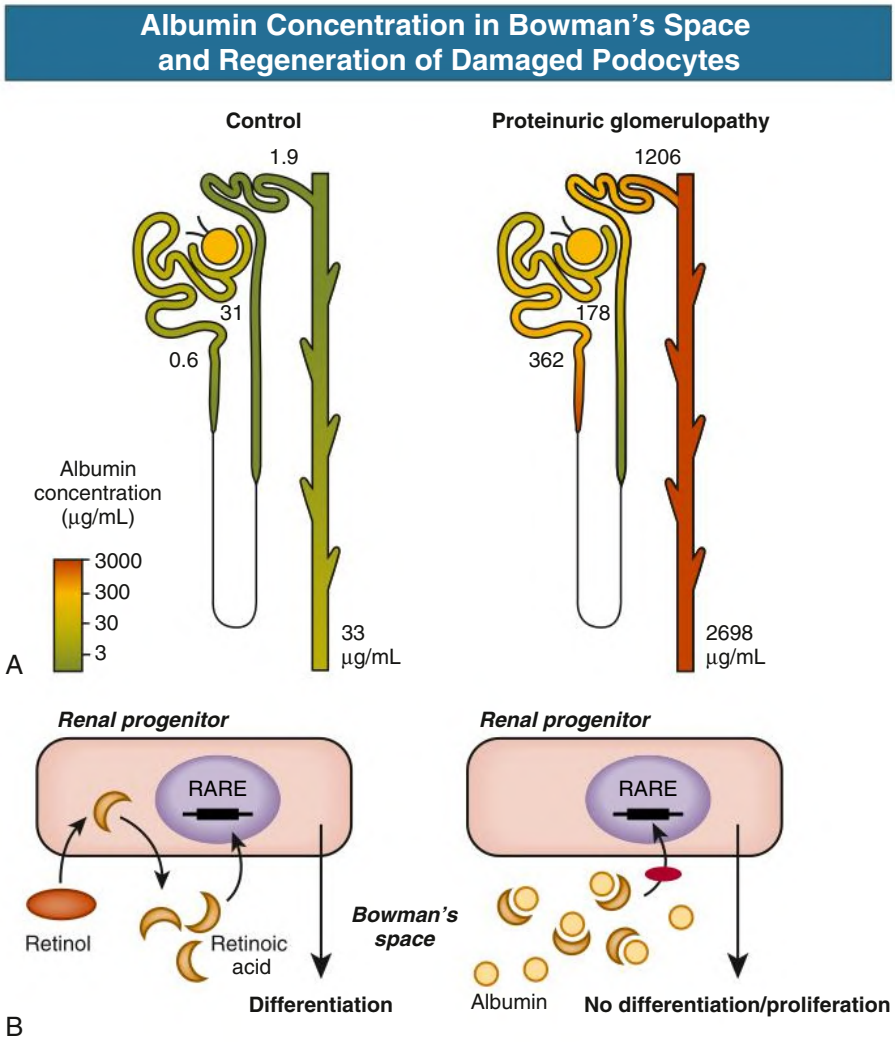

Fig. 81.4 Albumin Concentration in Bowman's Space and Regeneration of Damaged Podocytes. (A) In the proteinuric glomerulopathies, changes in glomerular perm-selective function results in a high concentration of albumin in Bowman's space. Color-coded representation of estimated albumin concentration along the entire nephrons in two animal groups (control and kidney mass ablation model). Numbers represent local group average albumin concentration in micrograms per milliliter. (B) In vitro albumin overload, prevented the differentiation to podocytes from human kidney progenitor cells by sequestering retinoic acid, thus impairing retinoic acid response element (RARE)-mediated transcription of podocyte-specific genes. After early podocyte injury, retinol is lost through the injured glomerular filtration barrier and transformed into retinoic acid. Albumin overload also promotes proliferation and migration of kidney progenitor cells into Bowman's space. (A, Modified from Sangalli F., Carrara F., Gaspari F., et al. Effect of ACE inhibition on glomerular permselectivity and tubular albumin concentration in the renal ablation model. *Am J Physiol Renal Physiol.* 2011;300[6]:F1291–F1300. B, Modified from Peired A, Angelotti ML, Ronconi E, et al. Proteinuria impairs podocyte regeneration by sequestering retinoic acid. *J Am Soc Nephrol.* 2013;24[11]:1756–1768.)

claudin$^+$ PECs increased in number, proliferated, and accumulated in Bowman's space, whereas parietal podocytes decreased. These findings suggested dysregulation of PECs' ability to differentiate into podocytes and to repair injury.[50]

PECs expressing the progenitor cell marker also have been reported to proliferate and accumulate into the multilayered cellular lesions in patients with glomerulonephritides characterized by extracellular capillary proliferation.[52] Upregulation of the CXCR4 chemokine receptor on these progenitor cells was found to be accompanied by high expression of its ligand, SDF-1, in podocytes.[52] Moreover, PEC proliferation was associated with increased expression of the AT_1 receptor. Renin-angiotensin system blockade normalized CXCR4 and AT_1 receptor expression on parietal progenitor cells concomitant with regression of crescentic lesions.[52] Together these findings suggest that the glomerular hyperplastic lesions derive from the proliferation and migration of kidney progenitor cells in response to injured podocytes and that the Ang II/AT_1 receptor pathway may contribute, together with SDF-1/CXCR4 axis, to the dysregulated response of PEC precursors. A recent study highlighted the key role of complement components C3 and C3a in determining podocyte dysfunction and loss leading to PEC activation.[53] Proliferation and migration of PECs in response to activated complement contribute to the development of glomerular sclerotic lesions.[53] Consistently, studies on kidney biopsy samples from patients with proteinuric nephropathies and PEC activation showed concomitant glomerular C3 and C3a deposition, indicating its key role in the development of glomerular lesions.[53]

PROXIMAL TUBULAR CELL INJURY

Glomerular ultrafiltration of excessive amounts of plasma protein–associated factors incites tubulointerstitial damage and further promotes the effects of glomerular disease on the tubulointerstitial compartment.

The harmful substances in the proteinuric ultrafiltrate may incite tubular epithelial injury with tubular apoptosis, secondary generation of inflammatory mediators, and peritubular inflammation.[41] The mechanisms by which increased urinary protein concentration leads to toxic injury are multifactorial and involve complex interactions among numerous pathways of cellular damage.

Tubular Cell Apoptosis

Kidney proximal tubular cells have a remarkable ability to reabsorb large quantities of albumin through clathrin- and megalin receptor–mediated endocytosis.[54] Kidneys in rats with albumin overload proteinuria[55] or passive Heymann nephritis (PHN)[56] showed increased numbers of terminal deoxynucleotidyl transferase nick-end labeling-positive apoptotic cells in the tubulointerstitial compartment. In tubules, most of the positive cells expressed Ang II type 2 (AT_2) receptors.[55] Findings of reduced phosphorylation of extracellular signal-regulated kinase and Bcl-2 suggested an AT_2 receptor–mediated mechanism underlying tubular cell apoptosis.[55] Similarly, apoptotic cells expressing both proximal and distal tubular phenotypes were detected in biopsy specimens from patients with primary focal segmental glomerulosclerosis (FSGS), and a positive correlation was documented between proteinuria and incidence of tubular cell apoptosis.[57]

Proximal tubular cell apoptosis has been shown to contribute to tubuloglomerular disconnection and atrophy in response to proteinuria in animal models of proteinuric nephropathies.[56] When passive PHN rats were given the ACE inhibitor lisinopril, which limits proteinuria, tubular atrophy and disconnection were remarkably prevented.[56] PHN animals that did not respond to ACE inhibition in terms of reduction of proteinuria had a glomerular population consisting mainly of atubular glomeruli and glomeruli connected with atrophic tubules, which again is consistent with the possibility that excessive protein tubular handling favors disconnection.[56]

Tubular Cell Phenotypic Changes

Excessive protein uptake at the apical pole of the proximal tubular cells is associated with phenotypic changes characteristic of an activated state.

Insights into specific mechanisms linking protein uptake to cell activation have come from in vitro studies using polarized tubular cells to assess the effect of apical exposure to proteins. Collectively, they show that protein overload induces a proinflammatory phenotype (Fig. 81.5).[58] Indeed, upregulation of inflammatory and fibrogenic genes and production of related proteins have been reported after a challenge of proximal tubular cells with plasma proteins. They

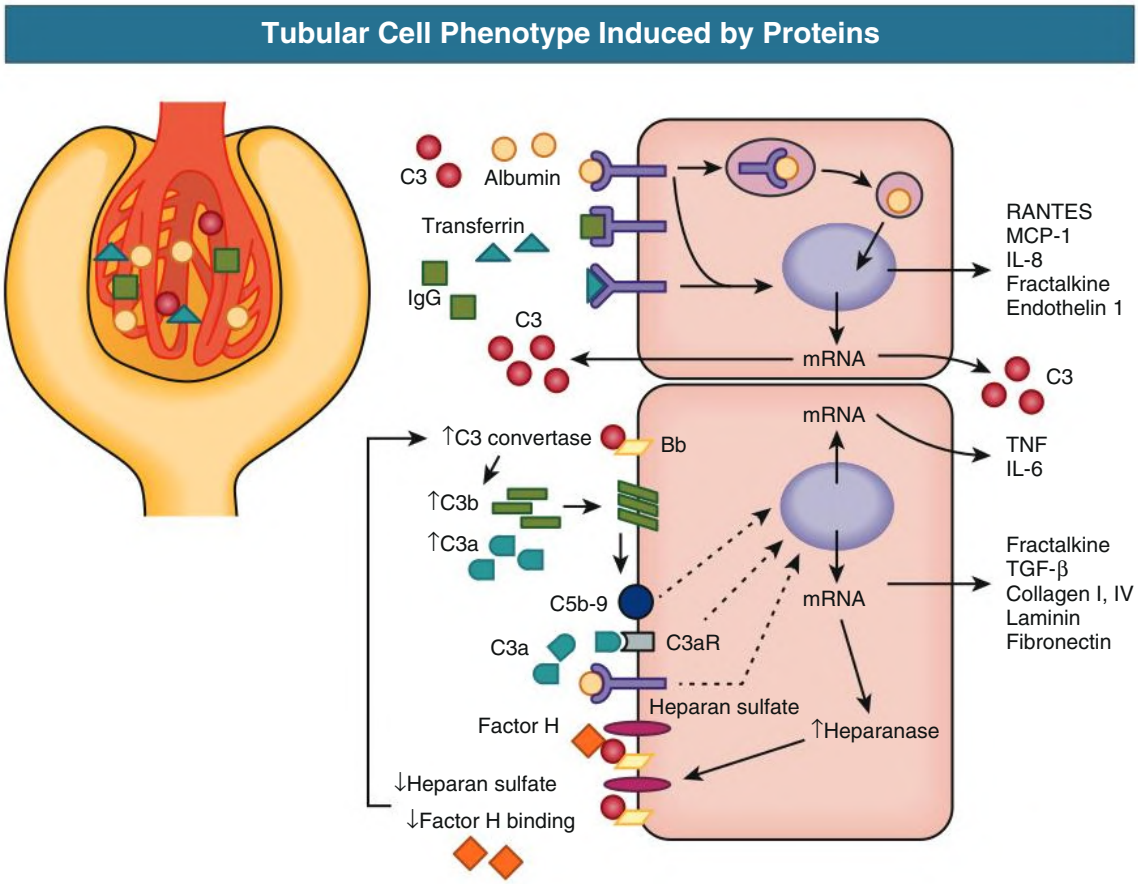

Fig. 81.5 Tubular Cell Phenotypic Changes Induced by Proteins. Protein overload of proximal tubular cells as a consequence of increased glomerular permeability to proteins activates intracellular signals that promote cell apoptosis or cause increased production of inflammatory and vasoactive mediators and growth factors. *IgG,* Immunoglobulin G; *IL-6,* interleukin-6; *IL-8,* interleukin-8; *MCP-1,* monocyte chemoattractant protein-1; *RANTES,* regulated upon activation, normal T cell expressed and secreted; *TGF-β,* transforming growth factor-β; *TNF,* tumor necrosis factor.

include cytokines, chemokines, and vasoactive substances, such as monocyte chemotactic protein-1 (MCP-1); regulated upon activation, normal T cell expressed and secreted (RANTES); interleukin-8; fractalkine; and ET-1.[58] Moreover, levels of the profibrogenic cytokine TGF-β and its type I receptor, tissue inhibitors of metalloproteinase (TIMP-1 and TIMP-2), as well as membrane surface expression of the αvβ5 integrin, were also highly increased in vitro on stimulation by plasma proteins.[58] Investigation of the molecular mechanisms underlying chemokine and growth factor upregulation in proximal tubular cells on protein challenge has focused on the activation of the transcription factor nuclear factor-κB (NF-κB).[58] In this context, a recent study showed that albumin is capable of inducing chromatin modification, making the promoter region of the gene encoding miR-184, which plays a key role in tubulointerstitial nephritis of diabetic rats, more accessible to NF-κB inducing the miR-184 transcription.[59] Other studies confirmed the role of the NF-κB pathway and revealed reactive oxygen as a second messenger.[60] The link of excessive protein reabsorption to tubular cell activation has been confirmed by in vivo studies in animal models. Evidence of early activation of proximal tubule cells during nonselective proteinuria was derived from experiments in megalin knockout/NEP25 mice treated with the immunotoxin LMB2, a model of nephrotic syndrome, FSGS, and tubulointerstitial injury.[61] Megalin-deficient proximal tubule cells reabsorbed fewer proteins in vivo and expressed fewer tubular injury markers, such as MCP-1 and heme-oxygenase.[61] Moreover, a report using podocin knockout mice as a model of FSGS demonstrated that increased reabsorption of abnormally filtered albumin and other proteins in proximal tubule cells was associated with massive increase of lysosomal proteolysis.[62] However, high expression of proinflammatory and profibrotic mediators (MCP-1 and TGF-β) in the kidney also occurred almost simultaneously with the increase in tubular content of megalin ligands.[62] This suggests that, despite the effective degradation of endocytosed proteins by lysosomes in this model, the excessive protein uptake by tubule cells was still capable of activating phenotypic changes by upregulation of proinflammatory and growth factor encoding genes.

With proteinuria, a putative key factor in tubular cell activation and damage is the excess glomerular filtration of plasma-derived complement C3, the central molecule in the complement system that exerts proinflammatory potential. Kidney tubule epithelial cells appear more susceptible to luminal attack by the C5b-9 membrane attack complex because of the relative lack of membrane-bound complement regulatory proteins, such as membrane cofactor protein (CD46), decay-accelerating factor, or CD55 and CD59 on the apical surface.[63] In rats with reduced kidney mass, C3 colocalized with proximal tubular cells engaged in high protein uptake. By limiting the transglomerular passage of proteins, treatment with ACE inhibitors was an effective manner to reduce the C3 load of tubular cells in remnant kidneys.[64] C3 and other complement proteins are also found in proximal tubules in kidney biopsy material from patients with nephrosis.[65] Furthermore, proximal tubular cells are able to synthesize C3 and other complement factors and to upregulate C3 in response to serum proteins in vitro.[66] Studies in C3-deficient kidneys transplanted into wild-type mice have helped clarify that ultrafiltered C3 contributes more to tubular damage induced by protein overload than locally synthesized C3.[67]

INTERSTITIAL INFLAMMATION AND FIBROSIS

In proteinuric kidney disease, progressive inflammation and injury to the kidney interstitium are secondary events after glomerular or vascular damage. Cytokines and chemokines synthesized by proximal tubular epithelial cells are released into the interstitium, where they contribute to recruit inflammatory cells and lymphocytes causing progressive fibrosis.[58]

Resident Monocyte and Lymphocyte Activation

The interstitium of normal kidneys contains numerous resident monocytic myelocytes, which express dendritic cell markers and can present antigens.[68] Dendritic cells have been described to form an immune sentinel network through the entire kidney, where they probe the environment in search of antigens.[69] An inflammatory environment converts the tolerogenic status of resident dendritic cells into an immunogenic one, favoring recruitment of T cells. The importance of kidney dendritic cell activation to kidney injury has been demonstrated by the fact that in transgenic NOH mice (which selectively express the model antigens ovalbumin and hen egg lysozyme in podocytes), dendritic cell depletion resolved established periglomerular mononuclear infiltrates.[70] In vitro experiments also have shown that exposure of rat proximal tubular cells to excess autologous albumin, as in the case of proteinuric nephropathies, results in the formation of the N-terminal 24-residue fragment of albumin ($ALB_{1–24}$).[71] This peptide is taken up by dendritic cells, where it is further processed by proteasomes into antigen peptides. These peptides were shown to have the binding motif for major histocompatibility complex (MHC) class I and to be capable of activating $CD8^+$ T cells. Moreover, in vivo, in the rat model of kidney mass ablation, accumulation of dendritic cells in the kidney parenchyma peaked 1 week after surgery and decreased thereafter, concomitant with their appearance in the draining lymph nodes. Dendritic cells from kidney lymph nodes loaded with the albumin peptide ALB_{1-24} activated syngeneic $CD8^+$ T cells in primary culture.[71] Thus, inflammatory stimuli released from damaged tubules after protein overload may represent danger signals that, in the presence of albumin peptides, alert dendritic cells to promote local immune response via $CD8^+$ T cells, which are activated in regional lymph nodes and recruited in the kidney interstitium (Fig. 81.6).

The interstitium infiltrate in most human chronic kidney diseases consists of a number of different effector cells, including macrophages and $CD4^+$ T cells, in addition to $CD8^+$ T cells.[72] However, there is substantial functional diversity among $CD4^+$ T cells, so that certain subpopulations, such as $CD4^+CD25^+$ T cells (T regulatory [Treg] cells), hinder rather than help the immune response.[73] Findings of a study using the green fluorescence protein *Foxp3* mouse suggest that *Foxp3* expression identifies the regulatory T cell population.[74] In the murine model of doxorubicin (Adriamycin) nephropathy, the adoptive transfer of *Foxp3*-transduced T cells protected against kidney injury. Urinary protein excretion and serum creatinine were reduced, and there were significant decreases in glomerulosclerosis, tubular damage, and interstitial infiltrates.[75] These findings highlighted a complex interplay between effector/inflammatory cells and regulatory T cells in the setting of proteinuric chronic kidney diseases.

The modulatory role of Treg cells has also been recently supported by a study in a rat model of kidney ischemia-reperfusion injury (characterized by early proteinuria and increase in serum creatinine levels), after activation of the angiotensin II type 2 receptor (AT2R).[76] Treatment with the AT2R receptor agonist Compound 21 (C21) 2 hours before ischemic surgery attenuated postischemic kidney dysfunction and $CD3^+$ and $CD4^+$ T cell infiltration during the acute injury phase (2 hours postreperfusion). During the chronic phase (3–5 days), C21 treatment modulated the kidney microenvironment, as highlighted by increased $CD4^+$ *Foxp3* cells and IL-10–secreting T $CD4^+$ cells along with reduced levels of kidney injury molecule-1 and neutrophil gelatinase-associated lipocain.[76] These findings pave the way to further explore AT2R-dependent kidney protective effects.

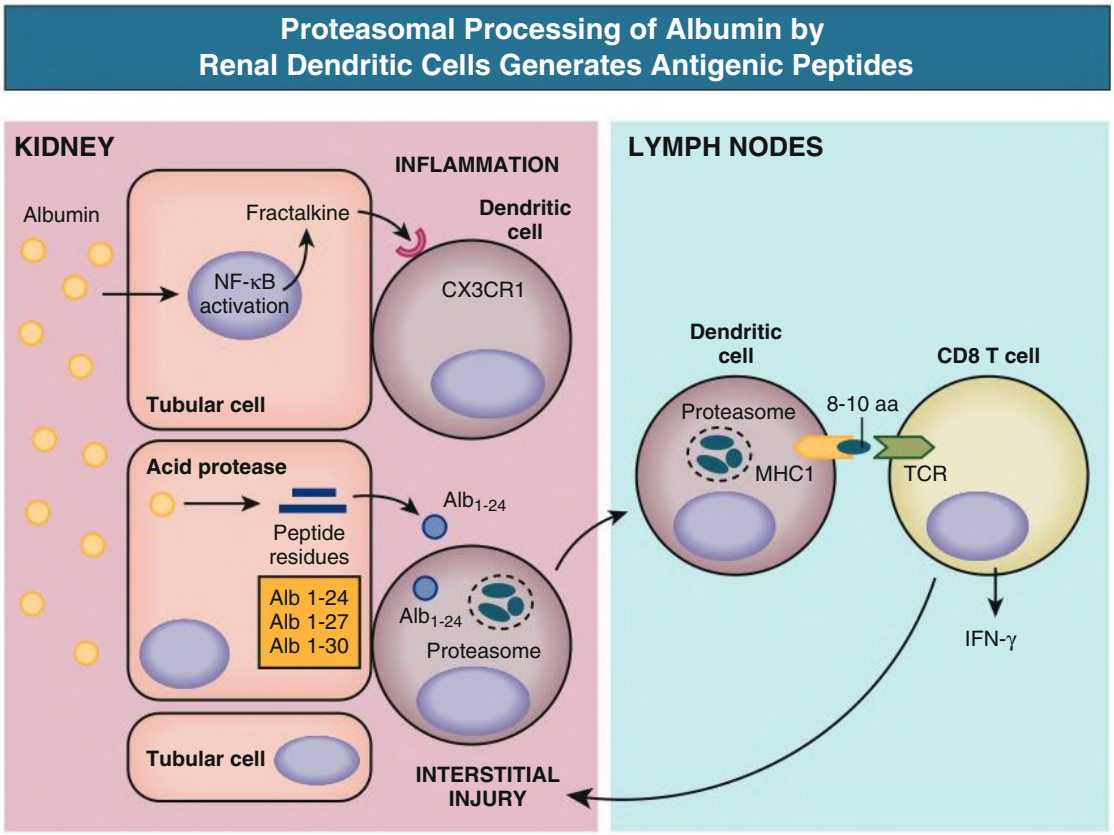

Fig. 81.6 Proteasomal Processing of Albumin by Kidney Dendritic Cells Generates Antigenic Peptides. Exposure of proximal tubular cells to excess autologous albumin, as in the case of proteinuric nephropathies, results in the formation of the N-terminal 24-residue fragment of albumin. This peptide is acquired by dendritic cells, where it is further processed by proteasome into antigenic peptides. Then dendritic cells move to regional lymph nodes, where they activate effector $CD8^+$ T cells. These cells are then recruited in the kidney interstitium. *Alb_{1-24},* N-terminal 24-residue fragment of albumin; *aa,* amino acids; *IFN-γ,* interferon-γ; *MHC,* major histocompatibility complex; *NF-κB,* nuclear factor-κB; *TCR,* T-cell receptor.

Fibroblast Activation and Extracellular Matrix Deposition

The process of interstitial fibrosis involves the accumulation of myofibroblasts and ECM proteins (Fig. 81.7).[77] Resident interstitial fibroblasts and myofibroblasts proliferate in response to macrophage-derived profibrogenic cytokines, and their number correlates with the subsequent formation of a scar.[77] These cells may derive from transdifferentiated tubular epithelial cells or pericytes of peritubular capillaries, a process promoted by profibrogenic cytokines, including TGF-β, expressed by macrophages.[78] Activated kidney fibroblasts may secrete chemokines that in turn may further attract macrophages and perpetuate interstitial injury.[79] Moreover, miRNAs are emerging as both downstream effectors of TGF-β–dependent regulation of the fibrogenic process.[80] TGF-β upregulates the expression of the profibrotic miR-21 in cultured proximal tubular epithelial cells via Smad3 signaling, both at the transcriptional and posttranscriptional level.[81] A functional link between miR-192 and TGF-β–driven kidney fibrosis also has been documented, although the effect of TGF-β on miR-192 expression is not consistent across various studies.[80]

Eventually, activated fibroblasts produce interstitial matrix components that contribute to interstitial collagen deposition and fibrosis. Increased tubulointerstitial fibrosis is a common feature of kidney injury and results from accumulation of ECM structural proteins. However, it is maintained by continuous remodeling through the proteolytic action of matrix metalloproteinases (MMPs) and the synthesis of new proteins. MMPs are inhibited by tissue inhibitors of TIMPs. Of note, TIMP-3 levels are upregulated in patients with diabetic nephropathy, which anticipates more interstitial fibrosis.[82]

A recent study suggests that an endoplasmic reticulum resident protein, thioredoxin domain containing 5 (TXNDC5), which was found to be specifically upregulated in collagen-secreting kidney fibroblasts, could be a key mediator in experimental kidney fibrosis.[83] Global deletion of *txndc5* gene markedly attenuated the extent of kidney fibrosis in three mouse models of chronic kidney disease, that is, unilateral ureteral obstruction, unilateral ischemia-reperfusion injury, and folic acid nephropathy. Mechanistically, TXNDC5 augmented kidney fibrosis by promoting kidney fibroblast activation/proliferation and ECM production through posttranslational stabilization and upregulation of type I TGF-β receptor.[83]

Accumulating evidence indicates that stimulation of AT2R may exert antifibrotic effects.[84] Indeed, AT2R-deficient mice were found to develop a more severe course of nephropathy and kidney fibrosis in models of diabetic kidney disease and 5/6 nephrectomy.[85,86] Consistently, in a mouse model of type 1 diabetic nephropathy, treatment with the AT2R agonist C21 significantly reduced the expression of several inflammatory and profibrotic mediators, and upregulated collagen degradation induced by MMP-2 and MMP-9.[87]

Chronic Hypoxia

One of the most important contributors to the development of tubulointerstitial fibrosis is chronic ischemia.[88] The production of

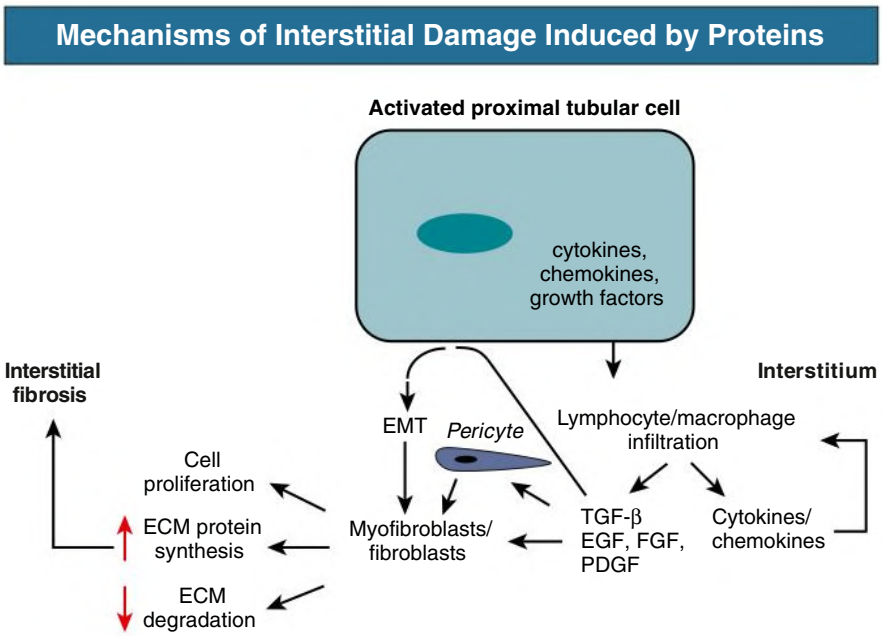

Fig. 81.7 Mechanisms of Interstitial Damage Induced by Proteins. Cytokines, chemokines, and growth factors are released from the activated tubule into the interstitium, where they contribute to recruit inflammatory cells and lymphocytes, causing progressive fibrosis. *ECM,* Extracellular matrix; *EGF,* epidermal growth factor; *EMT,* epithelial-to-mesenchymal transdifferentiation; *FGF,* fibroblast growth factor; *PDGF,* platelet-derived growth factor; *TGF-β,* transforming growth factor-β.

Ang II and the inhibition of the production of nitric oxide underlie chronic vasoconstriction, which may contribute to tissue ischemia and hypoxia.[89] In that regard, histologic studies of the human kidney have documented that there is often a loss of peritubular capillaries in areas of tubulointerstitial fibrosis.[89] Downregulation of VEGF may be functionally implicated in the progressive attrition of peritubular capillaries and tissue hypoxia. Moreover, given that the size of the interstitial compartment determines the diffusion distance between peritubular capillaries and tubular cells, interstitial fibrosis further impairs tubular oxygen supply. Focal reduction of capillary blood flow leading to the starvation of tubuli may underlie tubular atrophy and loss. Under these conditions the remaining tubules are subject to functional hypermetabolism, with increased oxygen consumption, which in turn creates an even more severely hypoxic environment in the kidney interstitium. Such hypoxia stimulates fibroblast proliferation and ECM production by tubular epithelial cells.[90]

PRIMARY CHRONIC TUBULOINTERSTITIAL INJURY

Tubulointerstitial disease is common to all chronic progressive kidney diseases, irrespective of the initial trigger or site of injury. Once viewed as an inconsequential corollary to pathologic events that overwhelm glomeruli, tubulointerstitial disease is now recognized as a key and prominent factor in the progression of kidney disease. In addition to the setting of proteinuric nephropathies, inflammation and injury of the kidney interstitium also can occur in nonproteinuric kidney disease, as exemplified by primary chronic tubulointerstitial diseases. In this case the key event is the expression of local nephritogenic antigens. They are derived from kidney cells and tubular basement membranes (TBMs) or exogenous antigens processed by tubular cells. The case of molecules, including drugs, which may become nephritogenic antigens by acting as haptens or through molecular mimicry, is particularly unusual. A humoral response underlies rare cases of interstitial nephritis in which a portion of a drug (e.g., methicillin) may act as a hapten, bind to the TBM, and elicit anti-TBM antibodies.[91] Among the numerous causes of primary chronic tubulointerstitial injury, drugs and toxins (see Table 65.1), in addition to genetic cystic diseases, are major players.

Analgesics and Nonsteroidal Antiinflammatory Drugs

Analgesic nephropathy is a specific form of kidney disease characterized by papillary necrosis and chronic interstitial nephritis, caused by prolonged and excessive consumption of analgesic mixtures. It is invariably caused by compound analgesic mixtures containing aspirin or antipyrine in combination with phenacetin, paracetamol, or salicylamide and caffeine or codeine, in popular over-the-counter proprietary mixtures.[92] The mechanisms responsible for the kidney injury are incompletely understood. Phenacetin is metabolized to acetaminophen and to reactive intermediates that can injure cells, in part by lipid peroxidation.[93] These metabolites tend to accumulate in the medulla along the medullary osmotic gradient (created by the countercurrent system). As a result, the highest concentrations are seen at the papillary tip, the site of the initial vascular lesions.[94] The potentiating effect of aspirin, with both phenacetin and acetaminophen, may be related to two factors. (1) Acetaminophen undergoes oxidative metabolism by prostaglandin H synthase to reactive quinonimine, which is conjugated to glutathione. If acetaminophen is present alone, there is sufficient glutathione generated in the papillae to detoxify the reactive intermediate. However, if acetaminophen is ingested with aspirin, the aspirin is converted to salicylate, which becomes highly concentrated and depletes glutathione in both the cortex and papillae of the kidney. With the cellular glutathione depleted, the reactive metabolite of acetaminophen then produces lipid peroxides and arylation of tissue proteins, ultimately resulting in necrosis of the papillae.[94,95] (2) Aspirin and other nonsteroidal antiinflammatory drugs suppress prostaglandin production by inhibiting cyclooxygenase enzymes. Kidney blood flow, particularly within the kidney medulla living at the edge of hypoxia, is highly dependent on systemic and local production of

vasodilatory prostaglandins. The final injury is therefore due to both the hemodynamic and the cytotoxic effects of these drugs, resulting in papillary necrosis and interstitial fibrosis.

Aristolochic Acid

In 1992 nephrologists in Belgium noted an increasing number of women presenting with kidney failure, often near end stage, after their exposure to a slimming regimen containing Chinese herbs.[96,97] The main histologic lesion in human biopsy samples, which is located principally in the cortex, is extensive interstitial fibrosis with atrophy and loss of the tubules. Cellular infiltration of the interstitium is scarce. Important tryptase-positive mast cells were observed in the fibrotic areas in kidney biopsy samples.[98] Thickening of the walls of the interlobular and afferent arterioles resulted from endothelial cell swelling. The glomeruli are spared, relatively speaking, and immune deposits are not observed. These findings suggest that the primary lesions may be centered in the vessel walls, thereby leading to ischemia and interstitial fibrosis.[99]

A plant nephrotoxin, aristolochic acid, has been proposed as the possible etiologic agent (see Chapter 65). Balkan endemic nephropathy, a chronic, familial, noninflammatory tubulointerstitial disease, most commonly seen in southeastern Europe, also has been potentially attributed to chronic exposure to dietary aristolochic acid (see Chapter 65).[100]

Autosomal Dominant Polycystic Kidney Disease

Autosomal dominant polycystic kidney disease (ADPKD) is the most common monogenic kidney disorder, accounting for 8% to 10% of patients receiving renal replacement therapy for ESKD worldwide.[101] In ADPKD patients, mutations in genes encoding for polycystin 1 or polycystin 2 lead to polycystin complex dysfunction. This results in reduced intracellular calcium concentration, leading to higher activity of adenylyl cyclase enzyme and upregulation of 3′,5′-cyclic adenosine monophosphate (cAMP) levels.[102] In turn, high intracellular cAMP levels lead to aberrant tubular epithelial cell proliferation and chloride-driven fluid secretion, the two key components of the process of cyst formation and growth in ADPKD.[103] In addition, activation of the Ser/Thr kinase mammalian target of rapamycin (mTOR) may also contribute to cyst expansion.[104] Uncontrolled cyst growth results in crowding of adjacent nephrons, injury of normal kidney parenchyma, interstitial inflammation and fibrosis, and eventually, substantial enlargement of the kidneys and progressive kidney failure.[105,106] It is assumed that kidney function starts to decline only after several decades, whereas cyst formation and growth already starts in utero. This preservation of GFR in early-stage ADPKD has been posited to be caused by compensatory hyperfiltration of remnant nephrons that have not yet been lost due to disease progression, a phenomenon referred to as glomerular hyperfiltration.[107] In the long term, however, this maladaptive response to reduced nephron number may translate into accelerated loss of residual hyperfunctioning nephrons and relentless progression to kidney failure. Indeed, evidence points to glomerular hyperfiltration as a risk factor for ADPKD progression. In particular, in 180 children with ADPKD, glomerular hyperfiltration (defined as creatinine clearance ≥140 mL/min/1.73 m^2) was associated with an increased rate of kidney growth and faster GFR decline.[108] Similarly, among 91 adult ADPKD patients, glomerular hyperfiltration at baseline (140 mL/min/1.73 m^2) was associated with higher GFR loss during the 15-year follow-up.[109] Therefore, the combination of cyst growth, tubulointerstitial injury, and maladaptive hyperfiltration of the remaining nephrons eventually results in ADPKD progression.

Insights into the pathophysiology of ADPKD have helped develop novel disease-modifying treatments (see Chapter 46).[110,111]

CONCLUSIONS

There is now clear evidence that, rather than simply a marker of damage, abnormal ultrafiltration of proteins can be toxic to the kidney and incites complex pathways and mediators that target glomerular, tubular, and interstitial cells, eventually promoting kidney disease progression to ESKD. Moreover, tubulointerstitial injury is also common in nonproteinuric kidney diseases and is critical for their progression to ESKD. More insights in the pathophysiologic mechanisms of progressive proteinuric and nonproteinuric kidney diseases will be instrumental to search for novel biomarkers that allow intervention in the earlier stages of CKD and may open the way to new treatments.

SELF-ASSESSMENT QUESTIONS

1. What is the pathologic podocyte response to protein trafficking throughout the glomerulus?
   - **A.** Podocytes start to proliferate.
   - **B.** Podocytes are damaged by excessive protein load and uptake of albumin.
   - **C.** Podocytes adhere to Bowman's capsule.
2. What is the main consequence of podocyte loss on endothelial cells during chronic kidney injury?
   - **A.** Endothelial cell apoptosis
   - **B.** Endothelial cell proliferation
   - **C.** Increase of vascularization of the kidney
3. What is the role of resident dendritic cells in the kidney during proteinuric diseases?
   - **A.** Dendritic cells proliferate.
   - **B.** Dendritic cells generate albumin peptides that activate $CD8^+$ T cells.
   - **C.** Dendritic cells undergo apoptosis.
4. How does the progressive enlargement of kidney cysts in autosomal dominant polycystic kidney disease develop?
   - **A.** It develops from mesangial cell proliferation.
   - **B.** It develops from endothelial cell proliferation.
   - **C.** It develops from tubular cell proliferation and fluid transport into the cyst cavity.

Slowing the Progression of Kidney Disease

Aminu K. Bello, Marcello Tonelli

INTRODUCTION

Prior to 2002, there was no standardized definition for chronic kidney disease (CKD). Instead, terms such as *chronic renal failure or insufficiency, chronic renal disease,* and *progressive renal insufficiency* were used.[1] In 2002, the US National Kidney Foundation established the Kidney Disease Outcomes Quality Initiative (KDOQI)[2]; an early goal was to define CKD and classify its severity using nomenclature that could be scaled and spread. The KDOQI framework defined CKD as structural or functional abnormalities of the kidney present for at least 3 months, manifested either as kidney damage (most frequently detected as persistent albuminuria) with or without a glomerular filtration rate (GFR) less than 60 mL/min/1.73 m^2, or as decreased GFR with or without other evidence of kidney damage.[2] In 2012, Kidney Disease: Improving Global Outcomes (KDIGO) updated the framework to enhance its capacity for predicting risk of progression to kidney failure or development of cardiovascular disease (CVD).[3] Central to this revision was to highlight the role of albuminuria as a marker of damage, an early manifestation of CKD, and an important prognostic factor for the progression of kidney disease and development of CVD.[3]

Developing a common framework for the presence and severity of CKD was instrumental in accelerating the pace of clinical research that led to better outcomes for people with kidney disease. In this chapter, we review techniques for evaluating and monitoring key indicators of CKD, describe factors associated with the risk of CKD progression, and outline measures to prevent adverse outcomes associated with CKD, such as kidney failure and CVD.

TECHNIQUES FOR EVALUATING AND MONITORING KEY INDICATORS OF CHRONIC KIDNEY DISEASE

Glomerular Filtration Rate

The key index of kidney function is the GFR, which cannot be measured directly but can be estimated from the urinary clearance of an ideal filtration marker. The most common methods used to estimate GFR are serum creatinine (SCr) concentration, creatinine clearance (CrCl), and estimation equations based on serum creatinine such as the Cockcroft-Gault (C-G) equation, and equations used in the Modification of Diet in Renal Disease (MDRD) study and the Chronic Kidney Disease Epidemiology Collaboration (CKD-EPI).[4] Details of GFR estimation are presented in Chapters 3.

Albuminuria

The preferred method of measuring proteinuria or albuminuria is by calculating urine protein-to-creatinine ratio (PCR) or albumin-to-creatinine ratio (ACR) on a random urine specimen, respectively.[3] Because it is highly accurate and convenient, ACR is preferred to the 24-hour urine collection for quantitative measurement of significant urinary albumin. Random daytime specimens are acceptable if the preferred first morning specimens are not available. The relative merits of the PCR compared with ACR for detection and monitoring kidney damage are unclear.[3] However, because albuminuria is a more sensitive marker than total protein in CKD due to diabetes, hypertension, and glomerular diseases, the ratio in adult spot urine samples should ideally be measured with ACR[3]; if ACR is high, PCR is acceptable. Methods are being developed to estimate ACR directly from PCR.[5]

EPIDEMIOLOGY AND BURDEN OF CHRONIC KIDNEY DISEASE

The number of individuals with kidney failure (end-stage kidney disease) represents less than 2% of those with CKD (stages 1–4). Although most people with CKD will not develop kidney failure, the minority that do pose a significant challenge to the health care system in terms of morbidity and cost, especially in low- and middle-income countries.

Globally, CKD is an important public health problem. According to estimates from the Global Burden of Disease Injuries and Risk Factors study, approximately 1.2 million people died from CKD worldwide in 2017, and the global all-age mortality rate linked to CKD increased over 40% between 1990 and 2017.[6] In absolute terms, CKD is estimated to affect approximately 700 million people around the world, with a global prevalence of 9.1% (range, 8.5%–9.8%), and the global all-age prevalence of CKD has increased over 29% over the last 3 decades.[6] CKD is associated with high risk of mortality and hospitalization, as well as high health care costs. Like diabetes, CKD has been described as a coronary artery disease "risk equivalent," reflecting the high risk of vascular disease in this population.[7]

Susceptibility to CKD is higher in certain families and among members of certain races. This highlights the possibility of genetic predisposition to CKD. For instance, in Canada, the disproportionate burden of CKD among Indigenous populations may reflect the high prevalence of major drivers of CKD such as hypertension and diabetes; patterns are similar for Indigenous populations in Australia and New Zealand. Among the key risk factors for the initiation of CKD are hypertension, diabetes, hyperlipidemia, obesity, and smoking. In low- and middle-income countries, key risk factors for initiation of CKD may also include communicable diseases such as HIV, hepatitis B and C, malaria, schistosomiasis, and tuberculosis. This double burden of communicable and noncommunicable risk factors has led to a growing burden of CKD across all world regions and population subgroups. Further details on the epidemiology of CKD are presented in Chapter 80.

RISK FACTORS FOR PROGRESSION OF CHRONIC KIDNEY DISEASE

The natural history of CKD progresses from susceptibility associated with the presence of risk factors (Table 82.1), to the development of

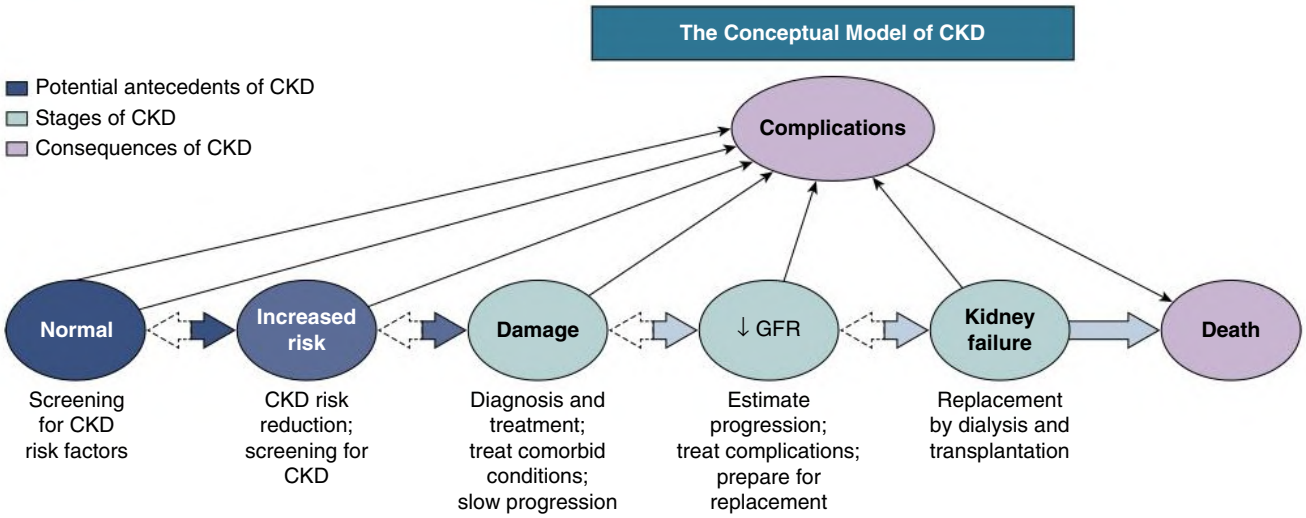

Fig. 82.1 Conceptual model of chronic kidney disease (CKD). *GFR,* Glomerular filtration rate. (Modified from Levey AS, Stevens LA, Coresh J. Conceptual model of CKD: applications and implications. *Am J Kidney Dis.* 2009;53[suppl 3]:S4–16.)

TABLE 82.1 Risk Factors Associated With the Initiation and Progression of Chronic Kidney Disease

Initiation Factors	Progression Factors
Systemic hypertension	Older age
Diabetes mellitus	Sex (male)
Cardiovascular disease	Race/ethnicity
Dyslipidemia	Genetic predisposition
Smoking	Poor BP control
Obesity/metabolic syndrome	Poor glycemic control
Hyperuricemia	Proteinuria
Low socioeconomic status	Cardiovascular disease
Nephrotoxin exposure: abuse of NSAIDs, analgesics, traditional herbal remedies; exposure to heavy metals, lead	Dyslipidemia
	Smoking
	Obesity/metabolic syndrome
	Hyperuricemia
	Low socioeconomic status
	Nephrotoxins (NSAIDs, contrast agents)
	Recurrent AKI events
	Metabolic acidosis

AKI, Acute kidney injury; *CKD,* chronic kidney disease; *NSAIDs,* nonsteroidal antiinflammatory drugs.

CKD and progression to kidney failure requiring renal replacement therapy, CVD, and/or death (Fig. 82.1).

The risk of progressive CKD is variable and affected by several factors, including demographic characteristics, clinical factors, and access to care (see Table 82.1).[8] Epidemiologic data suggest that the natural history of CKD stages 3 to 4 and development of other adverse health outcomes vary based on patients' baseline risk factor profiles (Fig. 82.2).[8] Many CKD patients with GFR less than 60 mL/min/1.73 m^2 do not reach stage 5 (kidney failure); among those with disease progression, the process is often not linear, with breakpoints in the progression pattern due to a number of factors, including the natural progression of underlying conditions such as infections, dehydration, CKD risk factors (blood pressure [BP], proteinuria), exposure to nephrotoxins (drugs, contrast agents), and acute kidney injury (AKI).

The rate of progression of CKD also varies based on the severity of underlying disease and between individual patients. Historically, the rate of decline in GFR of patients with diabetic nephropathy has been among the fastest, averaging around −10 mL/min/yr. Control of hypertension slows the rate of GFR decline to −5 mL/min/yr, with further improvement (−1 to −2 mL/min/yr) expected in patients with optimally controlled glycemia and hypertension. In nondiabetic nephropathy, patients with chronic glomerulonephritis exhibit a rate of CKD progression that is more than twice as fast as patients with chronic interstitial nephritis and 1.5 times faster than patients with hypertensive nephrosclerosis. The association of albuminuria and faster progression of CKD has been highlighted in a number of studies. Optimal hydration, relief of obstruction (where indicated), discontinuation of nephrotoxic agents, and control of hypertension often stabilize kidney function in a large percentage of patients. Patients with polycystic kidney disease and impaired kidney function (CKD stage 3b and beyond) may also have a faster rate of progression compared with other nephropathies. More rapid progression of CKD is linked to certain genetic, demographic, and clinical risk factors (see Table 82.1). Recently, the notion of a linear progression to the onset of kidney failure is being challenged with the proposition that the progression of CKD is strongly influenced by repeated AKI episodes, and that this is most often a hemodynamically driven process.[9]

SLOWING PROGRESSION OF CHRONIC KIDNEY DISEASE

Since the publication of the hyperperfusion-hyperfiltration hypothesis, considerable research has focused on understanding the pathophysiology of CKD,[10] mechanisms of progression, and prevention of kidney failure (Fig. 82.3). Clinical strategies were initially based on manipulation of dietary protein intake and evolved to include inhibition of the renin-angiotensin-aldosterone system (RAAS) and control of glycemia and dyslipidemia (Table 82.2),[11] along with appropriate follow-up based on the level of estimated glomerular filtration rate (eGFR) and severity of albuminuria (Fig. 82.4).

A key goal of clinical follow-up is to recognize reversible causes of acute-on-chronic kidney disease (mimicking progression), such as acute illnesses with volume depletion. Patients with significant comorbidity burden—in particular, chronic heart disease, older age, and use of specific medications (e.g., RAAS inhibitors, sodium-glucose

Associations of CKD Markers With Adverse Health Outcomes

All-cause mortality

	ACR <10	ACR 10–29	ACR 30–299	ACR ≥300
eGFR >105	1.1	1.5	2.2	5.0
eGFR 90–105	Ref	1.4	1.5	3.1
eGFR 75–90	1.0	1.3	1.7	2.3
eGFR 60–75	1.0	1.4	1.8	2.7
eGFR 45–60	1.3	1.7	2.2	3.6
eGFR 30–45	1.9	2.3	3.3	4.9
eGFR 15–30	5.3	3.6	4.7	6.6

TABLE 82.2 Evidence-Based Strategies to Slow the Progression of Kidney Disease

Risk Factor	Guideline Concordant Treatment Goals and Recommended Agents	Certainty of Evidence	Strength of Recommendation
Overweight	Maintain a healthy weight (BMI 20–25 kg/m²)	D	1
Diet	Lower or maintain salt intake to <90 mmol/day (equivalent to <2 g sodium/day or <5 g sodium chloride/day)	C	1
	Low protein intake: 0.8 g/kg/day in adults with diabetes or without diabetes and CKD (G4–G5), with appropriate education	C (diabetes-related CKD); B (nondiabetic CKD)	2
Smoking	Smoking cessation	Not graded	1
Exercise	Encourage 30–60 min of aerobic exercise at least 5 times/wk	D	1
Proteinuria/albuminuria	Monitoring and follow up; treatment with ACE inhibitors/ARBs, with proteinuria >300 mg/24 h	B	1
Blood pressure	<130/80 mm Hg (diabetes or proteinuric CKD),[a] <140/80 mm Hg (nondiabetic or nonproteinuric CKD)	B	1
Diabetes	HbA_{1c} <7% and use of newer agents (i.e., SGLT2 inhibitors may yield significant benefits for patients with CKD stages 1–4 with regard to CV and kidney outcomes)	A	1
Dyslipidemia	Use of lipid-lowering medications[b]	Not graded	
Metabolic acidosis	Bicarbonate supplementation with levels <20 mEq/L		
Other metabolic risk factors (elevated uric acid)	Insufficient evidence to support or refute the use of agents for hyperuricemia	Not graded	
Multifactorial risk modification/CV risk reduction	Multifactorial intervention strategy addressing BP control and CV risk (with secondary prevention measures, ASA, β-blockers, when appropriate); use of ACE inhibitors or ARBs, statins, and SGLT2 inhibitors where clinically indicated and appropriate	Not graded	

Strength of recommendation: 1, recommended for most patients; 2, suggested for the majority of people, but different choices will be appropriate for some patients; not graded: left to the discretion of care provider, guidance is based on common sense or the given topic does not allow adequate application of evidence.
Certainty of evidence: A, high; B, moderate; C, low; D, very low.
[a]Use of ACE inhibitors/ARBs recommended.
[b]"Fire-and-forget" strategy: a high-dose statin or moderate dose statin combined with ezetimibe recommended for all CKD patients aged >50 years regardless of serum lipid levels. Patients aged 18–50 years should be treated if they have established CV disease, diabetes, or an estimated 10-year risk of coronary death or nonfatal MI >10%.
ASA, Acetylsalicylic acid; *BMI,* body mass index; *ACE,* angiotensin-converting enzyme; *ARB,* angiotensin-receptor blocker; *BP,* blood pressure; *CKD,* chronic kidney disease; *CV,* cardiovascular; *HbA_{1c},* hemoglobin A_{1c}; *MI,* myocardial infarction; *SGLT2,* sodium-glucose cotransporter-2.

cotransporter-2 [SGLT2] inhibitors, diuretics, nonsteroidal antiinflammatory drugs [NSAIDs])—are at increased risk of acute-on-chronic kidney disease. Such drugs should be temporarily discontinued during acute intercurrent illnesses, particularly when there is evidence of volume depletion. This advice, termed "sick day rules," now appears in many CKD management tools (guidelines and pathways).[12]

For decades, BP control and RAAS inhibition have been the cornerstones for preventing progression of CKD. More recently, exciting new evidence has emerged concerning the benefits of SGLT2 inhibitors.[13,14] Two landmark studies have demonstrated the efficacy of these agents on adverse health outcomes (kidney failure, cardiovascular [CV] events, and mortality) among patients with CKD, irrespective of the presence or absence of diabetes. Thus, slowing progression of CKD in the current era will depend on BP control, RAAS inhibition, and use of SGLT2 inhibitors supplemented by nontherapeutic (lifestyle) and other therapeutic strategies, such as lipid-lowering therapy (Fig. 82.5).

Risk Factor Modification: Lifestyle Interventions

Lifestyle modifications such as dietary changes, exercise, weight loss, and smoking cessation are recommended to prevent CVD among CKD patients. These modifications may prevent progression of CKD, reduce risk of attendant complications, and improve patients' quality of life and survival, although evidence is based on observational studies or small clinical trials.[15]

High salt intake and impaired sodium handling by the kidneys are common in CKD and can lead to high BP. Data on the role of salt intake in the progression of kidney disease and risk of CVD in CKD patients is more limited. No large-scale randomized controlled trials (RCTs) on the influence of dietary sodium restriction have specifically enrolled CKD patients. Dietary salt restriction improves some risk factors associated with CKD progression, such as hypertension and albuminuria, and enhances long-term effects on renal function and reduce CV risk.[16] Furthermore, the Dietary Approaches to Stop Hypertension (DASH) study showed the beneficial effects of dietary salt restriction on BP control, which should translate into lower risk of CKD progression.[17] Guidelines recommend lowering sodium intake to less than 90 mmol (<2 g) per day (5 g of salt) in adults (see Chapter 36).

Numerous studies have examined the effects of weight loss (dietary or pharmacologic intervention, or bariatric surgery) on BP.[18] Nevertheless, there is no solid evidence demonstrating a beneficial effect of weight loss per se (i.e., independent of effects on systemic BP and/or diabetes) on progression of CKD.[19]

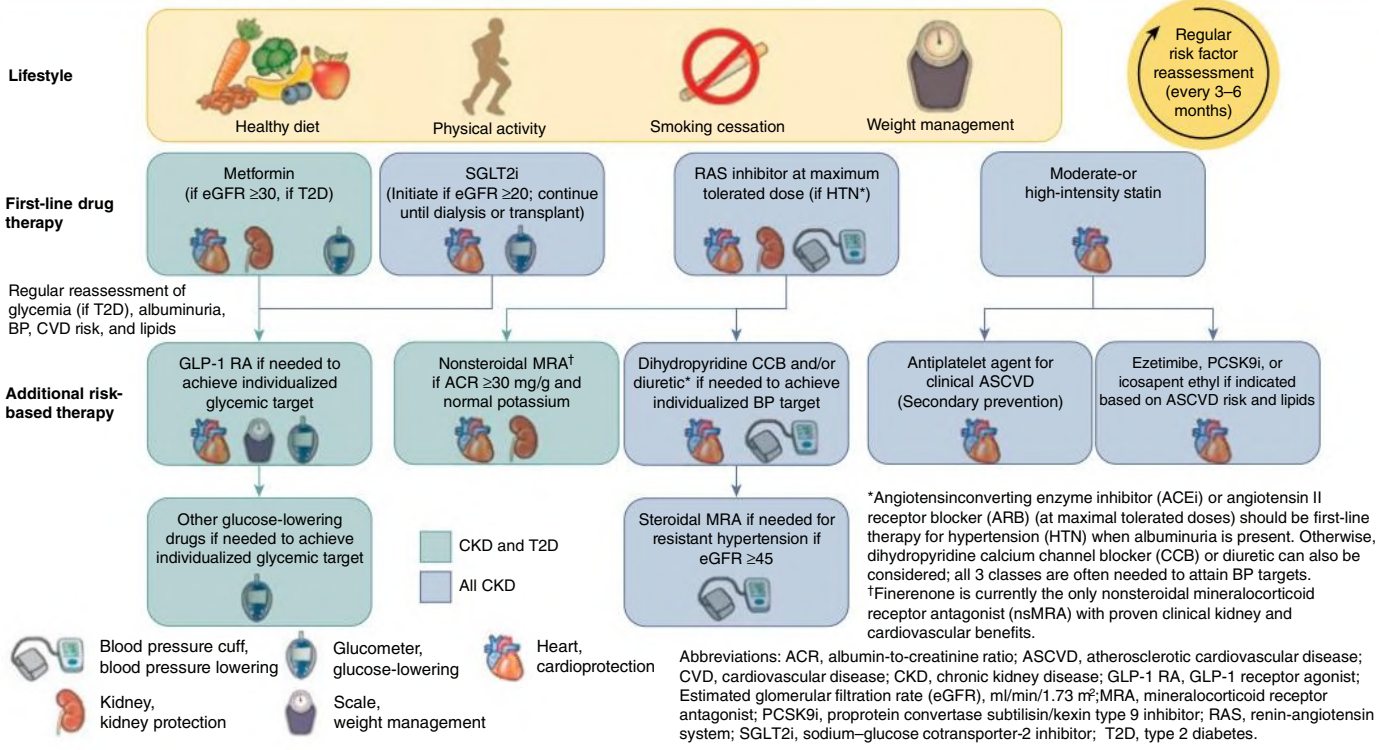
Exercise decreases the risk of incident CV events in numerous patient populations, although not in CKD populations specifically. Exercise can also lower BP, reportedly to a similar extent as a normal dose of an antihypertensive medication. However, adequately powered RCTs reporting the independent effects of exercise on the progression of kidney disease are lacking. One small trial ($n = 30$) randomized CKD

General Guide to Frequency of Monitoring by GFR and Albuminuria Categories

GFR categories (mL/min/1.73 m^2): Description and range				Persistent albuminuria categories: Description and range		
				A1	A2	A3
				Normal to mildly increased	Moderately increased	Severely increased
				<30 mg/g <30 mg/mmol	30–300 mg/g 3–30 mg/mmol	>300 mg/g >30 mg/mmol
	G1	Normal or high	≥90	1 if CKD	1	2
	G2	Mildly decreased	60–89	1 if CKD	1	2
	G3a	Mildly to moderately decreased	45–59	1	2	3
	G3b	Moderately to severely decreased	30–44	2	3	3
	G4	Severely decreased	15–29	3	3	4+
	G5	Kidney failure	<15	4+	4+	4+

Fig. 82.4 General guide to frequency of monitoring by glomerular filtration rate (GFR) and albuminuria categories. Numbers represent the frequency of visits for kidney care annually. For example, for CKD stage G5 A1, 4+ respresents recommended follow-up visits (as deemed clinically appropriate) at least four times or more per year to receive kidney care. *CKD,* Chronic kidney disease. (From KDIGO Chronic Kidney Disease Guidelines Working Group. *Kidney Int Suppl.* 2013; 3:1–150.)

BP Target in Comparison With Other Guidelines



*Angiotensinconverting enzyme inhibitor (ACEi) or angiotensin II receptor blocker (ARB) (at maximal tolerated doses) should be first-line therapy for hypertension (HTN) when albuminuria is present. Otherwise, dihydropyridine calcium channel blocker (CCB) or diuretic can also be considered; all 3 classes are often needed to attain BP targets.
†Finerenone is currently the only nonsteroidal mineralocorticoid receptor antagonist (nsMRA) with proven clinical kidney and cardiovascular benefits.

Abbreviations: ACR, albumin-to-creatinine ratio; ASCVD, atherosclerotic cardiovascular disease; CVD, cardiovascular disease; CKD, chronic kidney disease; GLP-1 RA, GLP-1 receptor agonist; Estimated glomerular filtration rate (eGFR), ml/min/1.73 m^2;MRA, mineralocorticoid receptor antagonist; PCSK9i, proprotein convertase subtilisin/kexin type 9 inhibitor; RAS, renin-angiotensin system; SGLT2i, sodium–glucose cotransporter-2 inhibitor; T2D, type 2 diabetes.

Fig. 82.5 Generic approach to the management of chronic kidney disease, including lifestyle and therapeutic interventions targeted to reduce risk of progression to kidney failure and other adverse health outcomes including cardiovascular events and risk of death. (Modified from de Boer IH, Khunti K, Sadusky T, et al. Diabetes management in chronic kidney disease: a consensus report by the American Diabetes Association [ADA] and Kidney Disease: Improving Global Outcomes [KDIGO]. *Kidney Int.* 2022. Epub ahead of print.)

patients to 30 minutes of daily aerobic exercise or usual care but did not show an effect on the progression of CKD.[20] Another observational study showed a 2.8% difference in eGFR decline between physically active people versus those who are sedentary.[18]

The association between cigarette smoking and more rapid progression of CKD has been repeatedly shown. A large population-based study in Norway (HUNT II) revealed smoking as a significant risk factor for incident kidney failure and showed that smoking cessation ameliorated this risk, at least among men. Although no RCTs have demonstrated that smoking cessation reduces the risk of progressive CKD,[21] it is expected that cessation of smoking will improve BP control and lower the risk of adverse kidney and CV outcomes. Thus, smoking cessation should be an integral component of strategies aimed at slowing CKD progression.[21]

In summary, lifestyle interventions are an important adjunct for preventing CKD progression, and guidelines recommend that people with CKD engage in physical activity at levels compatible with their CV health and tolerance (aiming for at least 30 minutes of aerobic exercise 5 times per week) and stop smoking. Moreover, CKD patients should receive expert dietary advice tailored to the severity of their CKD, and modify their diet (particularly salt intake) accordingly.

Risk Factor Modification: Therapeutic Interventions

Blood Pressure Control: Evaluation, Target, and Treatment

BP can be assessed using in-office manual or multiple in-office automated, home, and ambulatory measurements. In practice, BP is typically monitored via in-office manual measurements. Poorly controlled BP is associated with rapid progression of CKD to kidney failure and high risk for CV morbidity and mortality,[22-24] but unfortunately a relatively small proportion of patients with CKD meet the recommended BP targets.[25] Because CKD is accompanied by an increased risk of CVD, treatment of hypertension in patients with CKD serves two goals: to decrease the risk of CVD and to halt the progression of CKD. Based on new evidence, BP targets for treatment of hypertension in patients with CKD have been lowered in recent years to less than 130/80 mm Hg for those with albuminuria and/or diabetes and less than 140/90 mm Hg for those without diabetes or albuminuria in most guidelines.[26] The risk/benefit ratio of intensive BP reduction in patients with CKD continues to be debated. Details on BP targets can be found in Chapter 37.

Ample evidence reveals that lowering BP reduces the risk of major CV events among patients with and without reduced kidney function,[27] and this is irrespective of the type of BP-lowering agent, unlike with renoprotection. A meta-analysis of 18 RCTs shows that compared with less intensive BP reduction, intensive BP lowering is associated with lower mortality among patients with CKD stages 3 to 5.[25] In a subgroup analysis of 2646 CKD patients in the Systolic Blood Pressure Intervention Trial (SPRINT), outcomes for an intensive treatment group (target systolic BP <120 mm Hg) were compared with outcomes for a standard treatment group (<140 mm Hg) for a median follow-up period of 3.3 years.[28] The intensive treatment group had a lower rate of all-cause mortality and a higher rate of AKI as an adverse clinical event. In the main analysis of 9361 patients in SPRINT, risk factors for AKI were older age, non-White ethnicity, lower baseline eGFR, and presence of CVD at baseline.

In terms of renoprotection, overwhelming evidence accumulated over the last 25 years shows that BP control reduces the progression of CKD and supports the use of antihypertensive therapy, specifically with angiotensin-converting enzyme (ACE) inhibitors or angiotensin receptor blockers (ARBs) in patients with CKD (Table 82.3 and Fig. 82.6). In 1993 the first large RCT to yield supporting evidence showed that ACE inhibitors (captopril) decreased the likelihood of doubling of serum creatinine or kidney failure by 48% in patients with diabetic nephropathy over a 3-year follow-up period, compared with placebo.[29] This study was followed by the Irbesartan Diabetic Nephropathy Trial (IDNT), which showed that ARBs (irbesartan) significantly reduced the rate of CKD progression compared with placebo or amlodipine and also affected all-cause mortality.[30] Similar findings were reported in the Reduction of Endpoints in NIDDM With the Angiotensin II Antagonist Losartan (RENAAL) trial, in which losartan reduced the risks of a composite kidney outcome (doubling of serum creatinine or kidney failure) and mortality among patients with diabetic nephropathy, compared with placebo.[31]

Studies involving nondiabetic patients also show that lowering BP slows the progression of kidney disease. The first such study was the African American Study of Kidney Disease and Hypertension (AASK) trial that compared intensive and less intensive BP-lowering treatment targets among Black persons with CKD attributed to hypertensive nephrosclerosis.[32] Although this study did not find that more intensive BP lowering reduces the risk of death or of progressive CKD, it showed that ACE inhibitors had favorable benefits in slowing eGFR decline compared with β-blockers or calcium channel blockers among the Black population. The Ramipril Efficacy In Nephropathy (REIN) study addressed a similar question in proteinuric, nondiabetic nephropathy[33] and again demonstrated that ACE inhibitors decrease progression to kidney failure compared with other antihypertensive therapies, even in the setting of a similar BP control.

In SPRINT, the composite outcome of 50% or greater decrease in eGFR from baseline or kidney failure did not differ between the intensive and less intensive therapy groups. Although more intensive BP control was associated with similar risk of adverse events and similar kidney outcomes compared with standard treatment, the lower risk of CVD associated with more intensive control might suggest that a lower BP target in CKD patients is preferable. These findings have resulted in debate about the optimal BP targets for CKD patients. For example, the American College of Cardiology/American Heart Association has lowered the target to 130/80 mm Hg in their guidelines for the management of hypertension. In contrast, the KDIGO-recommended BP target for CKD patients endorses this goal for albuminuric and diabetic patients but remains less than 140/90 mm Hg for the group of patients without proteinuria and/or diabetes. The KDIGO 2021 Clinical Practice Guideline for the Management of Blood Pressure in CKD was published proposing an SBP target of less than 120 mm Hg in situations where standardized office readings are feasible in the management of CKD.[34] This recommendation stemmed from the CV and survival benefits with this level of intensive BP control from the SPRINT trial. The uptake of this new treatment target will be affected by the casual nature of BP measurements in practice and the challenges associated with it.[34]

In addition to controlling hypertension, RAAS inhibition is essential for preventing CKD progression.[31,35] Most guidelines recommend the use of RAAS inhibitors to control hypertension, reduce proteinuria, and slow the progression of CKD. The consensus seems to be that in diabetic and nondiabetic CKD where significant albuminuria is present, RAAS inhibition is the preferred first-line approach, whereas in nonproteinuric disease, the benefit of RAAS inhibition specifically is less well established.[3] It is important to recognize and address common situations that may limit the utilization of RAAS inhibition (Fig. 82.7).

RAAS inhibitors are shown to be effective in slowing CKD progression, even in later stages. In post hoc analyses of the REIN[33] and RENAAL[31] studies, the reduction of kidney failure events with ACE inhibitors and ARBs was independent of baseline GFR. A similar finding was seen in patients with CKD stage 4 treated with benazepril, in

which carefully selected patients derived a benefit from ACE inhibitor therapy, even at very low eGFR.[36] Taken together, these trials suggest that RAAS inhibition effectively reduces the risk of kidney failure for patients even when CKD is severe.[37] This position has been reinforced in guideline recommendations for the management of CKD that in the absence of severe hyperkalemia (potassium >6 mmol/L), AKI, or a decrease in eGFR of more than 30%, these medications should be continued, irrespective of baseline eGFR or stage of CKD. Administration of RAAS inhibitors is associated with lower all-cause mortality and a substantial survival benefit for patients with nondialysis CKD (stages G1–5), even with adjustment for confounders and propensity matching across studies.[37] Utilization of ACE inhibitors/ARBs remains suboptimal, and discontinuation rates remain relatively high in clinical practice, representing an opportunity to further reduce the number of people who experience progressive CKD. RAAS inhibitors should only be discontinued in situations involving substantial GFR decline (acute-on-chronic kidney disease), and/or severe hyperkalemia that cannot be readily modified or symptomatic hypotension.

Reduction in Albuminuria and Impact on Progressive Kidney Function Loss

Albuminuria is common but not universal in CKD. It is the earliest marker of glomerular diseases, including diabetic glomerulosclerosis, where it generally appears prior to a reduction in kidney function. It is also associated with hypertension/vascular causes in nondiabetic CKD patients, often after a reduction in kidney function.[38] Multiple studies show that proteinuria is associated with a faster rate of progression[35] and high risk of kidney failure and CVD,[39,40] irrespective of the underlying cause of CKD. Conversely, reduction of albuminuria via lifestyle and therapeutic measures is associated with better outcomes; the extent of reduction in albuminuria is often proportional to the benefit accrued by such interventions on CKD progression. The superiority of RAAS inhibition compared with other antihypertensive treatments is due at least in part to its efficacy in reducing albuminuria (see Chapter 81).

Recent studies show that SGLT2 inhibitors reduce the risk of adverse outcomes in patients with CKD (see Table 82.3). In clinical trials involving patients with type 2 diabetes mellitus, these agents

TABLE 82.3 Recommended Medications in the Management of Chronic Kidney Disease

Category	Drug	Dose	Adjustment Based on Level of Kidney Function
ACE inhibitors	Benazepril	10–80 mg once daily	eGFR ≥30 mL/min: no dosage adjustment needed eGFR <30 mL/min: reduce initial dose to 5 mg PO once daily
	Captopril	12.5 mg to 50 mg 2–3 times/day (up to 450 mg/day)	eGFR 10–50 mL/min: administer 75% of normal dose every 12–18 hours
	Enalapril	5 mg once daily	eGFR ≤30 mL/min: in adult patients, reduce initial dose to 2.5 mg PO once daily
	Fosinopril	10–80 mg once daily	No dosage adjustment necessary
	Lisinopril	10–40 mg once daily	eGFR 10–30 mL/min: reduce initial recommended dose by 50% for adults (maximum: 40 mg/day) eGFR <10 mL/min: reduce initial dosage to 2.5 mg PO once daily
	Perindopril	2–8 mg once daily	Not recommended when eGFR <30 mL/min
	Quinapril	10–80 mg once daily	eGFR 61–89 mL/min: start at 10 mg once daily eGFR 30–60 mL/min: start at 5 mg once daily eGFR 10–29 mL/min: start at 2.5 mg once daily
	Ramipril	2.5–20 mg once daily	Administer 25% of normal dose when eGFR <40 mL/min
	Trandolapril	1–4 mg once daily	eGFR <30 mL/min: reduce initial dose to 0.5 mg/day
ARBs	Azilsartan	20–80 mg once daily	Dose adjustment not required in patients with mild to severe kidney impairment or kidney failure
	Candesartan	8–32 mg once daily	Use with caution in patients with eGFR <30 mL/min
	Irbesartan	75–300 mg once daily	No dosage adjustment necessary
	Losartan	50–100 mg once daily	No dosage adjustment necessary
	Olmesartan	20–40 mg once daily	No initial dosage adjustment recommended for patients with moderate to significant reduction in kidney function kidney impairment (eGFR <40 mL/min)
	Telmisartan	40–80 mg once daily	No dosage adjustment necessary
	Valsartan	80–320 mg once daily	Use with caution in eGFR <30 mL/min
SGLT2 inhibitors[a]	Canagliflozin	100–300 mg once daily	No dose adjustment if eGFR >60 mL/min/1.73 m^2 100 mg daily if eGFR 30–59 mL/min/1.73 m^2 Avoid initiation with eGFR <30 mL/min/1.73 m^2 Discontinue when initiating dialysis
	Dapagliflozin	5–10 mg once daily	Initiate at 10 mg/day if eGFR ≥20 mL/min/1.73 m^2 Avoid initiation with eGFR <25 mL/min/1.73 m^2 Discontinue when initiating dialysis
	Empagliflozin	10–25 mg once daily	Initiate at 10 mg/day for eGFR ≥20 mL/min/1.73 m^2 Avoid initiation with eGFR <20 mL/min/1.73 m^2[a]

[a]These recommendations may change with emerging evidence.

reduced albuminuria by 30% to 50% and the incidence of composite hard kidney outcomes by 40% to 50%. Furthermore, they appear to interfere with the major mechanism of proteinuric CKD progression (i.e., glomerular hypertension and hyperfiltration). The Canagliflozin and Renal Events in Diabetes with Established Nephropathy Clinical Evaluation (CREDENCE) study involving 4401 diabetic patients with CKD showed that canagliflozin substantially reduces the risk of progression to kidney failure or mortality associated with kidney or CVD causes.[13] Recently, the Study to Evaluate the Effect of Dapagliflozin on Renal Outcomes and Cardiovascular Mortality in Patients With Chronic Kidney Disease (DAPA-CKD) involving 2510 diabetic patients and 1803 nondiabetic patients with CKD showed a significant reduction in the risk of CKD progression, kidney failure, or mortality from kidney or CVD causes.[14] The benefits of these agents appear to be similar in patients with or without diabetes-related CKD, including patients with chronic glomerulonephritides. It is important to consider the baseline level of kidney function before these agents are initiated (Fig. 82.8).[41,42]

Epub ahead of print.)

In patients treated with RAAS inhibitors (ACE inhibitors or ARBs), aldosterone breakthrough occurs that ameliorates by using aldosterone antagonists (spironolactone, eplerenone) added to ACE inhibitors or ARBs.[43] This strategy reduces proteinuria, risk of CKD progression, and CVD, particularly in patients with diabetes.[44] A recent Cochrane Review demonstrated the benefits of aldosterone antagonists in reducing both albuminuria and BP in patients with mild to moderate CKD; however, the use of these agents was linked to increased risk of hyperkalemia, AKI, and gynecomastia (common with the use of spironolactone [Aldactone]), particularly when combined with RAAS inhibition.[45]

Although earlier guidelines recommended tighter BP control to less than 125/75 mm Hg for patients with albuminuria greater than 1 g/24 h (based on weak evidence from the MDRD trial[46]), this approach is no longer recommended.

Dyslipidemia

Dyslipidemia is often viewed as a consequence of CKD, but experimental data suggest that lipid abnormalities also could accelerate the progression of CKD.[47] Experimental data show that statins may have synergistic effects with RAAS inhibitors in slowing CKD progression.[48] Clinical data also show an association between dyslipidemia and a decline in GFR, and that lipid reduction with treatment may preserve kidney function.[49] Beyond their effects on cholesterol, statins have additional ("pleiotropic") effects, including antiinflammatory and antifibrotic influences that could theoretically be of benefit in slowing progression of CKD. Small clinical studies suggested a clinical benefit of statin treatment for progressive kidney function loss, and large meta-analyses of patients with stage 3 CKD and coronary disease found small reductions in the rate of kidney function loss over 5 years. However, these potential benefits were not supported in the most rigorous RCT to date, the Study of Heart and Renal Protection (SHARP), which found that combination treatment with simvastatin and ezetimibe did not reduce the risk of progressive kidney function loss or incident albuminuria.[50,51] However, statins have been consistently shown to reduce mortality and major CV events by 20% in people with CKD not requiring dialysis.[51] Thus, KDIGO guidelines recommend initiation of treatment with a statin or statin/ezetimibe combination in adults 50 years or older with eGFR less than 60 mL/min/1.73 m^2 but not kidney failure,[52] irrespective of baseline cholesterol level (a "fire-and-forget" approach). Statin initiation is also recommended for adults with CKD (aged 18–49 years) if they have known coronary artery disease, diabetes mellitus, a history of ischemic stroke, or a greater than 10% estimated 10-year risk of coronary death or nonfatal myocardial infarction. Overall, the indication for statin treatment is prevention of CVD events rather than preventing progressive CKD.

Glycemic Control

Diabetes-related CKD (diabetic nephropathy) is the leading cause of kidney failure worldwide and is considered a microvascular complication of diabetes. Substantial evidence shows that effective management of diabetes ameliorates risk of kidney failure and incident CV events (see Chapter 32). In 2020 KDIGO released clinical practice guidelines for the management of patients with diabetes and CKD, consisting of 12 recommendations and 48 practice points addressing various facets of care, including glycemic monitoring and targets, antihyperglycemic therapies, and educational and integrated care.[53]

Other Measures

Infection Risk and Prevention

Immunizations against common infections are recommended for patients with CKD, because patients with CKD are at greater risk of infection and related complications. In addition to routine vaccinations, CKD patients should carefully consider the risks and benefits of vaccinations for influenza, pneumococcal, hepatitis B, zoster, and now COVID-19.[54] For further details, see Chapters 83 and 87.

Hyperuricemia

Experimental data suggest a link between uric acid concentrations and the progression of hypertensive and toxic nephropathies.[55] In humans, a link between hyperuricemia and the development of systemic hypertension, CVD, and kidney disease has been postulated.[55-57] Although recently published studies (PERL and CKD-Fix trials) were important contributions, both showed that urate-lowering therapy does not significantly delay CKD progression in the populations studied, suggesting that lowering uric acid is unlikely to yield benefits for patients with CKD. The major critique of both studies was the fact that neither trial restricted inclusion to people with clinical gout and/or hyperuricemia who are presumably at risk for CKD progression. In fact, individuals with history of gout were excluded, despite the fact that gout affects at least one-third of patients with CKD.[55]

Dietary Interventions

A number of studies investigated the impact of dietary protein restriction on the progression of CKD in the 1970s and 1980s. The MDRD study showed that there was no beneficial effect of dietary protein restriction on progressive kidney function loss.

Avoidance of Nephrotoxins

Chronic lifetime exposure to nephrotoxins such as phenacetin and NSAIDs, heavy metals, and traditional Chinese herbal remedies has been associated with the development of hypertension and CKD progression. For further details, see Chapter 79.

Metabolic Acidosis

A number of studies have linked metabolic acidosis with adverse health consequences in CKD.[58] The decrease in serum bicarbonate concentration (HCO_3) begins to manifest at lower levels of eGFR (<30 mL/min). This acidosis is linked to progressive kidney function loss and increased mortality risk in CKD.[58] A few clinical studies have suggested that bicarbonate supplementation may slow the progression of CKD, but the target HCO_3 is unclear, and supplementation is associated with increased pill burden and excess sodium load.[59,60] We advise bicarbonate treatment when HCO_3 is less than 20 mmol/L, but this is not evidence based.

Multifaceted Strategies

Polypills

Pill burden is high in CKD populations, which may negatively affect quality of life and perhaps reduce the likelihood of adherence. Accordingly, guidelines regarding pharmacologic treatments for patients with CKD recommend combining BP-lowering and lipid-lowering medications with glycemia-lowering medications (for those with diabetes)[61] in a single pill (polypill). These guidelines are similar to those regarding the management of established CVD.

Multidisciplinary Team–Based Care

Multidisciplinary teams (MDTs) have been established in many settings around the world to provide continuing and comprehensive CKD care, particularly for patients with more advanced disease. These teams typically include not only nephrologists but also nurses, surgeons, general practitioners/family physicians, pharmacists, psychotherapists, social workers, nutritionists, and other specialists (e.g., endocrinologists). Emerging evidence on the benefits of MDTs

Management of Common CKD Complications

Complication	Target	Management
Anemia	Hb 90–110 g/dL	Replace iron deficiency, erythropoietin, or HIF stabilizer
Mineral bone disease	Ca: 2.2–2.35 mmol/L PO_4 <1.8 mmol/L	Diet/phosphate binders active vitamin D
Metabolic acidosis	Serum bicarbonate >22 mmol/L	Sodium bicarbonate supplementation
Malnutrition	Adequate calorie and protein intake	Dietician support
General health measures: Vaccinations	—	Immunize for influenza and pneumococcus, possibly COVID-19

Fig. 82.9 Management of Common Chronic Kidney Disease (CKD) Complications. Ca, Calcium; Hb, hemoglobin.

BOX 82.1 Referral Criteria

- Acute deterioration of kidney function
- GFR < 30 mL/min/1.73 m^2
- Significant and sustained albuminuria (albumin/creatinine ratio ≥ 300 mg/g; equivalent to protein/creatinine ratio ≥ 500 mg/g or proteinuria ≥ 500 mg/24 h)
- CKD progression (sustained decrease in the GFR >5 mL/min/1.73 m^2 per year or due to a change of category [from G1 to G2, from G2 to G3a, from G3a to G3b, from G3b to G4, or from G4 to G5] when the latter is accompanied by a GFR loss of ≥ 5 mL/min/1.73 m^2)[a]
- Microhematuria not explained by other causes, sediment with >20 RBCs/field, especially in the case of RBC casts
- Resistant high BP (not controlled with a combination of three antihypertensive drugs, including a diuretic)
- Persistent serum potassium abnormalities
- Recurrent nephrolithiasis
- Hereditary kidney disease

Grade of recommendation: 1, recommendation, evidence B.

[a] Small fluctuations in GFR do not necessarily indicate progression. When the above progression criteria are detected, it is necessary to rule out potentially reversible exacerbation factors (progression vs. exacerbation) such as obstructive uropathy, volume depletion, situations of hemodynamic instability or use of NSAIDs, cyclooxygenase-2 inhibitors, nephrotoxic antibiotics, radiocontrast agents, or renin-angiotensin system blockers in certain hemodynamic conditions.

BP, Blood pressure; *CKD,* chronic kidney disease; *GFR,* glomerular filtration rate; *NSAIDs,* nonsteroidal antiinflammatory drugs; *RBCs,* red blood cells.

From KDIGO 2012 clinical practice guideline for the evaluation and management of chronic kidney disease. *Kidney Int Suppl.* 2013;3.

shows improvements in CKD care, as well as reductions in progressive kidney function loss and hard outcomes such as mortality and CV events.[62]

MDTs may also enhance the management of other CKD-related complications such as anemia, mineral bone disease, metabolic acidosis, and electrolyte imbalance that may accelerate loss of kidney function (or interfere with treatments that could prevent CKD, such as RAAS inhibition; Fig. 82.9). Appropriate referrals should be considered when the recommended criteria are met (Box 82.1); see Chapter 83 for details.

SELF-ASSESSMENT QUESTIONS

1. Which of the following are modifiable risk factors associated with progression of CKD to kidney failure?
   - **A.** Age
   - **B.** Race
   - **C.** Proteinuria
   - **D.** Blood pressure
   - **E.** C and D
2. Which of the following are adverse health consequences associated with CKD?
   - **A.** Heart failure
   - **B.** Increased risk of infections
   - **C.** Ischemic heart disease and strokes
   - **D.** Cognitive dysfunction
   - **E.** All of the above
3. A 65-year-old patient with a background history of hypertension, ischemic heart disease, and type 2 diabetes mellitus was referred with a serum creatinine of 175 µmol/L (eGFR of 32 mL/min) and a urine albumin-to-creatinine ratio of 300 mg/g (30 mg/mmol). The eGFR was 39 mL/min about a year ago. A diagnosis of CKD (stage G3b:A2) secondary to diabetes and vascular-related causes was made. The current medications include ramipril 5 mg orally daily, hydrochlorothiazide (HCTZ) 25 mg orally daily, atorvastatin 10 mg daily, and linagliptin 5 mg orally daily. The BP is 118/65 mm Hg, and most recent hemoglobin A_{1c} (HbA_{1c}) was 8.3%. You

SELF-ASSESSMENT QUESTIONS—Cont'd

decided to start the patient on canagliflozin at 100 mg orally daily to optimize the glycemia control and to reduce the risk of cardiovascular and kidney disease progression. The patient asked about the specific effects of this new medication on the risk of kidney failure. Which of the following is correct regarding the effects of canagliflozin on kidney function?

A. Canagliflozin has no effects on kidney function.
B. The rate of progression to kidney failure will be amplified over the coming years.
C. The risks of kidney stones and urinary tract infections are increased with the use of canagliflozin.
D. The risk of proteinuria is increased with the use of canagliflozin.
E. There will be an initial decline in kidney function (eGFR), and this will be accompanied by a slower rate of eGFR decline over time and slowing of progression to incident kidney failure.

4. A 60-year-old patient with a long-term history of hypertension, type 2 diabetes, and CKD (stage G3a:A3) is referred for progressive albuminuria. The patient is a current smoker (>20 pack-year history). Over the past year, the urine albumin-to-creatinine ratio has more than doubled from 500 mg/g (50 mg/mmol) to 1200 mg/g (120 mg/mmol). The physical examination was normal except for a slight overweight with body mass index of 30 kg/m^2. Current medications include irbesartan 300 mg daily, chlorthalidone 25 mg daily, and metformin 500 mg twice daily. BP and diabetes are well controlled and currently at 129/72 mm Hg and HbA_{1c} of 7%, respectively. In addition to continuing the current medications, which one of the following is the most appropriate management of the increased albuminuria?

A. Stop smoking
B. Recommend exercise and weight loss
C. Initiate statin
D. Initiate SGLT2 inhibitor
E. All of the above

5. You received a call from a general practitioner for advice regarding a 70-year-old patient with a known history of type 2 diabetes (metformin 500 mg twice daily and gliclazide 60 mg daily), hypertension (ramipril 10 mg daily and HCTZ 25 mg daily), and dyslipidemia (atorvastatin 10 mg orally daily). The patient was diagnosed with CKD (Stage G3a:A2) about a year ago. The general practitioner recently started the patient on canagliflozin 100 mg daily. The patient is now suffering from acute gastroenteritis following recent travel. The patient cannot maintain adequate fluid intake and is currently hypotensive from volume depletion upon assessment in clinic. Which of the following medications should be stopped until the patient recovers from the acute illness?

A. Angiotensin-converting enzyme inhibitors
B. Diuretics
C. Metformin
D. SGLT2 inhibitors
E. All of the above

Clinical Evaluation and Management of Chronic Kidney Disease

David C. Wheeler

Although many patients with chronic kidney disease (CKD) progress to end-stage kidney disease (ESKD) and require kidney replacement therapy (KRT), the majority die of nonrenal causes, particularly premature cardiovascular (CV) events.[1] Early diagnosis of CKD is therefore important because it provides opportunities to delay progression of CKD (see Chapter 82) and prevent CV complications (see Chapters 84 and 85).

DEFINITIONS

CKD is defined as abnormalities of kidney structure or function, present for at least 3 months, with implications for health (Table 83.1). The relevant Kidney Disease: Improving Global Outcomes (KDIGO) guideline recommends classification of CKD based on cause, category of glomerular filtration rate (GFR), and albuminuria (see Fig. 82.2).[2] Because of the impracticalities of using radioisotopes and 24-hour urine collections, the KDIGO classification system recommends that kidney function be assessed by estimating GFR (eGFR) from the serum creatinine concentration using an appropriate equation, except in circumstances in which eGFR estimations are known to be less accurate, such as when there is significant muscle wasting. Initially, the Modification of Diet in Renal Disease (MDRD) equation was used, but this has predominantly been replaced by the Chronic Kidney Disease Epidemiology Collaboration (CKD-EPI) equation, which more accurately categorizes the risk for mortality and progression to ESKD (see Chapter 3).[3] Recently, this formula has been updated in order to eliminate race from the equation (https://www.kidney.org/professionals/kdoqi/gfr_calculator/formula), and although the formula is less precise than the earlier CKD-EPI equation, it is sufficiently accurate for clinical practice. Although staging systems for CKD based on eGFR have limitations, they have proved useful in many clinical settings and are now deeply embedded in KDIGO and other guidelines developed for CKD management and in research.

The evidence base for the management of CKD is evolving. Although every effort has been made to ensure this chapter reflects current recommendations, the reader is advised to check for any new clinical trials and relevant guideline updates.

CLINICAL PRESENTATION

CKD is commonly detected by routine blood testing and is usually asymptomatic until late stage G4 or stage G5. Symptoms of CKD are nonspecific and need to be asked about directly (Box 83.1). There is some evidence that early diagnosis with appropriate management may slow the rate of decline of kidney function and reduce CV risk.[4] Screening of the general population for CKD is not recommended, but in the UK, the National Institute for Health and Care Excellence (NICE) proposes offering testing to people with conditions associated with an increased prevalence of CKD, which is termed *case-finding*. Subgroups of interest include those with diabetes, hypertension, previous acute kidney injury (AKI), CV disease (CVD), structural kidney tract disease, kidney calculi, prostatic hypertrophy, multisystem diseases with potential kidney involvement (e.g., systemic lupus erythematosus), a family history of category G5 CKD, and hereditary kidney disease, and after opportunistic detection of hematuria or proteinuria.[5]

Evaluation of Chronic Kidney Disease

Establishing Chronicity

When eGFR of less than 60 mL/min/1.73 m^2 is detected, careful attention should be paid to previous blood and urine test results and the clinical history to determine whether this is a result of AKI (i.e., an abrupt decrease in kidney function or CKD that has been present but asymptomatic for some time).

A detailed medical history covering issues, including other medical conditions, family history of kidney disease, prescribed medication, and recreational drug use, may suggest an underlying cause. There may be hints of a history of kidney problems (e.g., hypertension, proteinuria, microhematuria) or symptoms suggestive of prostatic disease. The findings of a physical examination are not always helpful, although skin pigmentation, scratch marks, left ventricular hypertrophy, and hypertensive fundal changes favor a chronic presentation (Fig. 83.1). Details of the social and personal circumstances are also crucial, particularly for patients with progressive kidney disease in whom KRT is likely to be required.

Blood tests for other conditions can be helpful because they may indicate evidence of an acute illness that could be the cause of kidney failure, such as systemic vasculitis or multiple myeloma. A normochromic normocytic anemia is usual in CKD but also may be a feature of acute systemic illnesses and therefore is not discriminatory. Low serum calcium and raised phosphate levels also have little discriminatory value, but normal levels of parathyroid hormone (PTH) are more in keeping with AKI. Patients with grossly abnormal biochemical values (e.g., blood urea > 300 mg/dL [>50 mmol/L] and/or serum creatinine > 13.5 mg/dL [>1200 μmol/L]) who appear relatively well and are still passing normal volumes of urine are much more likely to have CKD than AKI.

Assessment of Glomerular Filtration Rate

For patients in whom the distinction between AKI and CKD is unclear, repeat testing of kidney function should be performed within 2 weeks of the initial finding of eGFR less than 60 mL/min/1.73 m^2. However, if previous results confirm that this is a chronic finding, or if repeated blood test results over a 3-month period are consistent, CKD is confirmed. Other tests (such as cystatin C or an isotope-clearance measurement of GFR) can be used to confirm CKD in circumstances in which eGFR based on serum creatinine is known to be less accurate.

TABLE 83.1 Criteria for Definition of Chronic Kidney Disease (CKD)

CKD is defined as abnormalities of kidney structure or function, present for more than 3 months, with implications for health. These may include the following:	
Markers of kidney damage	Albuminuria (AER ≥ 30 mg/24 h; uACR ≥ 30 mg/g [≥ 3 mg/mmol])
	Urine sediment abnormalities
	Electrolyte and other abnormalities caused by tubular disorders
	Abnormalities detected through histology
	Structural abnormalities detected through imaging
	History of kidney transplantation
Decreased GFR	GFR < 60 mL/min/1.73 m^2

AER, Albumin excretion rate; *GFR,* glomerular filtration rate; *uACR,* urinary albumin-to-creatinine ratio.
From Kidney Disease: Improving Global Outcomes (KDIGO) CKD Work Group. KDIGO 2012 clinical practice guideline for the evaluation and management of chronic kidney disease. *Kidney Int Suppl.* 2013;3:1–150.

Fig. 83.1 Uremic Pigmentation. Diffuse brown pigmentation as seen here suggests chronic kidney disease rather than acute kidney injury.

BOX 83.1 Symptoms and Signs of Severe Chronic Kidney Disease

- Difficulty sleeping
- Nocturia
- Headache
- Restless leg syndrome
- Metallic taste in the mouth
- Shortness of breath on exertion or at rest, paroxysmal nocturnal dyspnea
- Fatigue, often profound
- Muscle cramps and twitches
- Seizures
- Lack or loss of appetite for food, abdominal pain, nausea, vomiting, and weight loss
- Itch, particularly on the trunk and worse at night
- Altered respiration including Kussmaul breathing and Cheyne-Stokes respiration
- Icteric sclera or "red eye" because of calcium deposition
- Muscle weakness
- Oral lesions including gingival bleeding or petechiae, xerostomia, periodontitis, and candidiasis
- Pericardial and/or pleural rub
- Pulmonary and peripheral edema
- Skin changes including xerosis (abnormal dryness), scratch marks, pallor, sallow coloration or hyperpigmentation
- Uremic flap (asterixis)
- Uremic fetor: Ammonia or urine-like odor to the breath
- Uremic frost: Crystallized urea deposits that can be found on the skin

Assessment of Proteinuria or Albuminuria

Dipstick testing of the urine and urine culture may reveal microhematuria, which can be a useful pointer toward an underlying diagnosis.[6] Workup of hematuria is discussed in Chapters 4 and 63. Whether or not proteinuria is detected by dipstick, there should be a further measurement of urinary albumin excretion. Albuminuria is an important diagnostic and prognostic marker, and its presence indicates a higher risk for both progression of kidney disease and CV complications.[7] KDIGO guidelines recommend that the preferred method of assessing proteinuria is by measurement of the urinary albumin-to-creatinine ratio (uACR) using an early morning urine sample where practical.[2] The degree of albuminuria is graded by the A1 to A3 category system, replacing previous terms such as *microalbuminuria* (see Fig. 82.1). However, it is important to be aware that some patients will excrete proteins other than albumin, and a urine protein-to-creatinine ratio (uPCR) may be more useful for certain conditions.[8] Serial uPCR measurements may be particularly useful in glomerular disease because of the higher variability of uACR and the greater cost of determining albumin in urine. Where appropriate, urine tests for Bence Jones protein (immunoglobulin light chains) may be required because this is not detected by standard proteinuria or albuminuria testing.

Kidney Imaging

Imaging of the kidneys with ultrasound is useful for a number of reasons. Small kidneys with reduced cortical thickness, showing increased echogenicity, scarring, or multiple cysts, suggest a chronic process. Structural abnormalities such as those observed in autosomal dominant polycystic kidney disease (ADPKD), hydronephrosis caused by obstruction, or coarse kidney scarring may be detected. NICE guidelines propose that kidney ultrasound scanning is important only in certain circumstances and suggest counseling patients if ADPKD is suspected before imaging.[5] In some situations, imaging with computed tomography (CT), magnetic resonance (MR), or angiography may be useful, taking into account the risks of administering contrast media (see Chapter 6).

Further Investigations

Establishing the cause of CKD is important whenever possible, and further specific testing, as indicated by the history and results of initial investigations, may be required. There may be an underlying treatable condition that requires appropriate management, or there may be a genetic cause such as ADPKD, for which counseling should be offered. Furthermore, some kidney diseases may recur after transplantation (see Chapter 113) and an accurate diagnosis may therefore influence later management. Despite thorough investigation, however, the cause of CKD is often unclear, with an unhelpful medical history, minimal abnormalities on urinalysis, and small kidneys on ultrasound. In such patients, investigation should not be pursued relentlessly because the implications for treatment are often minimal. Attempting to obtain biopsy material from small kidneys is associated with risk, and even if a biopsy is performed, histologic assessment may simply show nonspecific chronic scarring rather than diagnostic features that explain the cause of kidney damage.

PREDICTING PROGNOSIS

With the cause of CKD established if possible, the GFR and the level of albuminuria measured, and other comorbidities categorized, it is possible to estimate the risk for CKD progression and likely future need for KRT. KDIGO recommends consideration of the GFR and the albuminuria categories together according to a heatmap of risk (see Fig. 82.2),[2] and there are online tools to assist with risk prediction using this approach (e.g., kidneyfailurerisk.com). Other factors associated with CKD progression may help inform prognosis. These include the cause of CKD, age, sex, ethnicity, dyslipidemia, smoking, obesity, history of CVD, ongoing exposure to nephrotoxic agents, and degree of control of hypertension and hyperglycemia. However, often the best guide to future change in kidney function is the previous pattern of decline, highlighting the importance of considering results of previous blood and urine testing during the initial assessment.

Monitoring and Defining Progression

Once CKD has been identified, arrangements should be made to ensure regular monitoring of kidney function and proteinuria. In patients at low risk for rapid eGFR decline, this can be done annually in either a primary or secondary care setting. However, assessment should be undertaken more regularly if the trajectory of the disease is not clear and in patients at higher risk for progression.

Determining a true change in kidney function over time may be difficult because small fluctuations in eGFR are common and not necessarily indicative of progression. These fluctuations may be caused by reversible factors, such as intravascular depletion or high meat intake, so repeat testing may be required. Both NICE and KDIGO guidelines define accelerated progression as a sustained decrease in GFR of 25% or more and a change in GFR category within 12 months.[2,5] In addition, the NICE guidance refers to accelerated progression as a sustained decrease in GFR of 15 mL/min/1.73 m^2 or greater per year.[5] In patients with accelerated CKD progression, consideration should be given to detection of reversible causes (e.g., kidney tract obstruction) and a specialist referral may be required.

When to Refer to the Nephrologist

Chronic management of patients with early nonprogressive CKD is becoming the responsibility of primary care physicians in many well-developed health care systems, with follow-up in secondary care limited to those likely to progress to ESKD and require KRT. However, early assessment by nephrologists is useful for all patients newly diagnosed with CKD in whom a treatable underlying cause is suspected, even in those with advanced disease at presentation, to rule out treatable causes. Timely referral of those with progressive CKD allows preparation for dialysis, kidney transplantation, or initiation of a palliative approach if more appropriate. Substantially similar criteria for referral have been developed by NICE and KDIGO (Table 83.2). Such criteria are not absolute but should provide a guide to the primary care physician as to which patients are likely to benefit from specialist care. For example, many patients with stable category G4 CKD are successfully managed in the community, often after initial assessment by or with virtual advice from secondary care colleagues.

Unfortunately, a substantial proportion of patients with advanced CKD are referred late, often at the time when they need KRT. Late referral is often avoidable, although in some cases, patients may have had a truly silent illness or an acute presentation of a disease with rapid decline in kidney function.[9] Over recent years, the introduction of routine reporting of eGFR in some health care systems has facilitated better communication between primary and secondary care providers and has led to a substantial fall in late referrals.[10]

Late presentation is disadvantageous to the patient because it limits the time to select the mode of dialysis or to be listed for "preemptive" kidney transplantation. There may be increased psychological stress, making it difficult for the patient to come to terms with the illness. Furthermore, because an arteriovenous fistula (AVF) takes several weeks to mature, patients presenting late start hemodialysis (HD) with

TABLE 83.2 Suggested Criteria for Referral of Patients With CKD to a Nephrologist

	NICE 2021	KDIGO 2012
Advanced CKD	Category G4 and G5 CKD A 5-year risk of needing kidney replacement therapy of >5% (measured using the 4-variable Kidney Failure Risk Equation)	Category G4 and G5 CKD
Proteinuria	*High proteinuria:* uACR ≥ 70 mg/mmol unless known to be caused by diabetes and appropriately treated	*Consistent proteinuria:* uACR ≥ 300 mg/g (≥ 30 mg/mmol)
Hematuria	Proteinuria (uACR ≥ 30 mg/mmol) together with hematuria	Urinary RBC casts, RBCs > 20/hpf sustained; not readily explained
Progression of CKD	*Rapidly declining eGFR:* Sustained decrease in GFR of ≥25% and a change in GFR category within 12 mo Sustained decrease in GFR of ≥15 mL/min/1.73 m^2 within 12 mo NEW: 5-year risk of needing kidney replacement therapy of >5% (measured using the 4-variable Kidney Failure Risk Equation)	*Progression of CKD:* Sustained decrease in GFR of ≥25% and a change in GFR category within 12 mo Sustained decrease in GFR of ≥5 mL/min/1.73 m^2 within 12 mo
Uncontrolled hypertension	Hypertension that remains poorly controlled despite the use of at least four antihypertensive drugs at therapeutic doses	CKD and hypertension refractory to treatment with four or more antihypertensive agents
Hereditary kidney disease Other conditions	Known or suspected rare or genetic causes of CKD Suspected renal artery stenosis	Hereditary kidney disease Recurrent or extensive nephrolithiasis Persistent abnormalities of serum potassium

central venous catheters. Catheters are prone to infectious complications and inevitably damage central veins, leading to thromboses and stenoses, which may manifest at a later stage when venous return from one or the other arm is increased by the subsequent construction of an AVF (see Chapter 96).[11] Late presentation of CKD also precludes effective treatment of complications such as hypertension and anemia, which may contribute to CVD and ultimately limit life span.[12] Most importantly, late referral is associated with greater subsequent costs of medical care and a worse prognosis.[13]

PREVENTION OF CHRONIC KIDNEY DISEASE PROGRESSION

Management of CKD should be aimed at slowing the rate of decline of kidney function and minimizing the effects of other complications. Except for specific management of the underlying kidney disease where possible, the most effective intervention is control of blood pressure (BP) and introduction of nephroprotective medications including (in patients with albuminuria) angiotensin-converting enzyme (ACE) inhibitors or angiotensin receptor blockers (ARBs; see Chapter 82) and sodium glucose cotransporter 2 (SGLT2) inhibitors. Control of glycemia in patients with diabetes and CKD is covered in Chapter 33.

Hypertension and Renin Angiotensin Aldosterone System Blockade

Hypertension is very common in patients with CKD, the level of BP being associated with the rate of loss of kidney function,[14] and BP control slows the rate of decline (see Chapter 82). BP targets have changed to reflect the available evidence. Although observational studies link low BP to higher mortality,[15] interventional trials such as SPRINT have demonstrated the advantages of more intensive BP control in CKD patients.[16] Guidelines by both NICE and KDIGO emphasize the importance of considering coexistent CVD, other comorbidities, and side effects when choosing medications and BP targets, particularly for elderly patients.[5,17] Lifestyle modifications should be encouraged, including maintenance of a healthy weight, reductions in salt and alcohol intake, and regular exercise (see Chapter 36).

Although current recommendations are based on office BP recordings, these should be standardized if possible (i.e., obtained according to a recommended preparation protocol).[18] Home and ambulatory monitoring readings, where available, should be used to complement standardized office recordings. It has been shown that up to 30% of CKD patients who were thought to have hypertension have normal BPs at home, whereas 40% of patients who were thought to be normotensive (or to have adequately treated hypertension) were hypertensive at home.[19] Although ambulatory monitoring is not universally recommended, there should be a low threshold for undertaking 24-hour monitoring or asking patients to undertake self-measurements at home if they prefer.

Target BP levels and antihypertensive therapy in CKD patients are discussed in Chapter 82. ACE inhibitors or ARBs are recommended as first-line agents for patients with evidence of proteinuria, both to slow progression of CKD and to reduce CV risk.[20] However, multidrug regimens are usually required to obtain good control. Patients with CKD are vulnerable to drug side effects, particularly during intercurrent illness, when they may develop hyperkalemia and AKI. The KDIGO guidelines recommend the temporary discontinuation of certain drugs that may exacerbate AKI or are prone to increased adverse events at low GFR (including ACE inhibitors, ARBs, aldosterone inhibitors, direct renin inhibitors, diuretics, nonsteroidal anti-inflammatory drugs, metformin, lithium, and digoxin) in patients with a GFR of less than 60 mL/min/1.73 m^2 (CKD categories G3a–G5) who have serious intercurrent illness.

Sodium Glucose Cotransporter 2 Inhibitors and Mineralocorticoid Receptor Antagonists

SGLT2 inhibitors enhance urinary excretion of sodium and glucose by blocking their uptake in the proximal tubule. Although originally developed as drugs to improve glycemic control in patients with type 2 diabetes (see Chapter 33), these agents have both kidney and cardioprotective effects that extend to patients with CKD who do not have diabetes.[21] A new nonsteroidal mineralocorticoid receptor antagonist (Finerenone) has also recently been demonstrated to have cardiorenal benefits in patients with CKD and type 2 diabetes.[22] It seems likely that these newer agents will be used more extensively in the future in the management of CKD in addition to ACE inhibitors and ARBs.

Dietary Advice

Detailed dietary advice and education, along with ongoing support from an appropriately trained professional, are important in the management of patients with CKD. Obesity is associated with a more rapid decline of kidney function, so in early CKD, weight loss may be appropriate. However, in advanced CKD, malnutrition is common (see Chapter 90). The causes are multifactorial but include anorexia, acidosis, insulin resistance, inflammation, oxidative stress, and urinary protein loss. Biochemical indicators may demonstrate a decrease in serum albumin, transferrin, and cholesterol. Weight should be monitored in patients who progress to CKD categories G4 and G5. Serum creatinine concentrations, which, in part, reflect muscle mass, may stop rising despite a progressive loss of kidney function because of compromised nutritional status.

In light of this, recommendations to restrict protein intake are controversial. Although reduced protein intake may slow progression of decline of kidney function, many patients develop protein-calorie malnutrition on a low-protein diet.[23] KDIGO has recommended that protein intake should be lowered to 0.8 g/kg/day in adults with CKD and GFR less than 30 mL/min/1.73 m^2, whereas high protein intake (>1.3 g/kg/day) should be avoided in adults with CKD at risk for progression. When this recommendation is followed, detailed dietary assessment and supervision are needed to ensure that malnutrition is prevented (see Chapter 90).

One of the earliest effects of CKD is to limit the ability of the kidney to compensate for large changes in sodium and water intake (see Chapter 8). Salt and water retention are major factors contributing to hypertension in CKD patients and, in more advanced stages, to morbidity and mortality through systemic or pulmonary edema. Therefore, sodium intake should ideally be restricted to less than 90 mmol/day (5 g/day of sodium chloride), except in salt-wasting conditions. Advice about optimal fluid intake at each stage of CKD is needed to prevent volume overload. Salt substitutes containing potassium should be avoided because of the risk for hyperkalemia. In stages G4 and G5 CKD, education and advice about restriction of potassium and phosphate may be required.

MANAGEMENT OF COMPLICATIONS OF CHRONIC KIDNEY DISEASE

A detailed discussion of the complications of CKD is provided in Chapters 84 to 92. With the exception of hypertension, there are usually few clinical manifestations associated with CKD stages G1 and G2 (GFR > 60 mL/min/1.73 m^2). Other complications (discussed in the following sections) tend to develop progressively as GFR declines to less than 60 and in particular less than 30 mL/min/1.73 m^2 (i.e., during CKD stages G4 and G5).

Anemia

Anemia is common in CKD stages G3a to G5 and is caused by a relative deficiency of erythropoietin, although reduced availability of iron and chronic inflammation are frequent contributory factors (see Chapter 86). Anemia may have multiple adverse effects, including worsening cardiac dysfunction by increasing cardiac output and exacerbating left ventricular hypertrophy, thereby accelerating the decline of kidney function. Anemia may also reduce cognition and concentration. However, clear evidence that reversal of anemia using erythropoiesis-stimulating agents (ESAs) is associated with improved clinical outcomes is lacking, and randomized trials have suggested that in some circumstances these agents may cause harm.[24] A new approach to the treatment of renal anemia is the use of oral small-molecule stabilizers of hypoxia inducible factor. These agents, which are currently being evaluated in phase 3 studies, could offer a simpler and cheaper therapy compared with ESAs, with potential benefits beyond increases in hemoglobin (Hb) level.[25]

The relevant KDIGO guideline recommends that all patients identified as having CKD categories G3a and below should have their Hb levels monitored annually, increasing to twice a year for stages G4 and G5.[26] Anemia in adults is diagnosed when the Hb concentration is less than 13.0 g/dL in males and less than 12.0 g/dL in females. NICE recommends that management of anemia should be considered in patients with CKD when the Hb level is up to 11 g/dL.[5] In anemic patients, investigations for other causes should be conducted, including measurement of iron stores, serum vitamin B_{12}, and folate levels. ESAs should not be started until treatment of iron deficiency or other underlying causes have been addressed and then only after considering the balance of benefits (from the reduced requirement for blood transfusions and abrogation of anemia-related symptoms) against the potential harms, which may include an increased risk for stroke and malignancy.

If anemia does not respond to correction of underlying causes, such as iron deficiency, KDIGO recommends that ESAs be commenced when Hb concentrations are less than 10.0 g/dL, if indicated.[26] Hb target ranges are discussed in Chapter 86.

Bone and Mineral Metabolism

Hyperphosphatemia, together with a deficiency of 1,25-dihydroxyvitamin D_3, can contribute to secondary hyperparathyroidism and ultimately to the development of renal bone disease. These biochemical and endocrine changes, in association with the closely related histologic abnormalities of bone and soft tissue calcification, are collectively termed the *CKD–mineral and bone disorder* (see Chapter 88).[27] Bone disease may already be manifested in CKD category G3b and may be well established in ESKD, even though patients may remain asymptomatic. In addition to the need to prevent bone complications, active management of CKD–mineral and bone disorder may help prevent some of the CV complications of CKD.[28]

KDIGO recommends measuring serum levels of calcium, phosphate, PTH, and alkaline phosphatase activity in adults with GFR less than 45 mL/min/1.73 m^2 (GFR stages G3b–G5). Determining the optimal level of PTH in CKD has been controversial. For patients with levels of intact PTH above the upper normal limit of the assay, efforts should be made to correct hyperphosphatemia, hypocalcemia, and vitamin D deficiency if present. KDIGO guidelines recommend that serum phosphate concentrations be maintained in the normal range according to local laboratory reference values,[29] whereas the UK Kidney Association support a level between 0.9 and 1.5 mmol/L for patients with category G4 and G5 CKD.[30] Early advice on dietary phosphate management by a specialist dietician or other professional is important in helping patients achieve this. Phosphate-binding drugs may be required, and their choice is discussed in Chapter 88. Prescription of vitamin D supplements or analogs, in the absence of documented deficiency, to suppress elevated PTH concentrations in patients with CKD not on dialysis is not recommended.[29] Calcimimetics are a group of drugs that mimic the action of calcium on parathyroid glands by activation of the calcium-sensing receptor and thus reduce the release of PTH. At present, cinacalcet (an oral calcimimetic) and etelcalcetide (which is given intravenously) are generally used in patients receiving dialysis, particularly those that are unfit for surgical parathyroidectomy. Whether these drugs have additional health benefits is not clear (see Chapter 88).

Metabolic Acidosis

The metabolic acidosis associated with CKD is caused by failure of hydrogen ion excretion and may be compounded by the accumulation of organic acids and bicarbonate loss, particularly in interstitial kidney diseases. Clinical symptoms resulting from acidosis are rare until patients reach CKD stage G5, when dyspnea may occur as a result of respiratory compensation. Other causes of dyspnea in advanced CKD, such as anemia and pulmonary edema, should always be considered. Acidosis aggravates hyperkalemia, inhibits protein anabolism, and accelerates calcium loss from bone where the hydrogen ions are buffered.[31] Correction of metabolic acidosis may slow progression of kidney disease,[32] although larger trials are required to confirm this.

KDIGO recommends that in patients with CKD and serum bicarbonate concentrations less than 22 mmol/L (NICE recommends a threshold of <20 mmol/L), oral bicarbonate supplementation should be given to maintain serum bicarbonate within the normal range, unless contraindicated. However, the associated sodium loading may aggravate hypertension and fluid retention, and severe metabolic acidosis associated with symptoms in a patient with CKD stage G5 may be an indication to start dialysis.[2] Novel pipeline drugs include an oral polymer designed to remove acid from the body with high capacity and specificity. This raises the possibility of treatment of acidosis without the problems associated with increased sodium intake.

Cardiovascular Risk

Patients with CKD have an increased prevalence of CVD and are far more likely to die of a CVD-related cause than to progress to ESKD (see Chapter 85). Therefore, appropriate management of existing CVD and minimization of future CV risk is vital for all patients with CKD. Agents used to slow progression of CKD, including ACE/ARBs, SGLT2 inhibitors, and mineralocorticoid receptor antagonists (MRAs), may themselves have cardiovascular benefits in the context of CKD.

Unfortunately, many trials of interventions for CVD have excluded patients with CKD,[33] and there is doubt about the relevance of existing standards of care of CVD to patients with CKD.[34] Nonetheless, the level of care for coronary heart disease offered to patients with CKD should not be prejudiced by their CKD. NICE suggests that antiplatelet drugs should be offered to patients with CKD for the secondary prevention of CVD, and some experts would extend this recommendation to primary prevention for those at risk for atherosclerotic events. However, there is an increased risk for minor bleeding, and a recent systematic review of antiplatelet agents for patients with CKD found that although the incidence of myocardial infarction is reduced, major bleeding is increased.[35] Thus, the risks may outweigh benefits among individuals with low risk for CV events, including those with early stages of CKD who do not have clinically evident occlusive arterial disease.

For reduction of cardiovascular risk, KDIGO guidelines recommend that statin treatment be routinely offered to patients with CKD who are aged older than 50 years and to younger patients with

additional risk factors, irrespective of baseline lipid values.[36] NICE recommends that all people with CKD should be offered atorvastatin 20 mg for the primary or secondary prevention of CVD.[37]

Risk for Infections

Infection is the second most common cause of death after CVD in patients with ESKD. This is, in part, because of defects in both cellular and humoral immunity, which make CKD a state of chronic immunosuppression (see Chapter 87).[38] T-cell responses to de novo antigens are deficient, partly because of impaired antigen presentation by monocytes. Neutrophil activation is defective, and although serum immunoglobulin levels are usually normal, antibody responses to immunization may be poor. Patients with CKD have an increased susceptibility to bacterial infection (particularly staphylococcal), increased risk for reactivation of tuberculosis (typically with a negative tuberculin skin test response), and failure to eliminate hepatitis B and C viruses after infection.

In view of these increased risks, the KDIGO guidelines recommend that all adults with CKD be offered annual vaccination with influenza vaccine unless contraindicated and that all adults with eGFR less than 30 mL/min/1.73 m^2 (GFR categories G4–G5) and those at high risk for pneumococcal infection (e.g., patients with nephrotic syndrome, with diabetes, or who are receiving immunosuppression) receive vaccination with polyvalent pneumococcal vaccine unless contraindicated.[2] Patients who have received pneumococcal vaccination are offered revaccination within 5 years. In addition, those at high risk for progression of CKD with eGFR less than 30 mL/min/1.73 m^2 (GFR categories G4–G5) should be immunized against hepatitis B and the response confirmed by appropriate serologic testing. This should happen as early as possible to maximize the chances of seroconversion.[39] Response to COVID-19 vaccination is also attenuated in CKD.[40]

Gastrointestinal Problems in Chronic Kidney Disease

Gastrointestinal (GI) symptoms and disease are common in patients with CKD (Table 83.3). Anorexia, nausea, and vomiting related to advanced CKD may contribute to malnutrition and wasting, which, in turn, herald an adverse prognosis (see Chapter 90). In addition, uremia-associated reduced taste sensation or abnormal taste can impair dietary intake. Gastroesophageal reflux is also common in patients with CKD and related to GI tract dysmotility or delayed gastric emptying, in particular in diabetes or amyloidosis or patients on peritoneal dialysis, given their increased intra-abdominal pressure.

Extensive peptic ulcer disease, gastritis, and duodenitis occur more commonly in CKD than in the general population, with the highest incidence in dialysis patients.[41] Peptic ulcers are often multilocular and postbulbar, but pain is less frequent. *Helicobacter pylori* infection is not increased in CKD. There is a risk for excess calcium and magnesium absorption with some antacids in CKD, and aluminum- or bismuth-containing preparations should be avoided, given their potential for accumulation in CKD.

In the large bowel, the incidence of diverticular disease is increased in patients with ADPKD (see Chapter 46). Constipation is common in CKD and results from dietary restrictions, restricted fluid intake, electrolyte abnormalities (including hypercalcemia), and commonly prescribed drugs, such as calcium-based phosphate binders, sevelamer, oral iron, opioid analgesics, and calcium resonium. In extreme cases, constipation may result in intestinal pseudo-obstruction, which may also be acutely precipitated by surgery and retroperitoneal hemorrhage. Patients with CKD are at risk for more frequent or severe *Clostridium difficile* infection, slower treatment response, and more frequent relapse and have a higher risk for death.[42]

Intestinal ischemia is an important cause of an acute abdomen in older CKD patients. Some cases result from nonocclusive mesenteric ischemia. Predisposing factors include hypotension, cardiac failure, hypoxia, increased plasma viscosity, and constipation. Abdominal examination can be misleadingly benign at presentation, but often peripheral neutrophil leukocytosis and progressive lactic acidosis are present. GI hemorrhage resulting from peptic ulcers, gastritis, duodenitis, angiodysplasia (Fig. 83.2), or nonulcer, nonvariceal bleeding because of uremic hemostatic defects is also common in CKD and is associated with high mortality. Idiopathic ascites with a high protein content may occur in HD patients, sometimes related to inadequate dialysis dose. The diagnosis is by exclusion of other causes. Management includes optimization of volume and small-solute clearance. The condition may resolve after transplantation or a modality switch to PD.

TABLE 83.3 Important Causes of Common Gastrointestinal Symptoms in Patients With CKD

Clinical Feature	Causes
Anorexia	Uremic toxicity Inadequate dialysis clearances Delayed gastric emptying
Nausea and vomiting	Uremic toxicity Delayed gastric emptying/gastroparesis Gastritis, duodenitis Peptic ulcer disease Drugs
Constipation	Drugs, including opioid analgesia GI pseudo-obstruction Diverticular disease
Diarrhea	Diabetic enteropathy Diverticular disease *Clostridium difficile* infection Dialysis-related amyloidosis (very rare)
GI hemorrhage	Gastritis, duodenitis Esophagitis Peptic ulcer disease Angiodysplasia Intestinal ischemia Vasculitis Dialysis-related amyloidosis (very rare)
Acute abdominal pain	Gastritis, duodenitis Complications of peptic ulcer disease Acute pancreatitis Intestinal ischemia Diverticulitis GI pseudo-obstruction Colonic perforation from fecal impaction Complications of peritoneal dialysis (peritonitis, dialysis catheter malposition, dialysate infusion or drain pain) Complications of autosomal dominant polycystic kidney disease Retroperitoneal hemorrhage

CKD, Chronic kidney disease; *GI,* gastrointestinal.

CARE OF THE PATIENT WITH PROGRESSIVE CHRONIC KIDNEY DISEASE

To optimize the care of patients with progressive CKD, management is provided in a multidisciplinary setting where a range of professionals are able to provide education and information about diet, different

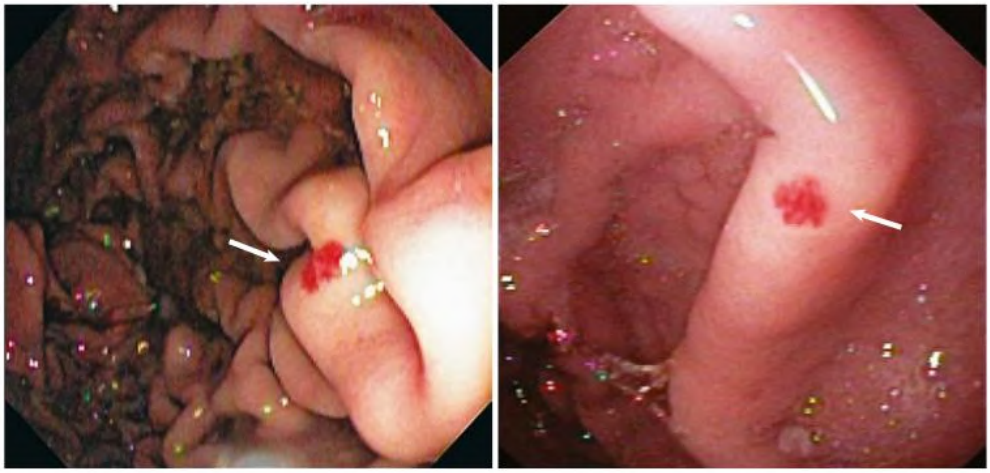

Fig. 83.2 Examples of gastric angiodysplasia *(arrows)* in a dialysis patient. (Courtesy Drs. R. Winograd and C. Trautwein, Aachen, Germany.)

KRT modalities, transplant options, vascular access surgery, and social care. Psychological comorbidity is common among patients with CKD. Health care professionals working with patients with CKD should take account of the psychological aspects of coping with the condition and offer access to support groups, counseling, or a specialist nurse. The aim is to create an environment in which patients can become informed and proactive in their care.

Chronic Kidney Disease and Risk of Acute Kidney Injury

All patients with CKD are at increased risk for AKI, and AKI is associated with the development and progression of CKD.[43,44] Imaging studies that require iodinated radiocontrast media carry a risk for AKI, and the benefit of a diagnostic scan needs to be balanced against the risks (Chapter 6). If the investigation is needed, the lowest dose of radiocontrast should be used, the patient should be adequately hydrated, and potentially nephrotoxic agents should be withdrawn before and after the procedure; however, the fear of radiocontrast-induced AKI should not prevent or impair a necessary diagnostic workup. The potential risk for nephrogenic systemic fibrosis from gadolinium-based contrast media and measures to reduce it are also discussed in Chapter 6.

Many commonly used medications increase the risk for AKI, and the level of GFR should be considered when any drug is prescribed. As discussed earlier, the need for temporary cessation of some medications should be considered during periods of severe intercurrent illness. Other causes of reduction in kidney perfusion can lead to AKI, including volume depletion from excessive diuretics, insufficient fluid intake in hot weather, diarrhea or vomiting, heart failure, myocardial infarction, and tachyarrhythmias. Severe hypercalcemia, resulting from either coadministration of high doses of vitamin D and calcium-containing phosphate binders or from underlying disease, can also cause AKI.

Clinicians should always consider whether acceleration of loss of kidney function is a result of relapse of the underlying disease or of a superimposed problem such as acute interstitial nephritis (see Chapter 64), obstructive uropathy (see Chapter 61), or renal vein thrombosis.

Timing the Initiation of Kidney Replacement Therapy

Despite all attempts to optimize the management of CKD, many patients will progress to needing KRT. Patients with eGFR less than 20 mL/min/1.73 m^2 and/or who are likely to progress to ESKD within 12 months should receive education and counseling, with the support of a multidisciplinary team, to aid their selection of the most appropriate KRT modality (see Chapter 95). If HD is the preferred option, an AVF should be constructed, remembering that it may take 8 to 12 weeks for veins to become adequately arterialized before needling can be attempted (see Chapter 96). Similar plans need to be made for preemptive insertion of a peritoneal dialysis catheter to allow time for healing and training before any acute need for commencement of dialysis (see Chapter 101).

Early kidney transplantation may be associated with improved long-term outcome,[45] so patients should be assessed for their suitability and, when feasible, activated on the waiting list before dialysis is commenced. This maximizes the chances of the potential recipient remaining in reasonable health. The availability of a living donor should be explored to increase the chances of preemptive transplantation before the patient begins dialysis. The KDIGO guidelines recommend that living donor preemptive kidney transplantation in adults be considered when GFR is less than 20 mL/min/1.73 m^2 and there is evidence of progressive and irreversible CKD over the preceding 6 to 12 months.[2]

Planned early initiation of dialysis is not associated with improvement in outcomes compared with commencement when indicated by signs and symptoms of uremia.[46] KDIGO suggests that dialysis be initiated when one or more of the following are present: symptoms or signs attributable to kidney failure (serositis, acid-base or electrolyte abnormalities, pruritus); inability to control volume status or BP; a progressive deterioration in nutritional status refractory to dietary intervention; or cognitive impairment.[2] These problems often but not invariably occur when the GFR is less than 15 mL/min/1.73 m^2 (see Chapter 95).

Conservative Management

The potential burden of commencing KRT in terms of high short-term mortality rates, recurrent hospitalizations, time spent traveling, and limited improvement in quality of life for some elderly patients and those with multiple comorbid disease is increasingly recognized. This has led to the practice of offering patients with incipient kidney failure the option of choosing not to start dialysis but to maintain ongoing follow-up and symptomatic support through conservative management. Although dialysis may offer longer survival, those choosing conservative management may have as many hospital-free days as those who choose HD.[47] The symptoms of advanced uremia can be distressing, and it is important to ensure that patients who choose this pathway have access to members of the multidisciplinary team with expertise in palliative care to facilitate a death free of suffering.

SELF-ASSESSMENT QUESTIONS

1. Which of the following is the most common cause of death for people with CKD and eGFR < 60 mL/min/1.73 m^2?
   - **A.** Failure of dialysis access
   - **B.** Sepsis
   - **C.** Withdrawal from dialysis
   - **D.** Cardiovascular disease
   - **E.** Cerebrovascular disease
2. The equation recommended by KDIGO for estimating GFR is:
   - **A.** The Modification of Diet in Renal Disease (MDRD) equation
   - **B.** The Cockcroft-Gault formula
   - **C.** The CKD-EPI formula
   - **D.** The Mayo Clinic Quadratic formula
   - **E.** The Schwartz formula
3. Which of the following variables is *not* needed to calculate eGFR from the CKD-EPI formula?
   - **A.** Age
   - **B.** Weight
   - **C.** Race
   - **D.** Sex
   - **E.** Creatinine
4. Which of the following symptoms is suggestive of CKD, regardless of cause?
   - **A.** Pain in the renal angle
   - **B.** Nocturia
   - **C.** Urinary frequency
   - **D.** Tremor
   - **E.** Anuria
5. In a well patient, which of the following biochemical or hematologic abnormalities is suggestive of CKD rather than acute kidney injury?
   - **A.** Calcium 3.5 mmol/L
   - **B.** Potassium 7.5 mmol/L
   - **C.** Hemoglobin 10.7 g/dL
   - **D.** Creatinine 13.5 mg/dL
   - **E.** Sodium 132 mmol/L

Pathogenesis and Risk of Cardiovascular Disease in Chronic Kidney Disease

Peter Stenvinkel, Nikolaus Marx, Charles A. Herzog

Diminished estimated glomerular filtration rate (eGFR) and albuminuria are powerful graded, independent predictors of cardiovascular (CV) morbidity and mortality[1] and all-cause mortality. Even subtle kidney dysfunction, as suggested by albuminuria, increases CV risk because it may reflect microvasculature health, including endothelial function. Patients with end-stage kidney disease (ESKD) face an extraordinary risk for premature death, largely because of CV complications in the setting of accelerated vascular aging. Patients with eGFR less than 60 mL/min/1.73 m^2 are much more likely to die than to develop ESKD, reflecting the burden of cardiovascular disease (CVD) in this population. The most effective strategy for reducing CV morbidity and mortality in this high-risk population would be to target patients with mildly reduced eGFR for prevention and treatment.

Patients with chronic kidney disease (CKD) were often excluded from randomized controlled trials targeting CVD, possibly reducing acceptance of evidence-based therapies (validated in nonrenal patients) and fostering "therapeutic nihilism" in clinicians who treat CKD patients. Thus, novel treatment strategies are urgently needed to reduce the unacceptable high CV event rate.

Like conventional atheromatous occlusive vascular disease, CKD is characterized by generalized vasculopathy, with other characteristics, including left ventricular hypertrophy, vascular calcification, and vascular noncompliance. Numerous CVD risk factors are specific to CKD and operate in addition to conventional risk factors found in the general population.

EPIDEMIOLOGY

Prevalence of Cardiovascular Complications in Chronic Kidney Disease

Interpretation of epidemiologic studies of CVD is problematic because of the difficulty in defining cause of death. Unexpected sudden death most likely results from arrhythmia, but a subarachnoid hemorrhage, massive embolic stroke, or aortic dissection might be indistinguishable from a primary arrhythmic event without an autopsy. Defining "coronary heart disease" (CHD) is also problematic: in the general population, sudden cardiac death is a primary complication of CHD, but this is unlikely to be true for dialysis patients. A history of angina cannot reliably classify a patient as having CHD because angina (resulting from supply-demand mismatch) can occur in patients with left ventricular hypertrophy and angiographically pristine coronary arteries. This probably relates to the increased myocardial fibrosis, diminished relative capillary density, and increased thickening of the intramyocardial vessel walls in uremia. At lower levels of eGFR (especially in dialysis patients), the burden of nonatherosclerotic (vs. atherosclerotic) CVD is relatively increased (Fig. 84.1).[2] Although occlusive CHD is common in CKD, acute myocardial infarction (MI) and coronary artery disease account for only 8% of cardiac deaths; 85% of cardiac deaths of hemodialysis (HD) patients in the US Renal Data System (USRDS) database are attributable to arrhythmic mechanisms (www.USRDS.org), continuing a temporal trend of an increasing proportion of deaths attributable to arrhythmic mechanisms. Data from the ERA-EDTA registry are encouraging because the absolute excess mortality for atheromatous CVD decreased between 2007 to 2015.[3]

Of incident dialysis patients, at least 75% have left ventricular hypertrophy, and 75% to 85% have hypertension. Hypertension, anemia, vascular noncompliance, elevated fibroblastic growth factor 23 (FGF23) levels, and volume overload contribute to left ventricular hypertrophy. Based on echocardiography, 85% to 90% of patients have a left ventricular ejection fraction of 50% or greater despite frequent congestive heart failure (i.e., heart failure with preserved ejection fraction [HFpEF]). Therefore, many volume overload episodes in dialysis patients may be attributable to diastolic dysfunction or circulatory congestion. Fig. 84.2 provides a snapshot of CVD event rates (by modality) in prevalent ESKD patients in 2018.[4]

Cardiovascular Disease Is Present Long Before the Start of Kidney Replacement Therapy

In elderly patients with stage 2 to 3 CKD, traditional risk factors seem to be the major contributors to CV mortality. Atherosclerosis Risk in Communities (ARIC) data suggest that both traditional and novel risk factors are relevant at CKD stage 4, and novel risk factors are far more prevalent in dialysis patients than in the general population (Fig. 84.3).[5] The Framingham predictive instrument does not accurately predict coronary events in CKD. Mild to moderate CKD is associated with increased risk for venous thromboembolism, supporting the concept of hypercoagulability in CKD (see also Chapter 87). Because the incidence of CV events is much higher in the first weeks after HD initiation, concerns have been raised that the dialysis procedure per se may trigger CV events.[6]

Racial and International Differences in Cardiovascular Disease Prevalence

In the United States, survival is better for African American than for White dialysis patients. However, overall CV mortality among dialysis patients from the United States is significantly greater than is observed in Japan and Europe, even after adjustment for standard risk factors and dialysis dose. Higher mortality rates in US dialysis patients may be related to higher prevalence of sicker or diabetic patients, differences in dialysis practice patterns, cultural habits, differences in diet, or genetic variations.

Reverse Epidemiology

Reverse epidemiology (preferably called *confounded epidemiology*) refers to the paradoxical observation that the association among hypercholesterolemia, hypertension, obesity, and poor outcomes, including CV

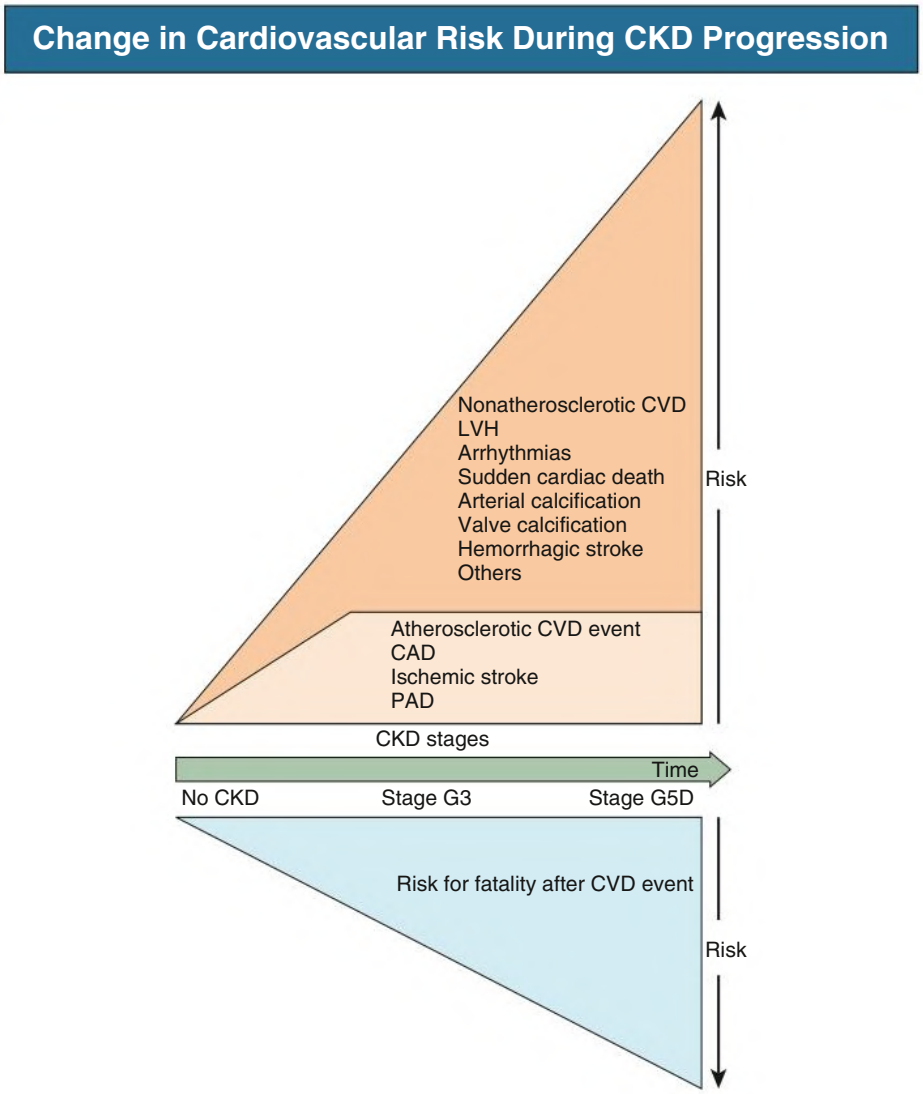

Fig. 84.1 Change in Cardiovascular Risk During Chronic Kidney Disease (CKD) Progression. Cardiovascular disease (CVD) event *(upper triangle),* contributions of atherosclerotic CVD *(tan),* nonatherosclerotic CVD *(orange),* and risk for fatality after CVD event *(blue). The heart and vascular system in dialysis. *Lancet.* 2016;388:76–284.)

death, in the general population does not exist and may be reversed in CKD. Patients with wasting and inflammation appear to mostly account for poor survival and confounded epidemiology.

ETIOLOGY AND RISK FACTORS

Traditional Risk Factors

Age, Sex, and Smoking

The US National Health and Nutrition Examination Surveys (NHANES) shows the prevalence of CV factors and CVD prevalence in relation to age and CKD stage. In the United States, the average age in 2018 at kidney replacement therapy (KRT) initiation was 63 years,[4] when CVD is common in the general population. The mean survival for patients who start dialysis in the United States is 3 years. An individual-level meta-analysis including more than 2 million participants showed that low eGFR and high albuminuria were independently associated with mortality and ESKD regardless of age. Female sex is associated with a 4% independent increased risk for mortality in incident dialysis patients and smoking with a 52% increased risk for death in dialysis patients.

Diabetes Mellitus

Diabetes accounted for 47% of incident US ESKD patients between 2014 and 2018[4] and is a common cause of ESKD in many countries. Diabetic patients starting KRT have numerous cardiovascular risk factors, including dyslipidemia, hypertension, persistent inflammation, gut dysbiosis, increased oxidative stress, and protein-energy wasting. Diabetes at dialysis initiation is a potent independent risk factor for all-cause and CVD-related deaths, including after coronary revascularization or acute MI. Nevertheless, the rate of incident acute MI is even higher for patients with CKD stages 3b-4 without diabetes than for patients with diabetes and CKD stages 1 to 2.

Hypertension

Hypertension predicts mortality in CKD patients before or at dialysis initiation. Isolated systolic hypertension with increased pulse pressure

Overall Prevalence of Common Cardiovascular Diseases in Adult Patients With End-Stage Kidney Disease

Overview of traditional (i.e., Framingham) risk factors and novel and uremia-related risk factors. *LDL,* Low-density lipoprotein. (From Stenvinkel P, Carrero JJ, Axelsson J, Lindholm B, Heimbürger O, Massy Z. Emerging biomarkers for evaluating cardiovascular risk in the chronic kidney disease patient: how do new pieces fit into the uremic puzzle? *Clin J Am Soc Nephrol.* 2008;3:505–521.)

TABLE 84.1 Common Patterns of Hyperlipidemia in Different Stages of Kidney Disease, Compared With the Healthy Population

	CHOLESTEROL			
Stage of Kidney Disease	**Total**	**High-Density Lipoproteins**	**Low-Density Lipoproteins**	**Triglycerides**
Nephrotic syndrome	↑↑↑	↓	↑↑	↑
Chronic kidney disease	No change	↓	No change[a]	↑↑
Hemodialysis	No change	↓	No change[a]	↑↑
Peritoneal dialysis	↑	↓	↑	↑
Transplantation	↑↑	No change	↑	↑

[a]Composition altered.

is by far the most prevalent blood pressure anomaly in dialysis patients, resulting from arterial medial sclerosis (i.e., arteriosclerosis) with secondary vascular stiffening. Stiff vessels cause increased pulse wave velocity, resulting in increased systolic blood pressure peak pressure by a prematurely reflected pulse wave, progressive left ventricular dysfunction, and finally congestive heart failure. At this stage, mean arterial and diastolic pressure may decrease. The relationship between blood pressure and mortality is U-shaped; isolated systolic hypertension and increased pulse pressure probably indicate high long-term risk in dialysis patients, whereas low mean and diastolic blood pressures predict early mortality. CKD patients are frequently "nondippers" and experience sleep apnea and sympathetic nervous system activation.

Dyslipidemia

The relationship between hypercholesterolemia, CVD, and mortality in CKD is weak because common uremic CV abnormalities, such as cardiomyopathy and arteriosclerosis (i.e., vascular calcification), are less dependent on dyslipidemia than on other factors. Low rather than high serum cholesterol level is associated with poor survival in HD patients, likely related to confounding by protein-energy wasting and inflammation.

Progressive CKD leads to changes in blood lipids typically associated with vascular disease, including decreased apolipoprotein A (apoA)-containing lipoproteins and increased apoB-containing lipoproteins (Table 84.1). Serum triglycerides are elevated in most ESKD patients, whereas total serum cholesterol is variable, depending on nutritional status and presence of inflammation. High-density lipoprotein (HDL) cholesterol is typically reduced, and low-density lipoprotein (LDL), intermediate-density lipoprotein, and very low-density lipoprotein cholesterol, as well as lipoprotein(a) levels, tend to be increased. Because of altered molecular composition, the antiinflammatory activity of HDL is lost in the uremic milieu. Compared with long-term HD patients, peritoneal dialysis (PD) patients more often have both hypercholesterolemia and hypertriglyceridemia. Both groups are characterized by low HDL and elevated oxidized LDL cholesterol levels; elevated lipoprotein(a) levels are associated with increased CVD mortality.

Insulin Resistance and Atherosclerosis

In the general population, impaired insulin-stimulated glucose disposal in muscle is often part of a metabolic syndrome that includes dyslipidemia, hypertension, endothelial dysfunction, and sympathetic overactivity. Many of these abnormalities are present in CKD. Although insulin resistance was found to be an independent predictor of CV mortality in dialysis patients, its magnitude of contribution in CKD mortality is uncertain. High urea levels have been linked to insulin resistance.[7]

Nontraditional and Uremia-Specific Risk Factors

Even mild CKD is an independent risk factor for CVD and similar in magnitude to diabetes and hypertension. The uremic milieu may affect both quality and quantity of the atherosclerotic plaques. Coronary lesions in uremic patients, compared with nonrenal controls, are characterized by increased media thickness, infiltration and activation of macrophages, and marked media calcification. The mechanism(s) by which a uremic milieu may promote vascular senescence and accelerate vascular aging[8] are not well established, but prevalence and magnitude of several nontraditional risk factors, such as oxidative stress, inflammation, gut dysbiosis, and advanced glycation end-products (AGEs), increase as kidney function deteriorates and uremic toxins accumulate. Many uremic retention solutes, such as asymmetric dimethylarginine (ADMA), guanidine, indoxyl sulfate, trimethylamine N-oxide (TMAO), interleukin (IL)-6, and *p*-cresol, which accumulate in CKD, may have proatherogenic properties.[9] Finally, failing kidneys produce fewer substances that may inhibit CVD and atherogenesis (e.g., renalase, a soluble monoamine oxidase that regulates cardiac function and BP).

Oxidative Stress

Oxidative stress may be implicated in the pathogenesis of atherosclerosis, the increased risk for atherosclerotic CV events, protein-energy wasting, and anemia.[10] Increased production of reactive oxygen species in the vascular wall characterizes atherosclerosis. Moderate CKD, and in particular ESKD, is a prooxidant state resulting from reduced antioxidant systems (vitamin C and selenium deficiency, reduced intracellular vitamin E levels, reduced activity of the cytoprotective transcription factor Nrf2, reduced glutathione system activity), and increased prooxidant activity is associated with advanced age, diabetes, chronic inflammation, retained uremic solutes, and dialysis membranes and solutions. Four oxidative stress pathways operate in CKD: carbonyl stress, nitrosative stress, chlorinated stress, and classic oxidative stress.

Inflammation

Most dialysis patients are in a state of chronic low-grade inflammation, which associate with premature aging processes (i.e., inflammaging).[11] Inflammatory biomarkers, such as C-reactive protein (CRP), interleukin-6 (IL-6), pentraxin 3 (PTX3), fibrinogen, and white blood cell count, are independent predictors of mortality in CKD. It has been argued that repeated CRP measurements will improve dialysis patient care because persistent inflammation (i.e., CRP > 5 mg/L) may be a silent reflection of different pathophysiological alterations that require attention.[12] Hypoalbuminemia, strongly associated with systemic inflammation, is another strong outcome predictor in CKD. Whereas both dialysis-related factors and non–dialysis-related factors, infection, gut dysbiosis with a leaky gut, comorbidity, genetic factors, hypogonadism, diet, and kidney function loss may contribute to chronic inflammation, its primary causes are not always evident. The senescence-associated secretory phenotype caused by increased numbers of senescent cells in the uremic milieu[13] also may be a

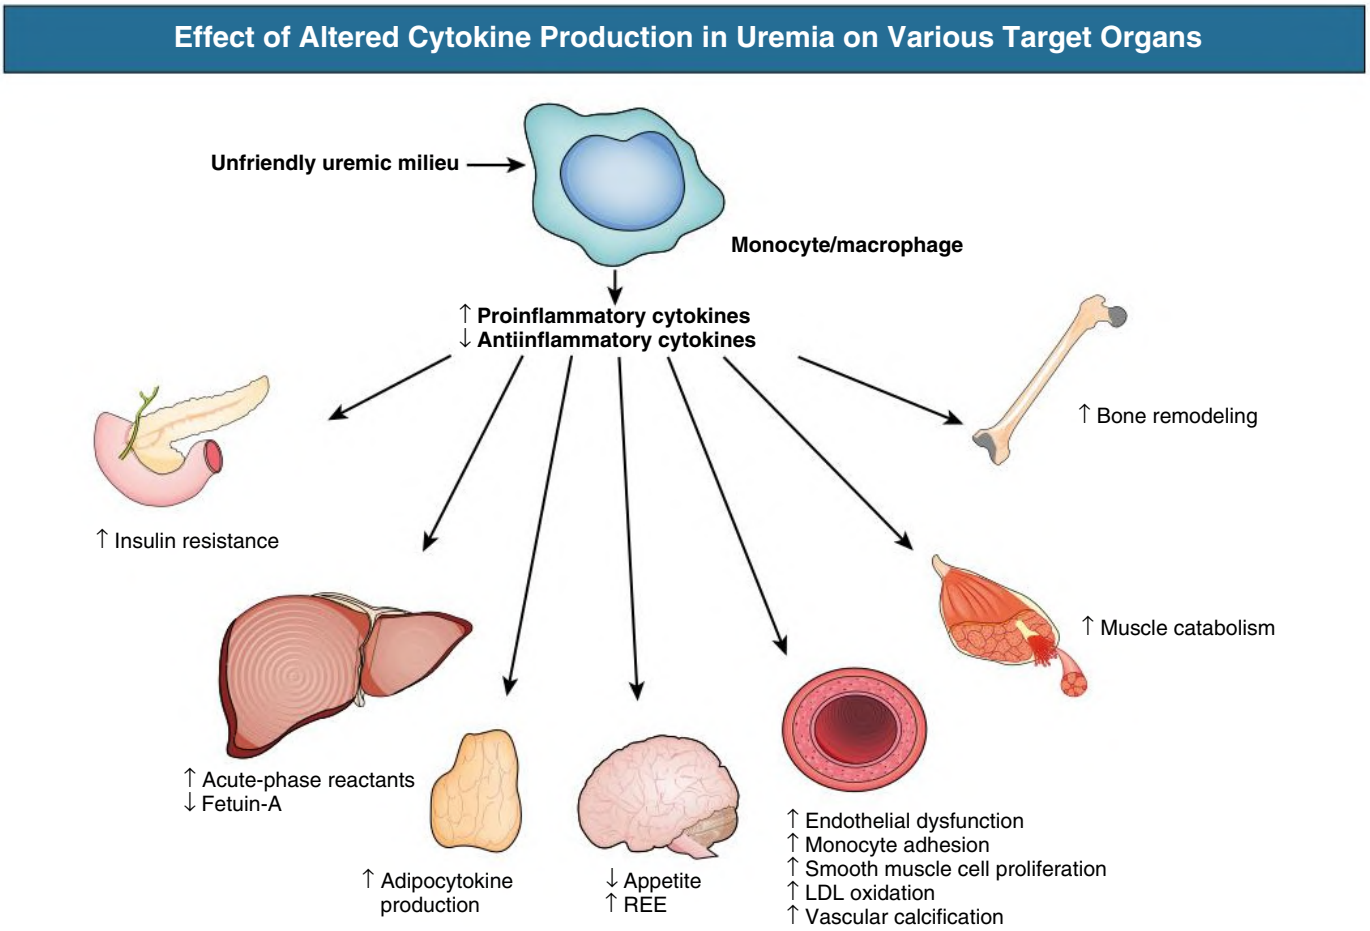

Fig. 84.4 Potential mechanisms by which elevated circulating levels of proinflammatory and anti-inflammatory cytokines may promote accelerated atherosclerosis, other uremic complications, and wasting. *LDL,* Low-density lipoprotein; *REE,* resting energy expenditure. (From Stenvinkel P, Carrero JJ, Axelsson J, Lindholm B, Heimbürger O, Massy Z. Emerging biomarkers for evaluating cardiovascular risk in the chronic kidney disease patient: how do new pieces fit into the uremic puzzle? *Clin J Am Soc Nephrol.* 2008;3:505–521.)

significant contributor to uremic inflammation. Whether the acute-phase response reflects only established atherosclerotic disease or is involved in the initiation and progression of atherosclerosis is unclear. Some inflammatory biomarkers, such as IL-6, PTX3, and tumor necrosis factor, have proatherogenic properties, such as promoting vascular calcification, oxidative stress, and endothelial dysfunction (Fig. 84.4). Evidence suggests associations between inflammation and development of albuminuria. Persistent inflammation may change the risk factor profile for traditional risk factors, such as cholesterol and obesity.[14] The link between septicemia and subsequent increased risk for death and CV events, including acute MI, further supports inflammation as a trigger for CV events.

Gut Dysbiosis

The uremic milieu affects the intestinal microbiota and the integrity of the intestinal wall, possibly contributing to inflammation and increased production of uremic toxins, such as proatherogenic indoxyl sulfate, phenylacetic acid, and *p*-cresol sulfate. The uremic milieu and volume retention may damage the intestinal wall, promoting increased leakiness of endotoxins and translocation of intestinal bacteria. The microbial metabolite and water-soluble uremic toxin TMAO contributes to the development of atherosclerotic heart disease and vascular calcification, and it is related to adverse CV outcomes in both the general population and in CKD.[15]

Endothelial Dysfunction

Endothelial dysfunction (as evaluated by impaired endothelium-dependent vasodilation) is common in CKD. Reasons include inflammation, ADMA retention, elevated TMAO, oxidative stress, elevated FGF-23, dyslipidemia, hyperglycemia, and hypertension. Serum ADMA concentrations are associated with endothelial function in uremic resistance vasculature. Surrogate markers of endothelial dysfunction, such as ADMA, PTX3, and adhesion molecules, independently predict death.[16] Detached circulating endothelial cells are potential markers of endothelial damage and have prognostic value in HD patients. Normally, in response to an ischemic insult and cytokine stimulation, endothelial progenitor cells are mobilized from the bone marrow to repair endothelial injury, and this seems to be impaired in CKD.

Anemia

Anemia is a major cause of left ventricular hypertrophy and left ventricular dilation in CKD. Although partial correction of anemia with erythropoiesis-stimulating agents (ESAs) results in left ventricular

hypertrophy regression, current information suggests no CV outcome benefit of normalized hemoglobin (see Chapter 86).

Secondary Hyperparathyroidism and Mineral Metabolism

Disturbances of calcium and phosphate metabolism might accelerate calcifying atherosclerosis and arteriosclerosis (see also Chapter 88). Chronically elevated FGF-23 levels are associated with high rates of left ventricular hypertrophy, atrial fibrillation, and mortality. In registry data, a strong independent mortality risk is predicted by hyperphosphatemia, an intermediate risk by elevated serum calcium levels, and a weak risk by high or low serum intact parathyroid hormone levels.[17] The overall proportion of mortality risk that is potentially attributable to mineral metabolism disorders is estimated to be about 17% in HD patients.

Cardiovascular Calcification

CV calcification may affect the arterial media, atherosclerotic plaques, myocardium, and heart valves. Medial calcification causes arterial stiffness and, consequently, increased pulse pressure.[18] The pathophysiologic role of plaque calcification is less clear because soft plaques are assumed to rupture and cause acute MI; atherosclerotic calcification is a potent risk marker for CV events, but its utility as a risk marker for clinical management of CKD patients remains controversial. Valvular calcification mostly affects the aortic and mitral (annulus) valves in dialysis patients and contributes to progressive stenosis and associated morbidity and mortality. In dialysis patients, extensive vascular (especially coronary artery) calcification can occur at young ages. Calciphylaxis (calcific uremic arteriolopathy) is discussed in Chapter 91.

Vascular calcification is not derived only from passive calcium and phosphate precipitation. Rather, it involves differentiation of vascular smooth muscle cells toward osteoblasts induced by phosphate, calcium, and other factors, such as calcitriol and proinflammatory cytokines. Uremic bone disease, senescence, vitamin K deficiency, genomic damage, persistent inflammation, somatic mutations, posttranslational protein modification and protein-energy wasting may be additional risk factors for vascular calcification.[19] One mechanism by which chronic inflammation promotes vascular calcification may involve downregulation of fetuin-A, the most potent circulating inhibitor of extraosseous calcification and a component of calciprotein particles. Apart from fetuin-A, other inhibitors, such as magnesium, probably counteract unwanted calcification. Leptin, matrix GLA protein, FGF-23, pyrophosphates, bone morphogenic proteins (e.g., BMP-2 and BMP-7), and osteoprotegerin may be related to accelerated vascular calcification in ESKD. Deficiency of vitamin K and/or treatment with vitamin K antagonists (warfarin) accelerate the vascular calcification process in the uremic milieu.[20] Recent studies using dual-energy computed tomography imaging show vascular urate crystalline deposits in the aorta and coronary arteries of a high percentage of subjects with gout, and these urate deposits sometimes colocalize with sites of vascular calcification.[21] While studies have not investigated whether this also may occur in CKD, it also raises the possibility that uric acid may also be involved as a nidus for calcification, similar to what occurs in the kidney tract.

Advanced Glycation End-Products

Advanced glycation end-products (AGEs) accumulate in CKD as a result of nonenzymatic glycation, oxidative stress, intestinal food components, and diminished clearance of AGE precursors. These AGEs interact with the receptor for advanced glycation end-products (RAGE); a key molecule in the genesis of CV and arterial thrombosis in CKD.[22] Stable AGE residues of long-lived proteins are biomarkers of cumulative metabolic, inflammatory, and oxidative stress; carbonyl stress is speculated to contribute to tissue aging and long-term CKD complications. Whether AGE inhibition may affect CV disease in CKD is unknown.

Dialysis Modality

Reports from dialysis registries are inconsistent regarding whether HD or PD is associated with better outcomes. Valid mortality comparisons between HD and PD modalities are not available because this would require stratification of patients according to underlying ESKD cause, age, and level of baseline comorbidity. Cardiac arrhythmias, such as atrial fibrillation, seem to occur more often on the day of HD compared with PD.[23]

SELF-ASSESSMENT QUESTIONS

1. Which of the following is *not* an established risk factor for CV disease in patients with advanced CKD?
   - **A.** Inflammation
   - **B.** Smoking
   - **C.** Dyslipidemia
   - **D.** Hyperhomocysteinemia
   - **E.** Diabetes
2. What is *not* true about cardiovascular complications in patients with ESKD?
   - **A.** Left ventricular hypertrophy is present in about 75% of the patients.
   - **B.** In dialysis patients the incidence of atrial fibrillation is about 15% per year.
   - **C.** Low levels of cholesterol predict death.
   - **D.** In dialysis patients, extensive vascular, especially coronary artery, calcification can occur even at young ages.
   - **E.** The calcific aortic stenosis progression rate is only slightly higher in dialysis patients compared with the general population.
3. What is the *most* common cause of death in dialysis patients?
   - **A.** Congestive heart failure
   - **B.** Infection
   - **C.** Arrhythmic death
   - **D.** Stroke
   - **E.** Valvular heart disease
4. Which drug has been shown to reduce mortality in dialysis patients with dilated cardiomyopathy and systolic heart failure?
   - **A.** Atorvastatin
   - **B.** Digoxin
   - **C.** Carvedilol
   - **D.** Metoprolol
   - **E.** Atenolol

Practical Management of Cardiovascular Disease in Chronic Kidney Disease

Nikolaus Marx, Peter Stenvinkel, Charles A. Herzog

PREVENTION AND CARDIOVASCULAR RISK REDUCTION

Control of traditional risk factors and other factors contributing to cardiovascular risk in chronic kidney disease (CKD) is critical to reducing morbidity and mortality burden in this high-risk population.

Lifestyle Factors and Smoking

Because physical inactivity is associated with albuminuria and cardiovascular mortality, CKD patients should be advised to be as physically active as possible and to avoid smoking.

Weight and Diet

Lifestyle changes, including balanced diets with regard to saturated fat and carbohydrates (in diabetic patients), probably reduce cardiovascular morbidity and should be encouraged. However, in all CKD stages, protein-energy wasting must be avoided (see Chapter 90). Especially in dialysis patients, increased body mass index is associated with better outcomes, possibly reflecting worse outcomes among underweight or normal weight patients who also have inflammation. Alternatively, obesity may act as a physiologic reserve against acute illness.

Hypertension

Blood pressure (BP) targets for CKD patients, in particular those with diabetes or proteinuria greater than 1 g/day, are discussed in Chapter 82. Key goals of therapy include volume control (see Chapter 82) and prevention of sodium overload, particularly through dietary sodium restriction. Longer or more frequent hemodialysis (HD) sessions may be beneficial in controlling hypertension. Because of their cardioprotective effects, angiotensin-converting enzyme (ACE) inhibitors and angiotensin receptor blockers (ARBs) are the first-line drugs to treat hypertension in patients with CKD or end-stage kidney disease (ESKD). Diuretics, calcium channel blockers, and most other antihypertensive drugs, including centrally acting sympathetic inhibitors, are useful in combination with first-line agents, especially given that combination therapy is usually required to achieve recommended BP targets in CKD. Pure vasodilators (e.g., minoxidil) should be avoided because they may increase volume overload or occasionally cause pericardial effusion. Because sleep-disordered breathing occurs in about 50% of patients in CKD stages 4 to 5 and is associated with hypertension, sleep apnea should be considered in therapy-resistant hypertension.

Diabetes Mellitus

Optimal control of BP and glycemia (see Chapter 32) and treatment of dyslipidemia are crucial in managing diabetic CKD patients. Cardiovascular disease (CVD) should be treated aggressively in this high-risk group. Because the harm associated with severe hypoglycemia might counterbalance the potential benefit of intensive glucose-lowering treatment, treating to a hemoglobin A_{1c} (HbA_{1c}) level less than 7.0% (53 mmol/mol) is not recommended in CKD stages 3 to 5.[1] Sodium-glucose cotransporter 2 (SGLT2) inhibitors and glucagon-like peptide-1 receptor agonists reduce cardiovascular events in patients with type 2 diabetes at high cardiovascular risk. Thus, various guidelines recommend these agents in CKD and non-CKD patients with CVD and/or multiple cardiovascular risk factors.[2-4]

Mineralocorticoid Receptor Antagonism

Mineralocorticoid receptor antagonists reduce the aldosterone-mediated proinflammatory effects that are involved in the fibrotic remodeling processes. The new selective nonsteroidal mineralocorticoid receptor antagonist finerenone also blocks the damaging effects of the overactivated aldosterone system. In contrast to the mineralocorticoid receptor antagonists spironolactone and eplerenone, finerenone is equally distributed in myocardial and kidney tissue. Finerenone binds to the same ligand domain but to different amino acids, leading to a different expression pattern of cardiac genes compared with spironolactone and eplerenone. Finerenone also reduced cardiac fibrosis and inflammation more than eplerenone in animal experiments at a comparable dose. In a large cardiovascular outcome trial (FIDELIO-DKD [Finerenone in Reducing CV Mortality and Morbidity in Diabetic Kidney Disease]) in type 2 diabetic patients with CKD, finerenone compared with placebo reduced the risk of kidney failure, cardiovascular death, nonfatal myocardial infarction (MI), nonfatal stroke, or hospitalization for congestive heart failure (CHF) with a low incidence of hyperkalemia.[5] Based on the inclusion criteria of the trial, patients with diabetes and moderately increased albuminuria and impaired estimated glomerular filtration rate (eGFR) or severely increased albuminuria and eGFR should be treated with finerenone.

SGLT2 Inhibitor Treatment

SGLT2 inhibitors cause glucosuria and osmotic diuresis along with weight loss and natriuresis (see Chapter 32). In patients with diabetes, SGLT2 inhibitors significantly reduced cardiovascular morbidity and mortality. CREDENCE (Canagliflozin and renal outcomes in diabetic nephropathy) was the first study with an SGLT2 inhibitor in type 2 diabetic patients with CKD (eGFR ≥30 to <90 mL/min/1.73 m^2) with a combined primary kidney endpoint[6]: within 2.5 years, canagliflozin reduced the risk of kidney replacement therapy, doubling of serum creatinine and death due to kidney insufficiency by 33% versus placebo in addition to reductions of major cardiovascular events and hospitalization for CHF. The DAPA-CKD (Dapagliflozin And Prevention of Adverse outcomes in Chronic Kidney Disease) trial showed that in patients with nondiabetic CKD (eGFR 25–75 mL/min/1.73 m^2), dapagliflozin reduced not only the primary endpoint of sustained decline in eGFR of 50% or more, ESKD, and kidney or cardiovascular

death but also the secondary endpoint of heart failure hospitalization and cardiovascular death.[7]

Dyslipidemia

Because CKD, like diabetes, is considered a cardiovascular risk equivalent, CKD patients should be treated to achieve the guideline goal for secondary prevention for low-density lipoprotein (LDL) cholesterol (<55 mg/dL) if eGFR is less than 30 mL/min/1.73 m^2 or less than 70 mg/dL in patients with CKD stage 3.[4] Post hoc subgroup analyses in the Heart Protection Study, Cholesterol and Recurring Events (CARE) study and the Treating to New Targets (TNT) study support the use of statins in improving outcomes in CKD stages 1 to 2. The Study of Heart and Renal Protection (SHARP) showed that reducing LDL cholesterol with simvastatin 20 mg/day plus ezetimibe 10 mg/day safely reduced the incidence of major atherosclerotic events in patients with advanced CKD.[8] However, the negative results from the 4D study and A Study to Evaluate the Use of Rosuvastatin in Subjects on Regular Hemodialysis: An Assessment of Survival and Cardiovascular Events (AURORA) do not support initiation of statins (with or without ezetimibe) in dialysis patients. Overall, the beneficial effect of lipid-lowering therapies is attenuated in subjects with low glomerular filtration rate (GFR) and very limited in ESKD patients on HD (Table 81.1).

Anemia

Partial correction of severe anemia with erythropoiesis-stimulating agents (ESAs) results in regression of left ventricular hypertrophy (LVH), and treatment of severe anemia is also associated with fewer ischemic symptoms in coronary heart disease patients. However, randomized controlled trials in HD and CKD patients have shown no benefit of ESA treatment on mortality (see Chapter 86). Thus, anemia correction in patients with advanced CKD to a hemoglobin level of 10 to 12 g/dL is recommended (www.kdigo.org).

Inflammation

A careful search for infectious processes, such as periodontal disease, is recommended in dialysis patients with inflammation. Restriction of central venous catheter use is also important; short daily dialysis with better fluid status was associated with decreasing C-reactive protein (CRP) levels compared with conventional HD. Volume status should be carefully monitored to avoid inflammation. Altered intestinal microbial flora as a potential risk factor for systemic uremic inflammation merits further study. Medium cutoff dialysis membranes reduce uremic inflammation,[9] but larger trials with longer treatment periods are encouraged. Interestingly, the CANTOS trial (Canakinumab Antiinflammatory Thrombosis Outcome Study) demonstrated that inhibiting proinflammatory effector molecule interleukin-1β (IL-1β) with canakinumab reduced the risk of cardiovascular events, and that the benefit appeared larger in patients with eGFR less than 60 mL/min/1.73 m^2 than in those with eGFR greater than or equal to 60 mL/min/1.73 m^2.[10]

Chronic Kidney Disease–Mineral Bone Disorder

Recent meta-analyses and the updated Kidney Disease: Improving Global Outcomes (KDIGO) chronic kidney disease–mineral bone disorder (CKD-MBD) guidelines (www.kdigo.org) suggest that avoiding calcium-containing phosphate binders may reduce cardiovascular events, calcification progress, and mortality; however, there is a low level of evidence and multiple studies have not confirmed this (see Chapter 88). We suggest that these agents should be avoided in CKD patients with significant life expectancy, particularly in patients on the transplant waiting list, independent of the presence or absence of calcifications. The potential detrimental effects of sevelamer (and other commonly used drugs) on gut microflora require further studies.[11]

Results from the Dialysis Outcomes and Practice Patterns Study (DOPPS) call into question the survival advantage for HD patients taking vitamin D. In the Paricalcitol Capsules Benefits Renal Failure Induced Cardiac Morbidity in Subjects with CKD Stage 3/4 (PRIMO) study, 48 weeks of paricalcitol therapy did not alter cardiac mass index or improve measures of diastolic dysfunction.[12] Thus, the use of native vitamin D or vitamin D receptor agonists in CKD patients should primarily be governed by CKD-MBD parameters (see Chapter 88).

The Evaluation of Cinacalcet HCl Therapy to Lower Cardiovascular Events (EVOLVE) study[13] showed that cinacalcet only reduced the risk for death or major cardiovascular events in dialysis patients with moderate to severe secondary hyperparathyroidism after adjustment for age—a nominally significant finding. In a second trial in similar dialysis patients, cinacalcet plus low-dose vitamin D sterols tended to attenuate vascular and cardiac valve calcification compared with an exclusively vitamin D sterol–based approach.[14]

FGF-23, a bone hormone, is cardiotoxic and induces LVH but does not induce vascular calcification. In a post hoc analysis of EVOLVE data, treatment of secondary hyperparathyroidism with cinacalcet was associated with reduced FGF-23 levels, and patients with a 30% or 50% drop in FGF-23 levels experienced significantly fewer cardiovascular events.[15] In patients with advanced secondary hyperparathyroidism, treatment with a calcimimetic alone may therefore be preferred to combined therapy with a vitamin D agonist.

CORONARY ARTERY DISEASE IN PATIENTS WITH CHRONIC KIDNEY DISEASE

With respect to the diagnosis of coronary artery disease (CAD), noninvasive stress testing shows reduced accuracy in patients with CKD and in particular in those on HD. Both medical and interventional therapy of acute or chronic coronary syndromes are not different between patients with or without CKD, and patients with CKD should receive a similarly stringent treatment with drugs/procedures that have been shown to provide a prognostic benefit.

Chronic Coronary Syndrome

Diagnosis

CAD in patients with CKD differs from nonrenal controls by exhibiting more and larger plaques and more signs of inflammation.[16] Dialysis patients also exhibited more calcified plaques in coronary arteries, whereas plaques of nonrenal patients were mostly fibroatheromatous.[17] In addition, a lower eGFR was associated with increased numbers of newly formed intramural blood vessels and intraplaque hemorrhages,[17,18] suggesting a more vulnerable plaque phenotype.

In CKD patients with suspected obstructive CAD, special attention should be paid to the fact that symptomatic angina is less common, whereas silent ischemia is more common.[19] The diagnostic approach to CAD in CKD patients is similar compared with non-CKD patients,[4] except that accuracy of noninvasive testing is lower, particularly in dialysis patients.[20] The National Kidney Foundation's Kidney Disease Outcomes Quality Initiative (KDOQI) clinical practice guidelines for CVD in dialysis patients recommend an electrocardiogram at dialysis initiation and then annually.[21]

In addition, KDOQI guidelines recommend echocardiography in all dialysis patients after they achieve "dry weight" targets, preferably 1 to 3 months after dialysis initiation on an interdialytic day for HD patients and at 3-year intervals thereafter.[22] The rationale is that diminished left ventricular (LV) systolic function, an important independent risk factor for CVD and mortality,[23] is not accurately diagnosed

Accuracy of DSE vs MPS for Diagnosing CAD in Kidney Transplant Recipients

	Posttest Probability		
Test	**Pretest probability (%) of coronary artery disease**	**Posttest probability (%) after positive result**	**Posttest probability (%) after negative result**
Dobutamine stress echocardiography (DSE)	Low risk (10-29)	42-72	3-10
	Intermediate risk (30-59)	73-90	10-27
	High risk (60-90)	91-98	28-70
Myocardial perfusion scintigraphy (MPS)	Low risk (10-29)	24-54	5-15
	Intermediate risk (30-59)	55-81	16-38
	High risk (60-90)	81-96	39-79

Fig. 85.1 Pre test and post test probabilities of coronary artery disease (CAD) associated with positive and negative results of dobutamine stress echocardiography (DSE) versus myocardial perfusion scintigraphy (MPS) in renal kidney transplant candidates. (From Shroff GR, Herzog CA. Coronary revascularization in patients with CKD stage 5D: pragmatic considerations. *J Am Soc Nephrol.* 2016;27:3521–3529.)

by history, physical examination, or chest radiography. Detection of unsuspected cardiomyopathy is also important, given that carvedilol therapy in such patients improved LV systolic function, decreased hospitalization, and reduced mortality. As in the general population, CKD patients with left ventricular ejection fraction (LVEF) below 40% should be evaluated for coronary heart disease (exceptions are pediatric or young adult patients with nondiabetic CKD and other patients known to be at low risk for CAD).

Overall, noninvasive stress testing shows reduced accuracy (vs. invasive coronary angiography) in patients with advanced CKD[24] compared with patients with normal kidney function. The accuracy of both pharmacologic stress echocardiography and single-photon emission computed tomographic nuclear imaging is lowest in ESKD patients even under the most optimal circumstances (i.e., in clinics with a high level of expertise). Reviews cite overall sensitivity percentages in the mid-70s and specificity in the mid-80s for stress echocardiography and sensitivity and specificity in the mid-70s for SPECT myocardial perfusion imaging. Based on Medicare data, 87% of cardiac stress testing in US patients with CKD employs nuclear scintigraphy.[25]

ESKD patients are poorly suited for conventional exercise stress electrocardiography because of limited exercise tolerance and frequent resting electrocardiographic abnormalities. As noted earlier, even under optimal circumstances, the most widely used stress imaging techniques (compared with invasive coronary angiography) are at best imperfect, and in real-world clinical practice they may even be worse. For this reason, local institutional expertise with imaging of ESKD patients will dictate clinical practice irrespective of the published "theoretical" accuracy. Moreover, prediction of the likelihood of future events may differ considerably from predictions based on coronary anatomy. Noninvasive stress testing is probably better at predicting mortality than coronary anatomy—something that continues to vex clinicians, as typically in an individual patient we don't want to miss "significant" obstructive CAD (i.e., angiographic definition), yet from the broader perspective of population epidemiology, the focus is on events like MI or death (not angiographic stenoses). A meta-analysis concluded that presence of inducible myocardial ischemia by any stress-imaging test is independently predictive of increased acute MI risk and cardiac death, whereas a fixed or resting defect or abnormality is predictive of cardiac death but not acute MI.[26]

In kidney transplant candidates the sensitivities and specificities of stress nuclear and echocardiographic imaging for detection of coronary heart disease have been reported to range from 44% to 90%—not terribly helpful to the nephrologist or even cardiologist dealing with an individual patient. Consistent with others,[25] a meta-analysis (Fig. 85.1) concluded that dobutamine stress echocardiography is probably more accurate than myocardial stress nuclear scintigraphy for noninvasive

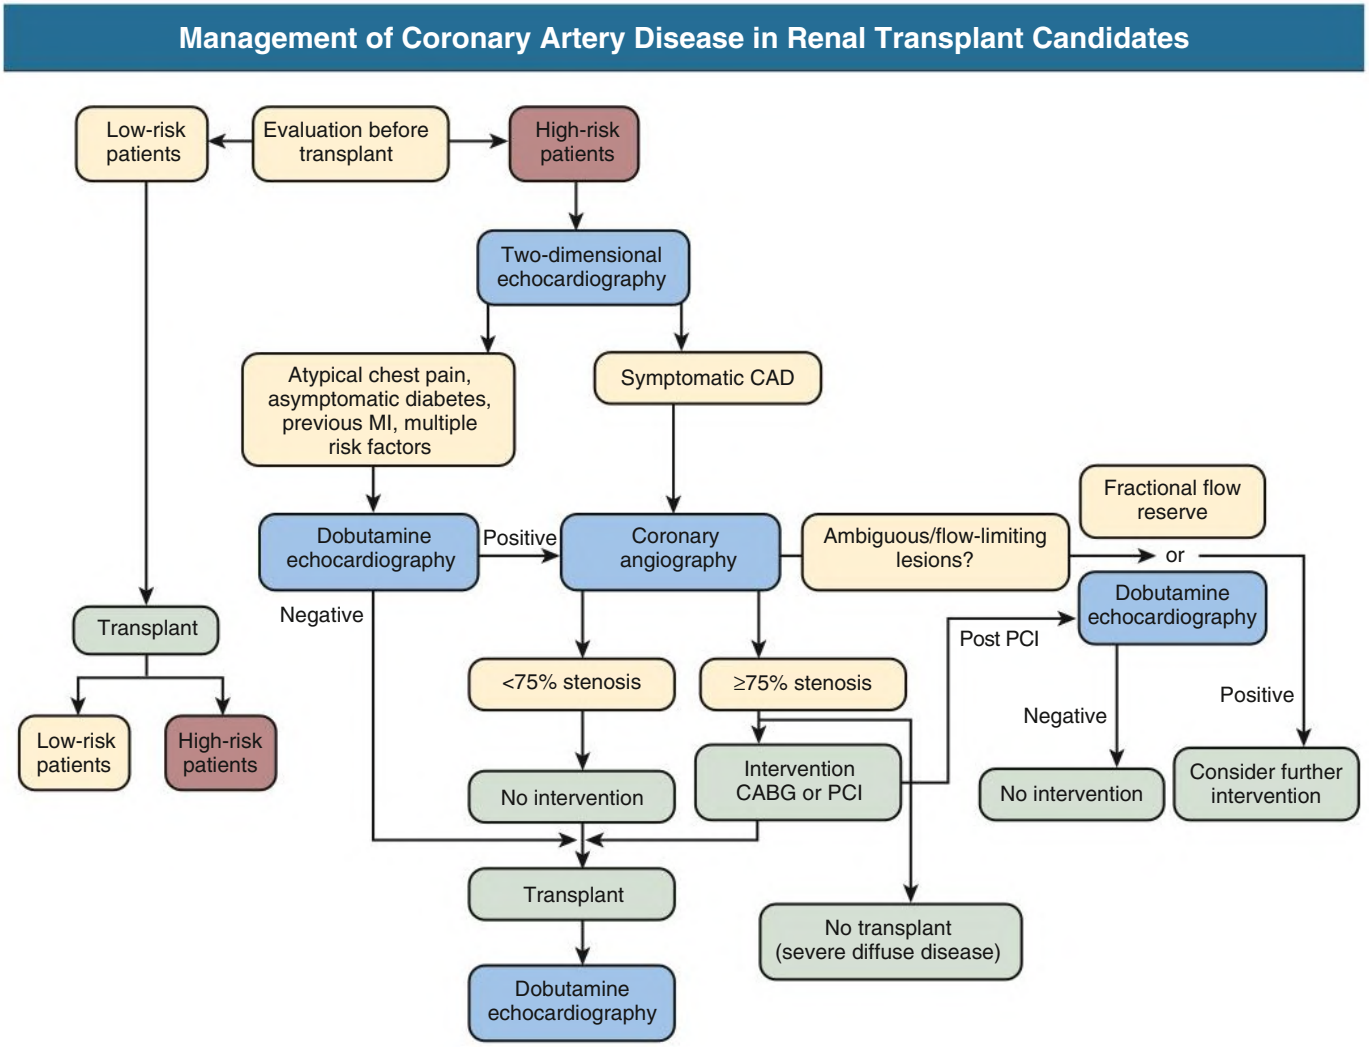

Fig. 85.2 Algorithm for management of coronary heart disease in kidney transplant candidates. *CABG,* Coronary artery bypass graft surgery; *CAD,* coronary artery disease; *MI,* myocardial infarction; *PCI,* percutaneous coronary intervention. (Modified from Herzog CA. Acute MI in dialysis patients: how can we improve the outlook? *J Crit Illn.* 1999;14[11]:613–621.)

detection of coronary heart disease in kidney transplant candidates.[27] However, a recent analysis concluded "there are no compelling reasons to routinely select one particular stress imaging modality in preference to others, although there may specific circumstances that favor a particular test."[25]

The major problem with searching for CAD in asymptomatic kidney transplant candidates (or dialysis patients) is that the evidence for prophylactic revascularization is weak.[21] The best observational data supporting preemptive coronary revascularization showed a 3-year cardiac event–free survival of 90% for transplant wait-listed revascularized patients.[28] Optimal medical therapy (which should constitute the treatment strategy for all patients) may potentially attenuate the putative benefit of prophylactic coronary revascularization. One algorithm for screening and management of CAD in kidney transplant candidates is presented in Fig. 85.2. However, challenging the rationale for this or any other algorithm employing prophylactic coronary revascularization, in the ISCHEMIA-CKD trial (see later) an invasive strategy of optimal medical therapy and coronary angiography (with revascularization) did not improve outcomes compared with optimal medical therapy alone.[29]

Biomarkers

Plasma brain natriuretic peptides (BNP and NT-proBNP), cardiac troponins (cTnT, cTnI), and high-sensitivity CRP (hsCRP) are prognostic risk markers in the evaluation of heart disease in ESKD.[30] BNP reflects cardiac filling pressures (not limited to the left heart), troponins reflect myocardial cell death (but not necessarily ischemia), and hsCRP reflects inflammation. Elevation of cTnT occurs even in pediatric CKD patients and is associated with cardiac dysfunction. Elevated levels of serum troponin in ESKD patients should not be uncritically attributed to myocardial ischemia caused by obstructive CAD as they also reflect the presence and severity of HD-induced myocardial stunning.[31] The cardiac biomarker–based diagnosis of acute coronary syndrome requires a time-appropriate rise and fall of the biomarker. Fig. 85.3 graphically displays the relationship of cTnT and cTnI levels in asymptomatic dialysis patients and long-term survival. On the basis of these data, the US Food and Drug Administration approved the measurement of cTnT in dialysis patients for risk stratification (mortality prediction).

High-sensitivity cardiac troponin (hs-cTn) assays are highly precise and serve two complementary roles: the diagnosis of acute MI

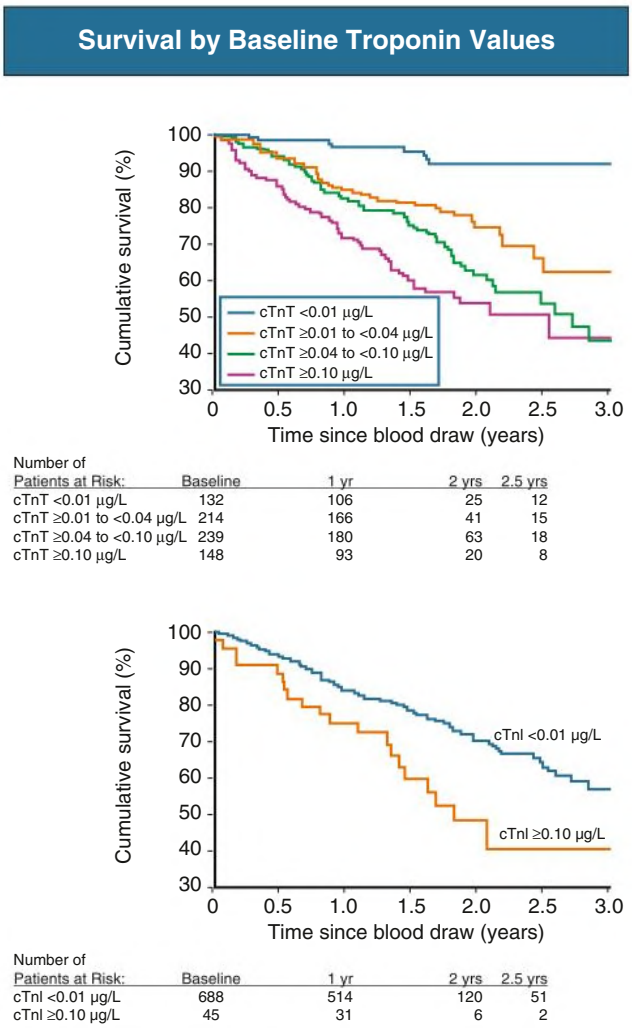

Fig. 85.3 Kaplan-Meier survival curves by baseline troponin values. *cTnI,* Cardiac troponin I; *cTnT,* cardiac troponin T. (From Apple FS, Murakami MM, Pearce LA, Herzog CA. Predictive value of cardiac troponin I and T for subsequent death in end-stage renal disease. *Circulation.* 2002;106:2941–2945.)

and risk stratification based on detection of hs-cTn in asymptomatic patients (e.g., perhaps a marker for apoptosis). Similar to elevated troponin serum levels discussed earlier, hs-cTn–based risk stratification should also employ changes in values over time, rather than simple thresholds.[32]

Coronary Angiography

Coronary angiography should be considered in stable ESKD patients with evidence for inducible myocardial ischemia, unstable patients with acute coronary syndrome (performed urgently for ST-segment elevation MI [STEMI]), and patients with LVEF less than 40%. In CKD and dialysis patients with residual kidney function, fear of contrast nephropathy may restrain use of coronary angiography (see Chapter 74 for preventive measures). However, one retrospective study of 76 nondialysis patients with mean eGFR of 12.5 mL/min/1.73 m^2 found no significant postangiographic deterioration in kidney function. Although acute kidney injury (AKI) after coronary angiography increases the risk of mortality, ESKD, and hospitalization,[33] fear of AKI should not deter clinically mandated coronary angiography. Echocardiography should be performed before any nonemergent coronary angiography in CKD patients to diagnose clinically unsuspected valvular disease or cardiomyopathy, to gauge preprocedure volume status, and to assess LV function (to avoid excessive exposure to radiocontrast media through unwarranted ventriculography).

Noninvasive coronary CT angiography may be problematic in dialysis patients because of medial calcification interfering with angiographic interpretation.[34] Coronary CT angiography is noninvasive and has similar accuracy to invasive coronary angiography but is associated with a lower risk of significant AKI in kidney transplant candidates. Noninvasive gadolinium-based magnetic resonance angiographic imaging in patients with severe CKD remains problematic because of residual concerns about nephrogenic fibrosing dermopathy (see Chapter 91).

Drug Therapy in Chronic Coronary Syndrome Patients With Chronic Kidney Disease

According to current guidelines, drug therapy in chronic coronary syndrome (CCS) patients with CKD should not differ from therapy in non-CKD patients, but renally excreted drugs used in CCS should be dose adjusted for kidney function.

Revascularization

CKD is a strong risk factor for death after coronary revascularization with percutaneous coronary intervention (PCI) or coronary artery bypass grafting (CABG).[35,36] Coronary revascularization complicated by AKI is associated with excess mortality; operative mortality for non-CKD patients who require acute dialysis after cardiac surgery is 44%.

Observational studies suggest lower mortality in CKD (including dialysis) patients undergoing coronary revascularization compared with no revascularization. A post hoc analysis of CKD patients in the Fast Revascularization During Instability in Coronary Artery Disease (FRISC II) trial indicated a superior outcome with an early invasive strategy in ACS compared with conservative management. However, the optimal coronary revascularization method in CKD remains controversial. A post hoc analysis of CKD patients enrolled in the Arterial Revascularization Therapies Study (ARTS) found similar outcomes for CABG or multivessel PCI with non–drug-eluting stents for death, MI, or stroke. In elderly non–dialysis-dependent CKD patients, the incidence of ESKD was lower after PCI (5.4% at 3 years vs. 6.8% for CABG), but long-term risk for death (3-year mortality with PCI 33% vs. 28% with CABG) or the combined event of death or ESKD was lower after CABG. The relative survival advantage of CABG versus PCI occurs only more than 6 months after revascularization.[37] Dialysis patient survival after CABG is better than after PCI with non–drug-eluting stents[38] and drug-eluting stents,[39] but 2-year mortality remains high at 44% versus 52% for PCI.[38] In the absence of data from dedicated cardiovascular outcome trials in patients with ESKD or on HD, recommendations are based on large observational studies. Current guidelines recommend that the revascularization strategy (PCI vs. CABG) should be chosen based on the general condition, preferences, and life expectancy of the patient, the least invasive approach being more appropriate in the most fragile and compromised patients.[40]

The ISCHEMIA-CKD trial compared an invasive or conservative care approach in CKD patients (eGFR <30 mL/min/1.73 m^2 or dialysis) with stable CAD. Patients with moderate or severe ischemia on stress testing were randomly assigned to an initial invasive strategy consisting of coronary angiography and revascularization (if appropriate) added to medical therapy or an initial conservative strategy consisting of medical therapy alone and angiography reserved for those in whom medical therapy failed. After a median follow-up of 2.2 years, there was no difference for the primary composite endpoint of death or nonfatal MI between groups. Compared with the conservative strategy, the invasive strategy was associated with a significantly

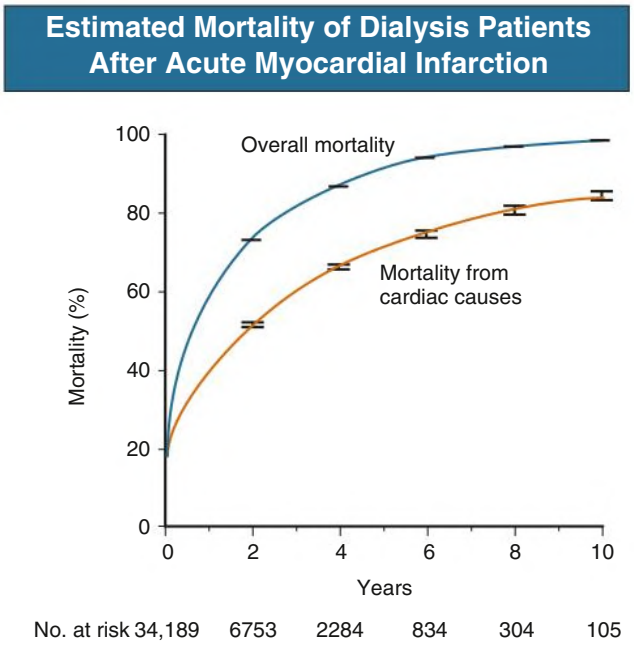

Fig. 85.4 Estimated mortality of dialysis patients after acute myocardial infarction. (From Herzog CA, Ma JZ, Collins AJ. Poor long-term survival after acute myocardial infarction among patients on long-term dialysis. *N Engl J Med* 1998;339:799–805.)

higher incidence of stroke and a higher incidence of death or initiation of dialysis.[29] In addition, both groups did not differ with respect to angina-related health status during follow-up.[41]

Acute Coronary Syndrome

Acute MI in dialysis patients is associated with poor long-term survival. Unadjusted 2-year mortality has not improved over time (71% in 1977–1984 and 72% in 2008[42]) despite dramatic improvements in acute MI outcomes in the general population (Fig. 85.4). Significant improvement has occurred only in dialysis patients with STEMI, specifically related to in-hospital mortality. Rates of non-STEMI (NSTEMI) mortality or postdischarge mortality have not improved.[42] In-hospital mortality increases with decreasing GFR, which has been attributed to underrecognition resulting from atypical presentations, underuse of appropriate diagnostic investigations, and undertreatment (therapeutic nihilism).[43] A US registry of dialysis patients hospitalized for acute MI found the following[43]:

- With respect to acute coronary syndrome, 45% of dialysis patients were diagnosed incorrectly versus 21% of nondialysis patients.
- ST-segment elevation was found in 19% of dialysis patients versus 36% of nondialysis patients.
- After other clinical exclusions, 10% of dialysis patients and 25% of nondialysis patients were eligible for acute coronary reperfusion.
- Of those who were eligible, 47% of dialysis patients and 75% of nondialysis patients actually received reperfusion.

Similar findings occur across the CKD spectrum; the likelihood of increased mortality and lower prevalence of both STEMI and chest pain are correlated with severity of non–dialysis-dependent CKD in patients with acute MI.[44,45] Compared with those with normal eGFR, patients with eGFR less than 45 mL/min/1.73 m^2 are three times as likely to present with acute MI as the initial manifestation of coronary heart disease, rather than stable angina.

Given the poor prognosis of patients with acute MI and the fact that CKD patients are less likely to receive appropriate therapy, current guidelines recommend that acute coronary syndrome patients with CKD should be treated as aggressively as in patients without CKD.

HEART FAILURE IN PATIENTS WITH CHRONIC KIDNEY DISEASE

Patients with CKD show an increased risk to develop heart failure, and the presence of this comorbidity tremendously impairs the prognosis of CKD patients. Some therapeutic approaches in heart failure in patients have not been tested in patients with advanced CKD. However, SGLT2 inhibitors have shown benefit in both patients with heart failure and CKD and should be used in CKD patients not on HD (see Chapter 82).

Heart failure in patients with CKD, in particular those on HD, is possibly related to maladaptive ventricular hypertrophy and fibrosis.[46] LVH occurs early in progressive CKD, probably because of high hypertension prevalence, including frequent nocturnal hypertension. Pressure overload, caused by hypertension and arterial stiffness, results in concentric hypertrophy. Volume overload manifests as eccentric hypertrophy. Left ventricular dilation strongly predicts poor outcome. It may be an end result of severe LVH, diffuse ischemic damage, or recurrent volume overload; a high-output arteriovenous fistula may contribute. Diastolic dysfunction is strongly associated with LVH and risk for intradialytic hypotension.

Hemodialysis can produce repetitive myocardial injury, leading to global and segmental reduction in left ventricular systolic function; HD-induced myocardial stunning is associated with increased 1-year mortality. Even pediatric HD patients can experience HD-induced myocardial stunning, indicating that large-vessel obstructive CAD is not a prerequisite for this pathologic finding. Biofeedback dialysis or reduced dialysate temperature can help reduce intradialytic hypotension and severity of HD-induced myocardial stunning.

With respect to HF diagnosis, NT-proBNP and BNP are equivalent predictors of decompensated heart failure in CKD, but NT-proBNP is a better predictor of survival.

Congestive Heart Failure Treatment in Patients With Chronic Kidney Disease

No treatments convincingly reduce morbidity and mortality in CKD patients with CHF and preserved ejection fraction (HFpEF; LVEF ≥50%) or moderately impaired left ventricular function (HFmrEF; LVEF 40%–49%).

Therapy of Heart Failure and Reduced Ejection Fraction in Chronic Kidney Disease

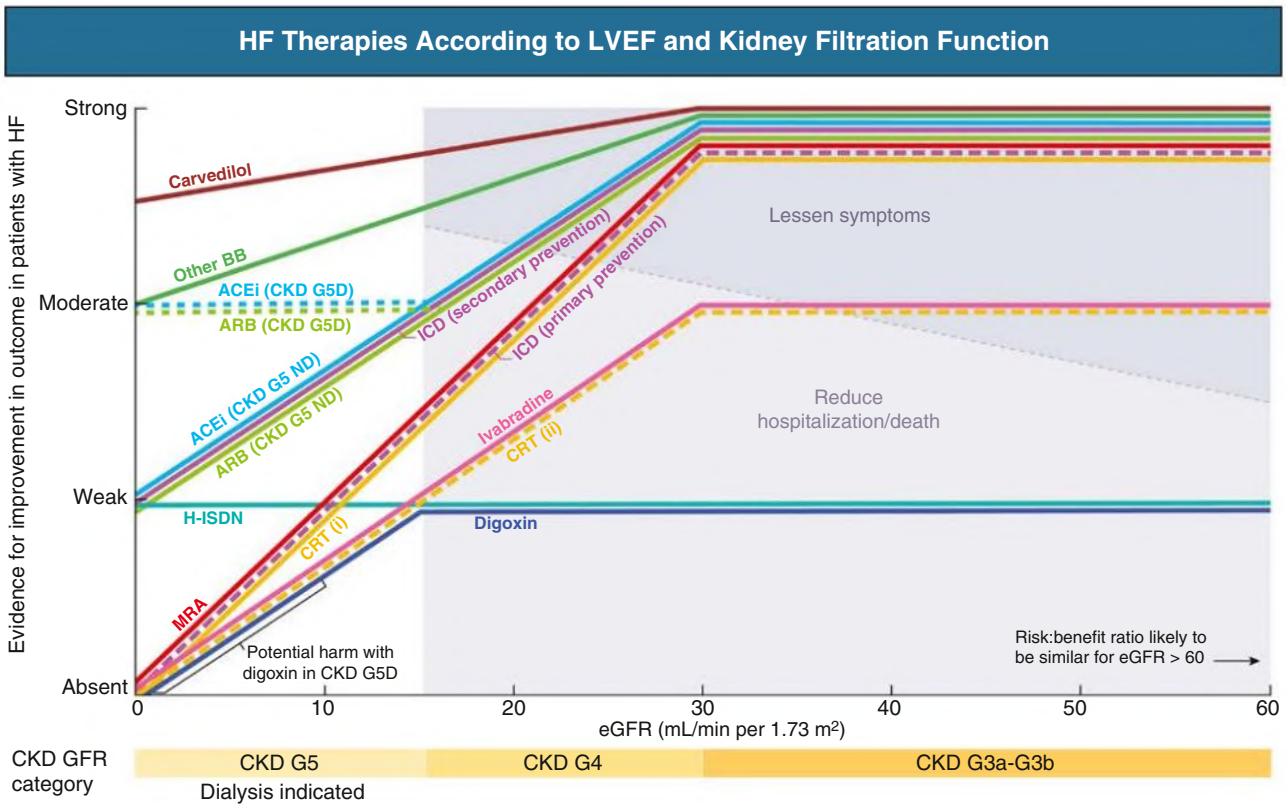
Treatment of CHF in the general population is based on data from large cardiovascular outcome trials that have led to the development of certain treatment algorithms.[47] However, patients with severe CKD were excluded from the landmark trials, and therefore recommendations for this group are largely based on data from the general population (Fig. 85.5).[48]

ACE Inhibitors/Angiotensin 2 Receptor Blockers

ACE-inhibitors reduce morbidity and mortality in patients with heart failure, and reduced ejection fraction (HFrEF) and solid data exist for the use of ACE-inhibitors in patients with CKD stage I–III plus HFrEF, but no data exist for those with CKD stages 4 to 5. In patients with ACE-inhibitor intolerance it is recommended to treat with an angiotensin receptor blocker (ARB).

β-Blockers

First-line therapy in patients with HFrEF also includes treatment with β-blockers. A meta-analysis of six studies analyzing the effect of β-blocker therapy in CHF and CKD stages 3 to 5 show that patients with advanced CKD benefited from β-blocker therapy.[49]



CRT (i) = QRS > 120 ms, LBBB QRS morphology, EF ≤ 35%; or QRS > 130 ms, EF ≤ 30%
CRT (ii) = QRS > 150 ms

Loop diuretics (p.o./i.v.) (furosemide, bumetanide, torsemide) and thiazide diuretics (metolazone [p.o.], chlorothiazide [i.v.]) = benefit uncertain

(From House AA, Wanner C, Sarnak MJ, et al. Heart failure in chronic kidney disease: conclusions from a Kidney Disease: Improving Global Outcomes (KDIGO) Controversies Conference. *Kidney Int.* 2019;95:1304–1317.)

Mineralocorticoid Receptor Antagonists

If patients with HFrEF and a medication of ACE inhibitors and β-blockers are still symptomatic, and if LV ejection fraction is 35% or less, they should be treated with a mineralocorticoid receptor antagonist with attention in particular to the development of hyperkalemia. These agents are effective in patients with CHF and CKD stages 1 to 3[50] but are contraindicated in CKD stages 4 to 5.

Diuretics

Treatment with diuretics is indicated in patients with venous congestion and New York Heart Association (NYHA) II, as well as in patients with CHF stage NYHA III and IV. Patients can be treated with loop diuretics or thiazides, but patients with CKD stages 4 to 5 should receive either loop diuretics alone or thiazides in combination with loop diuretics. In particular, the latter should be monitored for hypokalemia. After cardiac decompensation, at least a low-dose diuretic therapy should be continued.

Angiotensin Receptor Neprilysin Inhibitor

If patients treated with a combination of ACE inhibitors, β-blockers, and mineralocorticoid receptor antagonists are still symptomatic, and if ACE inhibitors have been well tolerated, it is recommended to change from ACE inhibitors or ARBs to angiotensin receptor neprilysin inhibitor (ARNI) treatment provided that kidney function permits. For LCZ696 (sacubitril + valsartan), a reduction of mortality, cardiovascular mortality, and CHF hospitalization has been shown in comparison to enalapril, and this benefit has also been found in patients with eGFR of 30 to 60 mL/min/1.73 m^2.[51] Therefore, ARNIs are effective in patients with heart failure and CKD stages 1 to 3; in patients with CKD stages 4 to 5, no data are available.

SGLT2 Inhibitors

Two large cardiovascular outcome trials conducted in patients with HFrEF with or without diabetes have shown that dapagliflozin or empagliflozin significantly reduce the combined endpoint of cardiovascular death and CHF hospitalization compared with placebo. In addition, these agents reduce kidney endpoints and worsening of nephropathy. Given that these studies included patients with eGFR as low as 30 mL/min/1.73 m^2 (DAPA-HF)[52] or 20 mL/min/1.73 m^2 (EMPEROR-Reduced),[53] these agents seem to be effective in patients with CKD stages 3 to 4. Based on these data, one of the SGLT2-inhibitors, dapagliflozin, has recently been approved for use in patients with HFrEF and eGFR as low as 30 mL/min/1.73 m^2 independent of the presence of diabetes.

Extracellular Volume Overload

Extracellular volume overload resulting from loss of sodium excretory capacity is the major cause of hypertension in dialysis patients.

Whether prevention of recurrent hypervolemia reduces cardiovascular morbidity and mortality remains unproven. If adjustments are made for comorbidity and advanced age, a strong, incremental risk for all-cause and cardiovascular mortality is associated with interdialytic weight gains. Recurrent hypervolemia may result in LVH and dilation, peripheral or pulmonary edema, jugular venous distension, or a third heart sound, or it may be largely asymptomatic. Tolerance of large ultrafiltration volumes intradialytic or increase in blood pressure may indicate that the dry weight target (see Chapter 99) has not been reached. Reaching the optimal dry weight does not necessarily lead to normotension; a lag phase of some weeks can precede improvement.

ARRHYTHMIAS IN PATIENTS WITH CHRONIC KIDNEY DISEASE

Atrial Fibrillation

Atrial fibrillation (AF) is the most common arrhythmia in advanced CKD, and its incidence is increasing in older patients initiating dialysis in the United States.[54] Incident AF is an independent risk factor for development of ESKD in CKD.[55] The historically reported prevalence among dialysis patients is 15% to 20%, but small series employing implantable loop recorders suggest that the true prevalence may be as high as 27% to 40%, if episodes of paroxysmal AF are included.[56]

No trials have examined the clinical benefits and risks of anticoagulation in CKD populations specifically. In observational studies, adjusted-dose warfarin was associated with a 76% reduction in the relative risk for ischemic stroke or systemic embolism among AF patients with CKD stage 3.[57] Irrespective of CKD severity, in nondialysis acute MI patients with AF, warfarin treatment was associated with a lower 1-year risk for the composite outcome of death, MI, and ischemic stroke without a higher risk for bleeding. In contrast, the usefulness of warfarin for primary prevention of stroke in dialysis patients with AF is controversial; some observational studies suggest harm, and a consensus statement from KDIGO did not advise routine warfarin therapy for primary prevention of stroke in AF patients with CKD stage 5D (however, warfarin for secondary prevention of stroke was suggested based on expert opinion).[58,59] Warfarin use in dialysis patients is also challenging given the difficulty of maintaining the optimal anticoagulation range and the potential for accelerated vascular calcification with vitamin K antagonists. Post hoc analyses from randomized controlled trials suggest beneficial effects of direct oral anticoagulants compared with warfarin in moderate CKD (Fig. 85.6); however, in dialysis patients, treatment with apixaban was not associated with a lower incidence of new stroke, transient ischemic attack, or systemic thromboembolism but was associated with a higher incidence of fatal or intracranial bleeding.[60]

No data support the sole use of aspirin for prevention of stroke in CKD patients with AF.

Sudden Cardiac Death

In the US Renal Data System database, 85% of all cardiac deaths and 34% of all-cause mortality in HD patients were attributable to arrhythmias; although overall cardiovascular and all-cause mortality have improved over time, deaths attributable to arrhythmic mechanisms have not, leading to a larger proportion of mortality attributable to arrhythmia (Fig. 85.7).[61] The reported rate of cardiac arrest in HD centers is 3.8 to 7.1 events per 100,000 dialysis sessions. Strong predictors of sudden cardiac death are a history of coronary heart disease, peripheral arterial disease, diabetes, elevated inflammatory biomarkers, and reduced LVEF. Even a modest reduction in LVEF to 40% to 50% is prognostically important in both HD and peritoneal dialysis (PD) patients. Factors probably contributing to the special vulnerability of ESKD patients to sudden cardiac arrest include LVH, rapid electrolyte

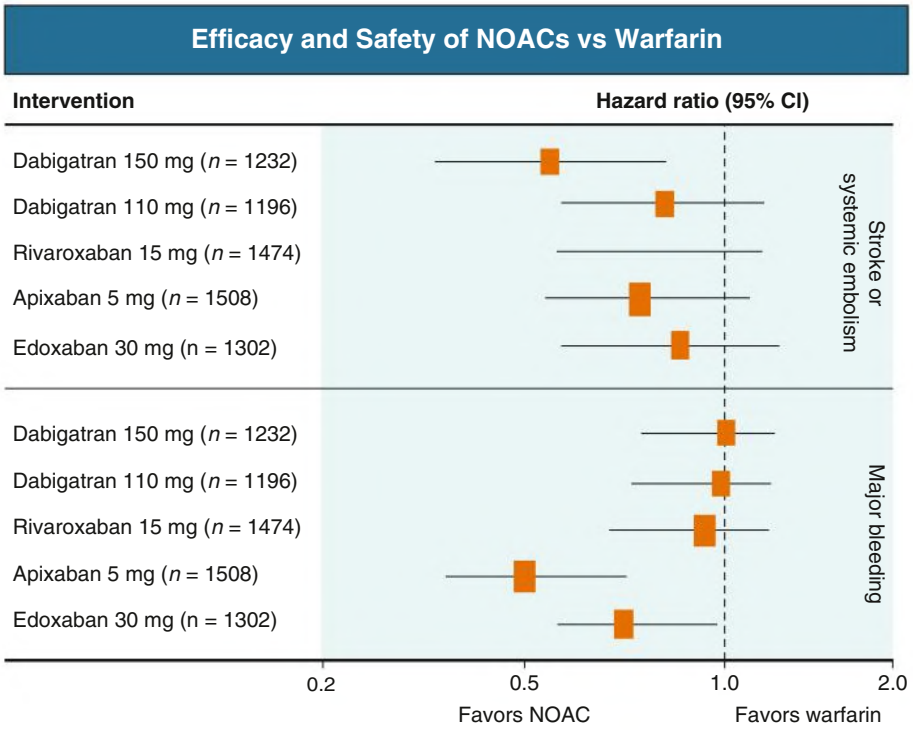


Fig. 85.6 Efficacy and safety of novel oral anticoagulants *(NOACs)* versus warfarin in the subgroup of patients with moderate chronic kidney disease from randomized, clinical trials in atrial fibrillation. *CI,* confidence interval. (From Qamar A, Bhatt DL. Stroke prevention in atrial fibrillation in patients with chronic kidney disease. *Circulation* 2016;133[15]:1512–1515.)

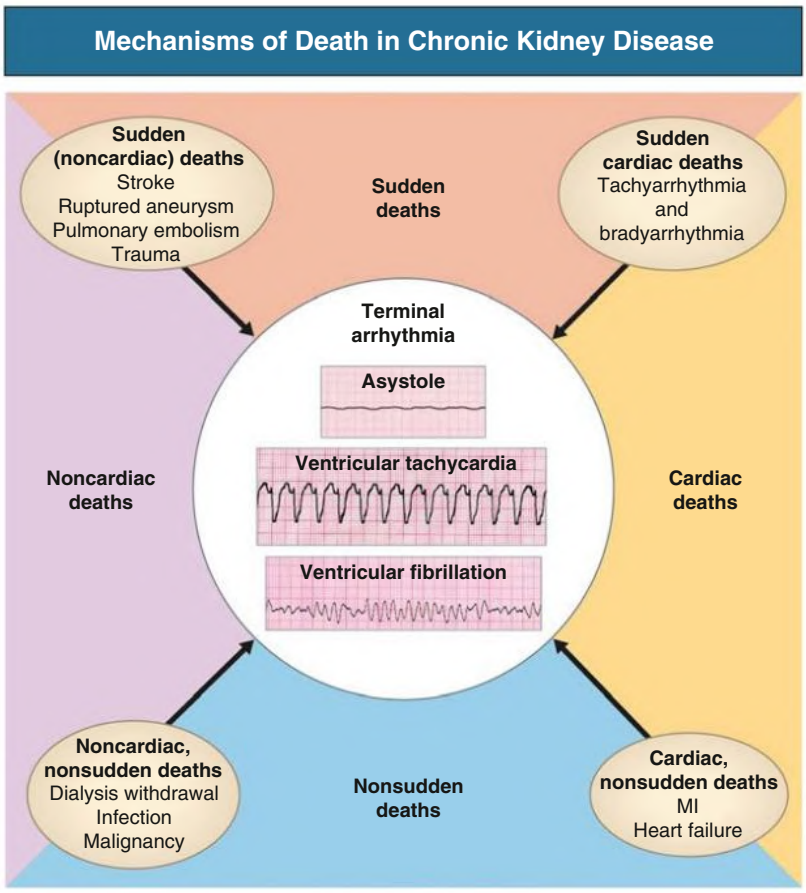

Fig. 85.7 Mechanisms of death in chronic kidney disease patients. *MI,* Myocardial infarction. (From Turakhia MP, Blankestijn PJ, Carrero JJ, et al. Chronic kidney disease and arrhythmias: conclusions from a Kidney Disease: Improving Global Outcomes (KDIGO) Controversies Conference. *Eur Heart J.* 2018;39:2314–2325.)

shifts and hyperkalemia in HD, autonomic dysfunction and sympathetic overactivity, including sleep apnea, and abnormalities in myocardial ultrastructure and function, including endothelial dysfunction, interstitial fibrosis, decreased perfusion reserve, and diminished ischemia tolerance.[62] Low-potassium dialysate (<2 mmol/L) doubles the risk for cardiac arrest.[63] The rate of cardiac arrest is 50% higher for HD than for PD patients at 3 months after dialysis initiation but is higher for PD patients at 3 years. The highest rate of sudden cardiac death occurs in the first 2 months after HD initiation.

On-site defibrillation capability in HD centers (preferably with automatic external defibrillators) was recommended in a US practice guideline in 2005. The role that implantable cardioverter-defibrillators (ICDs) may play in reducing mortality in CKD patients is controversial, particularly regarding primary prevention. CKD may attenuate the survival advantage of ICDs, but older age and medical comorbidity should not routinely exclude patients from receiving ICDs. Despite the small number of dialysis patients in clinical studies, guidelines also recommend primary prophylactic ICD implantation if the ejection fraction is 35% or less. A small randomized controlled trial for prevention of sudden cardiac death in dialysis patients with LVEF greater than 35%, the ICD-2 trial, was terminated for futility.[64]

VALVULAR DISEASE

The progression of calcific aortic valve stenosis is approximately three times faster in dialysis patients than in the general population (Fig. 85.8).[65] Annual echocardiography is recommended for asymptomatic dialysis patients with an aortic valve orifice area of less than 1.0

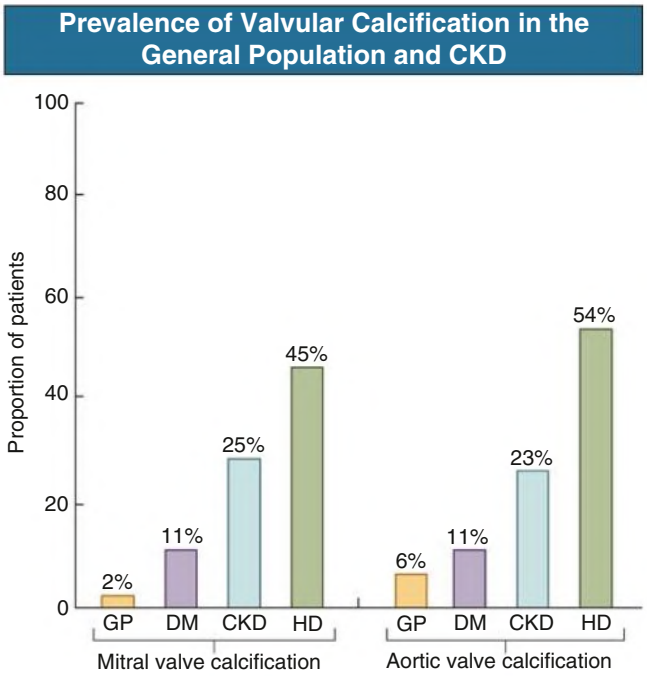

Fig. 85.8 Prevalence of valvular calcification in the general population and in patients with kidney disease. *CKD,* Chronic kidney disease; *DM,* diabetes mellitus; *GP,* general population; *HD,* hemodialysis. (From Marwick TH, Amann K, Bangalore S, et al. Chronic kidney disease and valvular heart disease: conclusions from a Kidney Disease: Improving Global Outcomes [KDIGO] Controversies Conference. *Kidney Int.* 2019;96:836–849.)

cm^2 who are suitable candidates for valve replacement. A meta-analysis of dialysis patients undergoing valve replacement surgery found no difference in survival for patients receiving tissue versus mechanical valves and fewer valve-related complications with tissue valves. The overall mortality is high, with in-hospital mortality about 20% (four times higher than in non-CKD patients) and a 2-year survival of 40%.[66] In kidney transplant recipients, in-hospital mortality was 11% for tissue and 15% for mechanical valve patients, and 2-year mortality rates were 62% and 60%, respectively. In the entire cohort of kidney transplant patients, the rate of endocarditis after valve surgery was 5% per year.[23]

Transcatheter aortic valve replacement may be appropriate in dialysis patients with symptomatic aortic stenosis who are not good candidates for surgery. Still, the prognosis of dialysis patients following transcatheter aortic valve replacement is worse compared with nondialysis patients.[67]

SELF-ASSESSMENT QUESTIONS

1. SGLT2 inhibitors have not been shown to reduce the risk of:
   A. hospitalization for heart failure.
   B. cardiovascular death.
   C. progression of kidney failure.
   D. myocardial infarction.
   E. progression to ESKD.
2. Strong predictors of sudden cardiac death in hemodialysis patients do not include:
   A. a history of CHD.
   B. a history of peripheral arterial disease.
   C. diabetes.
   D. reduced ejection fraction.
   E. a history of atrial fibrillation.
3. CKD patients with an estimated glomerular filtration rate less than 30 mL/min/1.73 m^2 should be treated to achieve the guideline goal for secondary prevention for low-density lipoprotein cholesterol of:
   A. less than 100 mg/dL.
   B. less than 70 mg/dL.
   C. less than 55 mg/dL.
   D. less than 40 mg/dL.
   E. less than 25 mg/dL.
4. Coronary artery disease in patients with CKD differs from non-CKD controls by exhibiting:
   A. more and larger plaques.
   B. fewer signs of inflammation.
   C. less calcification.
   D. fewer macrophages.
   E. fewer T-lymphocytes.

Anemia in Chronic Kidney Disease

Iain C. Macdougall, Kai-Uwe Eckardt

Anemia is an almost universal complication of chronic kidney disease (CKD). It contributes considerably to reduced quality of life (QOL) for patients with CKD and has been associated with a number of adverse clinical outcomes. Before the availability of recombinant human erythropoietin (EPO; epoetin), patients on dialysis frequently required blood transfusions, exposing them to the risks of iron overload, viral hepatitis, and human leukocyte antigen (HLA) sensitization, which reduced the chances of successful transplantation. The advent of erythropoiesis-stimulating agents (ESAs) in the late 1980s changed this situation completely. The ability to correct anemia has not only reduced fatigue and increased physical capacity but also improved a broad spectrum of physiologic functions. Thus, there is a strong rationale for managing anemia in CKD patients, and yet the optimal treatment strategies are still incompletely defined. Apart from therapy with ESAs, iron replacement is essential for anemia management, and thresholds for iron parameters in patients treated with maintenance dialysis must be more liberal than in those with normal kidney function to ensure optimal rates of red blood cell (RBC) production. The costs of anemia management have fallen but are still significant, and because full anemia correction may cause harm, careful consideration of the risks and benefits is mandatory.

PATHOGENESIS

The anemia associated with CKD is typically an isolated normochromic, normocytic anemia with no leukopenia or thrombocytopenia. Both RBC life span and the rate of RBC production are reduced, but the latter is more important. The normal bone marrow has sufficient capacity to compensate for the reduction in erythrocyte life observed in association with CKD, but this capacity is impaired in CKD. Serum EPO levels remain within the normal range and fail to show the inverse exponential relationship with blood oxygen content characteristic of other types of anemia. EPO is normally produced by interstitial fibroblasts in the kidney cortex, in close proximity to tubular epithelial cells and peritubular capillaries.[1,2] In addition, hepatocytes and perisinusoidal Ito cells in the liver can produce EPO (Fig. 86.1). Hepatic EPO production dominates during fetal and early postnatal life but does not compensate for the loss of kidney production in adult organisms. Subtle changes in blood oxygen content induced by anemia, reduced environmental oxygen concentrations, and high altitude stimulate the secretion of EPO through a widespread system of oxygen-dependent gene expression.[2–4] Central to this process is a family of hypoxia-inducible transcription factors (HIFs), composed of different oxygen-regulated α subunits and a constitutive β subunit. The production of HIF-α is largely independent of oxygen, but its degradation is related to cellular oxygen concentrations. Hydroxylation of specific prolyl and asparagyl residues of HIF-α, for which molecular oxygen is required as a substrate, determines proteasomal destruction of HIF and inhibits its transcriptional activity. Apart from EPO, several hundred HIF target genes have been identified. HIF-2, rather than HIF-1, is the transcription factor primarily responsible for the regulation of EPO production.[5,6] The discovery of the HIF pathway and the underlying mechanisms of oxygen sensing was awarded the Nobel Prize in Physiology or Medicine in 2019.[7]

The role of renal EPO production in the pathogenesis of the anemia associated with CKD is supported by the particularly severe anemia in anephric individuals. However, the mechanisms impairing EPO production in diseased kidneys remain poorly understood. The production capacity for EPO remains significant, even in kidney failure. Thus, patients with anemia and CKD can respond with a significant increase in EPO production to an additional hypoxic stimulus.[1] The main problem therefore appears to be a failure of EPO production to increase in response to chronically reduced hemoglobin (Hb) concentrations. In line with this view, endogenous EPO production can be induced in CKD patients by pharmacologic inhibition of HIF degradation (see later).

EPO is a glycoprotein hormone consisting of a 165–amino acid protein backbone and four complex, heavily sialylated carbohydrate chains.[1] The latter are essential for the biologic activity of EPO in vivo because partially or completely deglycosylated EPO is rapidly cleared from the circulation. This is why recombinant EPO must be manufactured in mammalian cells; bacteria lack the capacity to glycosylate recombinant proteins.

EPO stimulates RBC production by binding to homodimeric EPO receptors, which are primarily located on early erythroid progenitor cells, the burst-forming units erythroid (BFU-e) and the colony-forming units erythroid (CFU-e). Binding of EPO to its receptors salvages these progenitor cells and the subsequent earliest erythroblast generation from apoptosis, thereby permitting cell division and maturation into RBCs.[8] Inhibition of RBC production by yet unknown uremic inhibitors of erythropoiesis may contribute to the pathogenesis of anemia associated with CKD, and dialysis per se can improve the anemia and the efficacy of ESAs. Moreover, the interindividual dose requirements for ESAs vary considerably among CKD patients, and the average weekly dose is much higher than estimated production rates of endogenous EPO in healthy individuals. An alternative view to the accumulation of inhibitors of erythropoiesis in CKD is that in many patients there is overlap between renal anemia and the anemia of chronic disease, which is characterized by inhibition of EPO production and EPO efficacy, as well as by reduced iron availability, mediated through inflammatory cytokines.[9] The hepatic release of hepcidin, the key regulator of iron metabolism, is upregulated in inflammatory states. Hepcidin simultaneously blocks iron absorption from the gut and promotes iron sequestration in macrophages.[10]

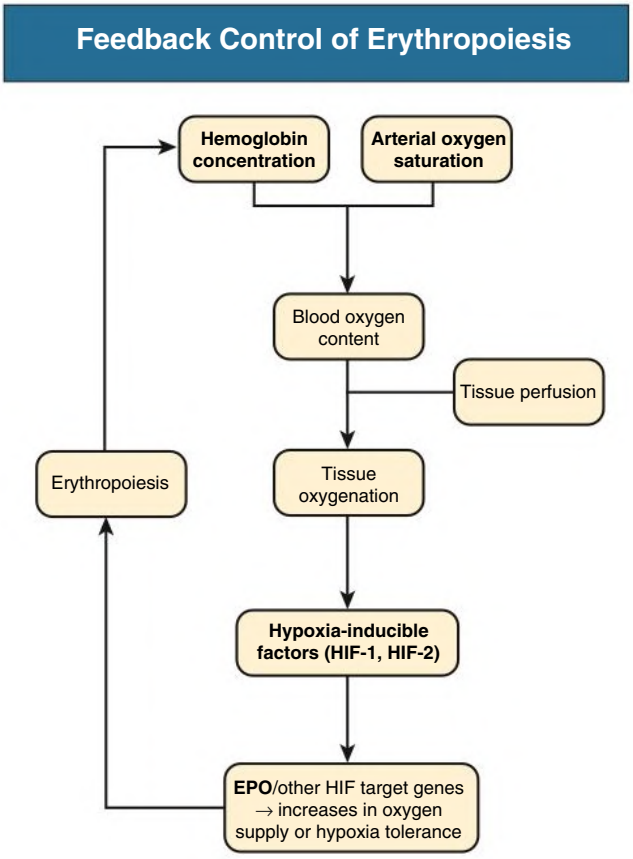

Fig. 86.1 Feedback control of erythropoiesis. *EPO,* Erythropoietin.

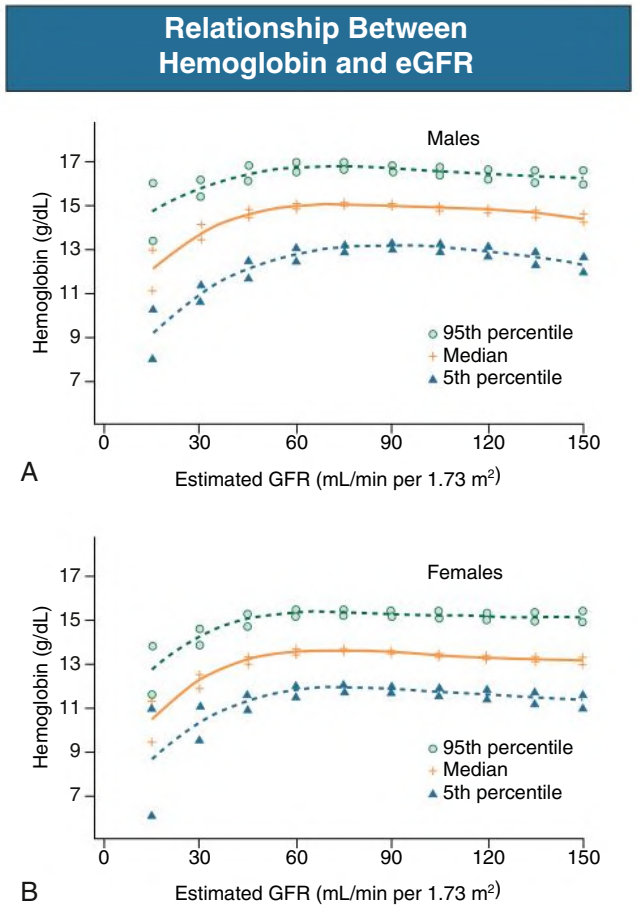

Fig. 86.2 Relationship Between Hemoglobin Concentration and Estimated Glomerular Filtration Rate (eGFR). Data are from a cross-sectional survey of individuals randomly selected from the general U.S. population (Third National Health and Nutrition Examination Survey [NHANES III]). Results and 95% confidence interval are shown for males (A) and females (B) at each estimated GFR interval. (From McClellan W, Aronoff SL, Bolton WK, et al. The prevalence of anemia in patients with chronic kidney disease. *Curr Med Res Opin.* 2004;20:501–510.)

EPIDEMIOLOGY AND NATURAL HISTORY

The incidence and severity of anemia progressively increases at lower glomerular filtration rate (GFR). The reported prevalence of anemia by CKD stage varies significantly and depends to a large extent on the definition of anemia and whether study participants are selected from the general population, are at high risk for CKD, have diabetes, or are already under the care of a nephrologist. Data from the National Health and Nutrition Examination Survey (NHANES) showed that the distribution of Hb levels starts to fall at estimated GFR (eGFR) less than 75 mL/min/1.73 m^2 in males and less than 45 mL/min/1.73 m^2 in females (Fig. 86.2).[11] The prevalence of Hb values less than 13 g/dL increases at eGFR less than 60 mL/min/1.73 m^2 in males and less than 45 mL/min/1.73 m^2 in females in the general population. Among patients under regular care for CKD, the prevalence of anemia was found to be much greater, with mean Hb values of 12.8 (CKD stages 1 and 2), 12.4 (CKD stage 3), 12.0 (CKD stage 4), and 10.9 g/dL (CKD stage 5).[12] Although anemia develops largely independently of the cause of kidney disease, there are two important exceptions. Patients with diabetes develop anemia more frequently, at earlier stages of CKD, and more severely at a given level of kidney impairment.[13,14] Conversely, in patients with polycystic kidney disease, Hb is on average higher than in other patients with similar severity of CKD, and polycythemia may occasionally develop.

With the advent of ESAs, Hb values in patients with CKD have changed. In particular, in patients on dialysis, average Hb values have steadily increased for many years and then declined again in view of later evidence recommending lower target levels.[13] The average Hb value still varies considerably among countries, reflecting variability in practice patterns (Table 86.1).[14] Moreover, Hb values vary considerably among patients in the same treatment setting and within patients over time, mainly reflecting persistent and time-dependent changes in responsiveness.

DIAGNOSIS AND DIFFERENTIAL DIAGNOSIS

It is best to diagnose anemia and assess its severity by measuring the Hb concentration rather than the hematocrit (Hct). Hb is a stable analyte that is measured directly in a standardized fashion, whereas the Hct is relatively unstable, indirectly derived by automatic analyzers, and lacks standardization. Within-run and between-run coefficients of variation in automated analyzer measurements of Hb are half and one-third those for Hct, respectively.[13]

There is considerable variability in the Hb threshold used to define anemia. According to the Kidney Disease: Improving Global Outcomes (KDIGO) guideline, anemia should be diagnosed at Hb concentrations of less than 13.0 g/dL in males and less than 12.0 g/dL in females,[15] consistent with the World Health Organization (WHO) definition. In children, age-dependent differences in the normal values must be considered. Normal Hb values are increased in high-altitude residents. It is important to note that thresholds for the diagnosis of anemia and evaluation of the causes should not be interpreted as being thresholds for the treatment of the anemia.[15]

TABLE 86.1 Hemoglobin Levels in Patients on Dialysis

	AMONG PATIENTS ON DIALYSIS FOR >180 DAYS			AMONG PATIENTS AT START OF DIALYSIS		
Country	*N*	Mean Hb (g/dL)	Hb < 11 g/dL (% of patients)	*N*	Mean Hb (g/dL)	Hb < 11 g/dL (% of patients)
Sweden	456	12.0	23	168	10.7	55
United States	1690	11.7	27	458	10.4	65
Spain	513	11.7	31	170	10.6	61

France	341	11.1	45	86	10.1	65
Japan	1210	10.1	77	131	8.3	95

Mean hemoglobin (Hb) levels and percentage of patients with Hb levels less than 11 g/dL who have been on dialysis therapy for more than 180 days and at the time of starting dialysis, by country. Data are from the Dialysis Outcomes and Practice Patterns Study, Phase II (DOPPS 2) and are derived from 308 randomly selected, representative dialysis facilities. Note that there are marked differences among countries, but at least one-fourth and up to three-fourths of dialysis patients, and, in most countries, more than two-thirds of patients starting chronic dialysis have Hb values less than the recommended lower target of 11 g/dL.

Modified from Pisoni RL, Bragg-Gresham JL, Young EW, et al. Anemia management and outcomes from 12 countries in the Dialysis Outcomes and Practice Patterns Study [DOPPS]. *Am J Kidney Dis*. 2004;44:94–111.

In addition to the Hb value, the evaluation of anemia in CKD patients should include a complete blood count (CBC) with RBC indices (mean corpuscular Hb concentration [MCHC], mean corpuscular volume [MCV]), white blood cell (WBC) count (including differential), and platelet count. Although the anemia associated with CKD is typically normochromic and normocytic, deficiency of vitamin B_{12} or folate may lead to macrocytosis, whereas iron deficiency or inherited disorders of Hb formation (such as thalassemia) may produce microcytosis. Macrocytosis with leukopenia or thrombocytopenia suggests a generalized disorder of hematopoiesis caused by toxins, nutritional deficit, or myelodysplasia. Hypochromia probably reflects iron-deficient erythropoiesis. The absolute reticulocyte count is a useful marker of erythropoietic activity (normal 40,000–50,000 cells/μL of blood).

Iron status tests should be performed to assess the level of iron in tissue stores or the adequacy of iron supply for erythropoiesis. Although serum ferritin is the only available marker of storage iron, several tests reflect the adequacy of iron for erythropoiesis, including transferrin saturation (TSAT), the percentage of hypochromic red blood cells (PHRC), the reticulocyte Hb content (CHr), the MCV, and the MCHC. Storage time of the blood sample may elevate PHRC, and MCV and MCHC are less than the normal range only after long-standing iron deficiency; in clinical practice, TSAT remains the most frequently used parameter.

Anemia in CKD patients may signify nutritional deficits, systemic illness, or other conditions that warrant attention. Moreover, even at modest degrees, anemia reflects an independent risk factor for hospitalizations, cardiovascular (CV) disease (CVD), and mortality.[13] The diagnosis of anemia caused by CKD requires careful judgment of the severity of anemia in relation to the level of GFR and exclusion of other or additional causes. Because there is significant variability in the degree of anemia in relation to the impairment in kidney function, no simple diagnostic criteria can be applied. Causes of anemia other than EPO deficiency should be considered when (1) the severity of anemia is disproportionate to the reduction in GFR, (2) there is evidence of iron deficiency, or (3) there is evidence of leukopenia or thrombocytopenia. Concomitant conditions such as sickle cell disease may exacerbate the anemia, as can drug therapy. For example, inhibitors of the renin-angiotensin system may reduce Hb levels through (1) the direct effects of angiotensin II (Ang II) on erythroid progenitor cells,[16] (2) accumulation of *N*-acetyl-seryl-lysyl-proline (Ac-SDKP), an endogenous inhibitor of erythropoiesis in patients treated with angiotensin-converting enzyme (ACE) inhibitors,[17] and (3) reduction of endogenous EPO production, possibly because of the hemodynamic effects of Ang II inhibition. Myelosuppressive effects of immunosuppressants may further contribute to anemia.[18] The measurement of serum EPO concentrations is usually not helpful in the diagnosis of anemia associated with CKD because there is relative rather than absolute deficiency, with a wide range of EPO concentrations for a given Hb concentration.

CLINICAL MANIFESTATIONS

In the early clinical trials of recombinant EPO performed in the late 1980s, the mean baseline Hb concentration was about 6 or 7 g/dL, and this progressively increased to about 11 or 12 g/dL under treatment. Patients subjectively felt much better, with reduced fatigue, increased energy levels, and enhanced physical capacity, and there were also objective improvements in cardiorespiratory function.[19] Thus, many of the symptoms previously attributed to the "uremic syndrome" may have been caused by severe anemia associated with CKD (Boxes 86.1 and 86.2). Although the avoidance of blood transfusions and improvement in QOL are obvious early changes, there are also possible effects on the CV system (see Box 86.1). The physiologic consequences of long-standing anemia are an increase in cardiac output and a reduction in peripheral vascular resistance. Anemia is associated with the development of left ventricular (LV) hypertrophy in CKD patients and is thought to exacerbate LV dilation. Sustained correction of severe anemia in CKD patients tends to reverse most of these CV abnormalities, with the notable exception of LV dilation (although anemia

BOX 86.1 Cardiovascular Effects Resulting From Anemia Correction

Reduction in high cardiac output
Reduced stroke volume
Reduced heart rate
Increase in peripheral vascular resistance
Reduction in anginal episodes
Reduction in myocardial ischemia
Regression of left ventricular hypertrophy
Stabilization of left ventricular dilation
Increase in whole blood viscosity

BOX 86.2 Other Effects of Anemia Correction

Beneficial
Reduced blood transfusions
Increased quality of life
Increased exercise capacity
Improved cognitive function
Improved sleep patterns
Improved immune function
Improved muscle function
Improved depression
Improved nutrition
Improved platelet function

Adverse
Hypertension
Vascular access thrombosis
Increased risk for stroke

correction may prevent further dilation in some patients[20]). Other effects of anemia correction reported in clinical trials include improvements in QOL, cognitive function, sleep patterns, nutrition, sexual function, menstrual regularity, immune responsiveness, and platelet function. The majority of these trials were not placebo controlled, so the spectrum and extent of possible benefits remain uncertain.

There has been considerable debate about the optimal target range of Hb in CKD patients. A presumed improvement in QOL and expectations of positive effects on CV function and kidney disease progression with increasing Hb concentrations led to a suggested level of greater than 10 to 11 g/dL in all CKD patients.[13,14] However, studies targeting Hb concentrations in the near-normal range found no survival benefit and showed various risks, including increased rates of thromboembolic events, strokes, and possibly death.[21–24] Thus, there is a possible tradeoff among improved QOL, reduced transfusion requirements, and risk for harm (see discussion later), and a target Hb level of greater than 13 g/dL should be avoided.[13,15]

TREATMENT

Erythropoiesis-Stimulating Agents and Hypoxia-Inducible Factor Stabilizers

Epoetin Therapy

Manufacture of recombinant human EPO (epoetin) is achieved by gene transfer into a suitable mammalian cell line such as Chinese hamster ovary (CHO) cells. The early clinical trials were conducted with both epoetin alfa and epoetin beta, both produced in CHO cells. Like the endogenous hormone, both epoetins consist of a 165–amino acid backbone with one *O*-linked and three *N*-linked glycosylation chains. Invariably, however, there are some differences in the glycosylation pattern among different recombinant preparations and the endogenous hormone. "Biosimilar" or "copy" epoetins have been approved in many countries of the world after demonstration of their efficacy and safety in clinical trials.[25]

Before 1998, epoetin alfa in Europe was formulated with human serum albumin, but the latter was replaced with polysorbate 80. Epoetin beta is formulated with polysorbate 20, along with urea, calcium chloride, and five amino acids as excipients. The importance of the formulation of epoetins was highlighted in 2002 when an upsurge in cases of antibody-mediated pure red cell aplasia (PRCA) was associated with the subcutaneous use of epoetin alfa after its change of formulation. Patients affected by this complication develop neutralizing antibodies against both recombinant and endogenous hormone, which result in severe anemia and transfusion dependence.[26,27] The development of neutralizing anti-EPO antibodies was also observed during a clinical trial with an epoetin alfa biosimilar,[28] and a low rate of PRCA also occurs with epoetin beta and darbepoetin alfa. Peginesatide was used to treat patients with EPO-antibody induced PRCA (see below), but since it is no longer available RBC transfusions and immunosuppressive therapy remain the only options.

The epoetins are administered either intravenously or subcutaneously. The earliest clinical trials of the epoetins used intravenous (IV) injections two or three times per week. This was partly because of the short half-life of IV epoetin (6–8 hours)[29] and partly because of the convenience for the patient on dialysis. With use of this regimen, more than 90% of patients show a significant increase in Hb concentration. Good iron management is pivotal for the success of epoetin therapy (see later discussion). Although the bioavailability of subcutaneous epoetin is 20% to 30%, the prolonged half-life after subcutaneous (SQ) administration compared with IV administration allows less frequent injections. Furthermore, the dose required to achieve the same Hb response is about 30% lower with SQ than with IV administration.[29] There appears to be little difference in efficacy among the thigh, arm, or abdomen as injection sites.

Darbepoetin Alfa

Darbepoetin alfa is a second-generation ESA that is a supersialylated analog of epoetin, possessing two extra *N*-linked glycosylation chains. This property confers a lower clearance rate in vivo, and the elimination half-life of this compound in humans after a single IV administration is 25.3 hours versus 8.5 hours for epoetin alfa. Thus, this agent can generally be given less frequently than the standard epoetins, with administration intervals of once weekly and once every 2 weeks with similar dose requirements.[30] In contrast to the epoetins, dosage requirements for darbepoetin alfa in CKD patients are the same for IV and SQ administration. The conversion factor for switching patients from epoetin alfa or beta to darbepoetin alfa is usually quoted as 200 to 1, but this may vary considerably depending on the population, the dose, and the route of administration.

Methoxy Polyethylene Glycol–Epoetin Beta

Alternative bioengineering techniques to prolong the half-life of EPO further resulted in the development of methoxy polyethylene glycol–epoetin beta (CERA), a pegylated derivative of epoetin beta with an elimination half-life of around 130 hours when administered either via IV or SQ. Many patients can be treated with once-monthly administration of CERA, which has greater efficacy than once-monthly dosing of darbepoetin alfa when administered via IV to hemodialysis (HD) patients.[31] Once-monthly CERA was also noninferior to shorter-acting ESAs with respect to rates of major adverse CV events or all-cause mortality.[32]

Adverse Effects of the Erythropoiesis-Stimulating Agents

Adverse effects of ESAs include a moderate increase in blood pressure and an increased rate of thromboembolic events, including vascular access thrombosis. Although these effects probably depend to a large degree on the increase in Hb concentration, ESAs may enhance thrombogenicity and tumor growth in patients with malignancy or exacerbate vascular events in CKD independently of Hb concentration. Thus, the lowest possible doses of ESA should be used to avoid the presumed pleiotropic effects of this class of drugs. Similarly, because no "safe" upper dose level has been determined, it is advisable to avoid repeated dose escalation.[15] In the Trial to Reduce Cardiovascular Events with Aranesp Therapy (TREAT), patients with a history of malignancy had an increased rate of cancer-related deaths when treated with darbepoetin.[24] Although no study has investigated anemia management in patients with CKD and active cancer, ESAs should be used only with great caution in such patients, in particular when cure from cancer is the anticipated outcome.[15] Similarly, in patients with a history of stroke or recent venous thromboembolic event, the benefit-to-risk ratio of ESA therapy should be carefully considered (see later discussion).

Peginesatide

Peginesatide (previously called Hematide) was an EPO-mimetic peptide that shared the same functional and biologic properties as epoetin and was shown to be an effective treatment for anti-EPO antibody–mediated pure RBC aplasia because of a lack of cross-reactivity with anti-EPO antibodies.[33] Approximately a year after its introduction, peginesatide was withdrawn from the market because of severe hypersensitivity reactions, including fatal anaphylactic events.

Hypoxia-Inducible Transcription Factor Stabilizers

The HIF stabilizers are competitive inhibitors of HIF prolyl hydroxylases[2,3,34] and asparagyl hydroxylase enzymes involved in the metabolism of HIF and its transcriptional activity. The HIF stabilizers, also referred to as *prolyl-hydroxylase domain protein inhibitors* (PHD inhibitors) cause an increase in endogenous EPO production from both the liver and the diseased, nonfunctioning kidneys.[34,35] Such compounds are orally active, and several of these drugs (e.g., roxadustat, daprodustat, vadadustat, and molidustat) are currently undergoing clinical development.[34,36] The results of phase II trials have shown efficacy in terms of increasing or maintaining the Hb level in both dialysis-dependent and non–dialysis-dependent CKD patients and revealed no evidence of acute adverse effects.[36] Levels of endogenous EPO induced by PHD inhibitors are lower than those observed under IV treatment with ESAs, potentially avoiding dose-dependent toxicity of ESAs. On the other hand, PHD inhibitors are likely to have a range of consequences additional to increasing levels of EPO through activation of other HIF-target genes or interference with other cellular pathways.[2,3,34] Such pleiotropic effects could be beneficial, for example, by improving iron availability or reducing lipid levels.[36] However, given the widespread biologic role of HIF, including its effects on neoangiogenesis and vascular function, the long-term benefit-to-risk relationship is difficult to predict and can be assessed only through rigorous long-term observation. Phase III trials comparing vadadustat with darbepoetin alfa showed noninferiority with respect to CV safety in dialysis-dependent CKD patients[37] but inferiority in non–dialysis-dependent CKD patients.[38] Several trials of a global phase III program comparing roxadustat to epoetin alfa or placebo in dialysis-dependent and non–dialysis-dependent patients have also been published.[39–43] Roxadustat is licensed for use in China, Japan, Chile, and South Korea, but its risk-benefit profile is still debated, and a Food and Drug Administration (FDA) Advisory Committee voted against approval in the United States in July 2021.[44] Daprodustat has shown noninferiority to comparator ESAs in both dialysis and nondialysis patients for both Hb and major adverse CV events (MACE) and a significant improvement in the physical component of a QOL measurement in nondialysis patients compared with placebo.[45,46] However, an FDA Advisory Committee recommended approval of daprodustat only in dialysis patients.[47]

Initiation of and Maintenance Therapy With Erythropoiesis-Stimulating Agents

Before ESA therapy is considered in CKD patients, it is essential to exclude and to correct causes of anemia other than EPO deficiency, such as iron and vitamin deficiencies (Fig. 86.3). If the serum ferritin concentration is less than 100 µg/L, the first therapeutic approach in anemic patients should be iron supplementation. Iron is best given by IV administration, although oral iron can be considered in patients not yet on dialysis.[48] Some patients may respond to IV iron alone (see later discussion). If the ferritin level is greater than 100 µg/L (in the absence of systemic inflammation) or there is a suboptimal response to iron, ESA therapy is an option. However, the Hb level at which ESAs should be initiated remains controversial, mainly because the topic has not been rigorously studied. In TREAT, the largest ESA trial so far, darbepoetin therapy (with a target Hb level of 13 g/dL) was compared with placebo, with a rescue protocol for Hb less than 9 g/dL.[24] In the darbepoetin arm, the number of patients transfused was lower and there was

an increase in QOL, but the stroke rate was twice as high, so that the benefit-to-risk relationship was clearly negative. Although these data argue strongly against the initiation of ESA therapy in patients with mild anemia, there is only one, much smaller randomized controlled trial (RCT) in HD patients that tested two different target ranges of 9.5 to 11.0 g/dL and 11.5 to 13.0 g/dL against placebo in patients with severe anemia.[49] Patients in both epoetin treatment arms experienced improved QOL and exercise capacity, but there was no difference between the arms. Based on these findings, the KDIGO guidelines recommend use of ESAs to prevent the Hb level from falling below 9 g/dL.[15] However, individualization is possible, acknowledging the fact that some patients have improved symptoms at higher Hb levels and are prepared to take increased risks. A commonly used target Hb range is between 10 and 12 g/dL. The Hb level should not be intentionally increased to 13 g/dL or more.

The usual IV or SQ starting doses are: for epoetin, about 25 to 50 international units (IU)/kg (e.g., 2000 IU two or three times weekly); for darbepoetin alfa, 20 to 30 μg once weekly; and for CERA, 30 to 60 μg once every 2 weeks. Within 3 to 4 days after treatment initiation, the reticulocyte count typically increases, and within 1 to 2 weeks, there is a significant rise in the Hb concentration, usually of the order of 0.25 to 0.5 g/dL/wk. Thus, over the course of 1 month, a significant increase of 1 to 2 g/dL in Hb concentration is usually achieved. If a patient fails to respond satisfactorily to ESAs, the dose is increased in stepwise upward titrations of 25% to 50%, and if there is still an inadequate response, causes of resistance to ESA therapy should be investigated (see later discussion).

Hyporesponsiveness to Erythropoiesis-Stimulating Agents

According to KDIGO guidelines, hyporesponsiveness to ESA therapy is identified when the Hb concentration does not increase from baseline after the first month of ESA treatment on appropriate weight-based dosages or if, after treatment with stable doses, patients require two increases in ESA doses up to 50% beyond the dose at which their condition had previously been stable.[15] Patients who are hyporesponsive have a worse prognosis than those who do respond.[50] The causes of resistance to ESA therapy are listed in Box 86.3, and it is important to correct them when possible. The major causes include iron deficiency (see later discussion), infection or inflammation, and underdialysis.[13,15] If the patient is self-administering (e.g., for PD patients), poor compliance with therapy must be excluded. If there is any doubt about the possibility of iron deficiency, a trial of IV iron may be useful. Vitamin B_{12}, folate, and thyroxine deficiency can be excluded easily by appropriate laboratory tests, as can severe hyperparathyroidism. Depending on the ethnic origin of the patient, a hemoglobinopathy should be excluded by performing Hb electrophoresis. Some patients taking ACE inhibitors or angiotensin receptor blockers may require higher doses of ESA therapy, although it is rarely necessary to stop these drugs. The possibility of a primary bone marrow disorder, such as myelodysplastic syndrome, should be investigated by a bone marrow examination if all other causes have been excluded. A bone marrow test also may be necessary in the diagnosis of antibody-mediated PRCA, although measurement of the reticulocyte count and anti-EPO antibodies may provide an earlier clue.[26] If a patient receiving ESA therapy has a high reticulocyte count, the bone marrow is generating more than adequate quantities of new RBCs and bleeding or hemolysis should be investigated by means of endoscopy or hemolysis screen (Coombs test, serum bilirubin, lactate dehydrogenase, and haptoglobin levels).

There is no defined upper dose limit of ESAs, and doses of 60,000 IU of EPO per week are not uncommon in the United States, but there is concern that high doses of ESAs may increase side effects independently of Hb concentrations, as described earlier. In patients with acute illness requiring hospitalization, Hb frequently falls despite continued ESA therapy, indicating increased blood loss and temporary hyporesponsiveness. The optimal management of anemia under these conditions remains unclear. Although cost considerations may speak for withholding of ESA therapy until responsiveness is reestablished, it has been proposed that doses should be increased in an attempt to overcome hyporesponsiveness. Anecdotally, very high doses can be effective even in critically ill patients in intensive care units, but an RCT failed to demonstrate a reduction in transfusion requirements and observed an increase in deep vein thrombosis.[51] From a practical point of view, and pending evidence to the contrary, it seems sensible to continue the same dose of ESA during acute illness.

BOX 86.3 Causes of a Poor Response to Erythropoiesis-Stimulating Agent Therapy

Frequent
Iron deficiency
Infection, Inflammation
Underdialysis

Less Common
Poor compliance to ESA therapy
Blood loss
Hyperparathyroidism
Aluminum toxicity (now rare)
Vitamin B12 or folate deficiency
Hemolysis
Primary bone marrow disorders (e.g., myelodysplastic syndrome)
Hemoglobinopathies (e.g., sickle cell disease)
ACE inhibitors, angiotensin receptor blockers
Carnitine deficiency
Anti-EPO antibodies causing pure red cell aplasia

ACE, Angiotensin-converting enzyme; *EPO,* erythropoietin; *ESA,* erythropoiesis-stimulating agent.

Iron Management

Iron is an essential ingredient for heme synthesis, and adequate amounts of this mineral are required for the manufacture of new RBCs. Thus, under enhanced erythropoietic stimulation, greater amounts of iron are used, and many CKD patients (particularly those on HD) have inadequate amounts of available iron to satisfy the increased demands of the bone marrow.[52] Even before the introduction of ESA therapy, many CKD patients were in negative iron balance as a result of poor dietary intake, poor appetite, and increased iron losses from occult and overt blood losses (see Chapter 83). Iron losses in HD patients are up to 5 or 6 mg/day compared with 1 mg in healthy individuals, which may easily exceed the absorption capacity of the gastrointestinal (GI) tract, particularly when there is any underlying inflammation. Iron absorption capacity in patients with CKD is considerably lower than in nonuremic individuals, particularly in the presence of systemic inflammation, and this is mediated by hepcidin upregulation.[10] For this reason also, traditional oral iron therapy (e.g., with ferrous sulfate) is ineffective in many CKD patients, and parenteral iron administration is required, particularly in those receiving HD.[51] However, a newer preparation of oral iron (ferric citrate) that shows greater absorption of iron from the gut is now available in the United States and Japan, and this agent can be used to concomitantly lower phosphate and increase iron levels in CKD patients.

TABLE 86.2 Recommended Iron Status Levels in Chronic Kidney Disease (CKD)

Test	Recommended Range
Serum ferritin	CKD: 100–500 μg/L Hemodialysis: 200–500 μg/L
Transferrin saturation	20%–40%
Hypochromic red cells	<10%
Reticulocyte hemoglobin content	>29 pg/cell
Serum transferrin receptor	Not established
Erythrocyte zinc protoporphyrin	Not established

An inadequate supply of iron to the bone marrow may be caused by an absolute or a functional iron deficiency.[51] Absolute iron deficiency occurs when there are low whole-body iron stores, as indicated by a serum ferritin level less than 30 μg/L. Functional iron deficiency occurs when there is ample or even increased storage iron, but the iron stores fail to release iron rapidly enough to satisfy the demands of the bone marrow. Several markers of iron status are available, but none of them is ideal (Table 86.2). Serum ferritin is a marker of storage iron but is spuriously raised in inflammatory conditions and liver disease. TSAT is a function of the circulating serum iron in relation to the total iron-binding capacity and is often regarded as a better measure of available iron; however, levels can be highly fluctuant because of significant diurnal variation in the measurement of serum iron.[52] The percentage of hypochromic RBCs and the CHr are RBC and reticulocyte parameters, respectively, that are indirect measures of how much iron is being incorporated into the newly developing or mature RBCs. No one measure of iron status is usually adequate to exclude iron deficiency, and the recommended levels for these measures are based on limited scientific evidence. Functional iron deficiency is usually diagnosed when there is a normal or increased ferritin level and a reduced TSAT (<20%) or increased hypochromic RBCs (>10%). The KDIGO guideline suggests a trial of iron in CKD patients with anemia who are not on iron and ESA therapy and in whom an increase in Hb concentration is desired and in patients on ESA therapy in whom an increase in Hb concentration or a decrease in ESA dose is intended when TSAT is up to 30% and ferritin level is up to 500 μg/L[15] (see Table 86.2). Levels of ferritin above this threshold usually do not confer any clinical advantage and may exacerbate iron toxicity. The optimal TSAT is greater than 20% to 30% to ensure a readily available supply of iron to the bone marrow. No upper limits of ferritin or TSAT were specified in the KDIGO anemia guideline, largely because there is no robust evidence to determine a threshold beyond which harm or loss of efficacy supervenes. However, until more information become available, the treating nephrologist should exercise caution in administering IV iron to patients with ferritin levels greater than 800 μg/L or TSAT greater than 30%. Several studies support maintaining the percentage of hypochromic RBCs at less than 6% and the CHr at greater than 29 pg/cell.

Oral iron is generally poorly absorbed in people with severe CKD, and there is a high incidence of GI side effects. Thus, IV administration of iron has become the standard of care for many CKD patients, particularly those receiving HD.[52] Several IV iron preparations are available worldwide, including iron dextran, iron sucrose, iron gluconate, and the newer iron preparations ferric carboxymaltose, ferumoxytol, and iron isomaltoside 1000. The last three iron preparations allow higher doses of IV iron to be administered more rapidly, without the need for a test dose. All of the iron preparations contain elemental iron surrounded by a carbohydrate shell, which allows them to be injected intravenously.

An RCT comparing proactive high-dose administration of IV iron sucrose (400 mg iron per month up to a ferritin of 700 μg/L) with reactive low-dose iron sucrose (0–400 mg iron per month) in 2141 incident hemodialysis patients (PIVOTAL)[53] showed lower ESA dose and transfusion requirements, as well as improved mortality and CV events with the high-dose regimen. Follow-up in the study was for a median of 2.1 years (maximum 4.4 years), and thus the longer-term safety of IV iron remains unknown.

All IV iron preparations also carry a risk for immediate hypersensitivity reactions, which may be characterized by hypotension, dizziness, and nausea. These reactions are usually short-lived and caused by too large a dose given in too short a time. Iron dextran also carries the risk for acute anaphylactic reactions because of preformed dextran antibodies, although this was largely a problem with the high-molecular-weight IV iron dextran preparations, which have now been withdrawn from the market.

In nondialysis patients, both oral and IV iron may be used and there are advantages and disadvantages for each route of administration, which have been compared in two RCTs. The FIND-CKD study showed that both routes of administration were effective in this patient population, although higher-dose IV iron resulted in a faster and greater rise in Hb, with no safety concerns.[48] However, the REVOKE study suggested that the rate of CV- and infection-related serious adverse events was greater in the IV iron treatment group compared with the oral iron group.[54] The reasons for these discrepant findings remain unknown. Thus, the physician has to balance the low costs and convenience of oral iron treatment with known poor adherence to treatment, GI side effects, and reduced efficacy; IV iron, on the other hand, requires special facilities and set-up for administration and carries a very small risk for hypersensitivity reactions and potential additional risks.

SELF-ASSESSMENT QUESTIONS

1. Which of the following statements is *false* regarding the characteristics of renal anemia?
   - **A.** The RBCs produced are usually normochromic and normocytic.
   - **B.** There is usually no associated leukopenia or thrombocytopenia.
   - **C.** The reticulocyte count is usually around 40,000 to 50,000/μL of blood.
   - **D.** Serum erythropoietin levels are usually within the normal range.
   - **E.** The RBC life span is usually normal.
2. Which of the following statements is *false*?
   - **A.** Dose requirements of epoetin are generally 20% to 30% less when the agent is administered subcutaneously compared with intravenously.
   - **B.** ESA therapy should be used with caution in patients with previous or current malignancy.
   - **C.** Patients who are hyporesponsive to ESA therapy have a worse prognosis than those who do respond.
   - **D.** The defined upper dose limit of epoetin is 60,000 IU/wk because it is known that CV toxicity occurs above this dose level.
   - **E.** ACE inhibitors may confer resistance to ESA therapy in some patients.
3. Which of the following statements is *false* regarding the TREAT study?
   - **A.** Patients receiving darbepoetin alfa were randomized to either a target hemoglobin (Hb) of 13 or a target Hb of 9 g/dL.
   - **B.** Patients randomized to a target Hb of 13 g/dL had a small increase in quality of life compared with the control arm.
   - **C.** There was a significant reduction in the use of RBC transfusions in patients randomized to a target Hb of 13 g/dL.
   - **D.** There was a doubling of the rate of stroke in patients randomized to a target Hb of 13 g/dL.
   - **E.** There was a significant increase in cancer-related mortality in the subset of patients with a history of malignancy who were randomized to a target Hb of 13 g/dL.
4. Which of the following statements is *true* regarding IV iron supplementation?
   - **A.** All IV iron preparations require a test dose before their first administration, as per their product label.
   - **B.** All the newer IV iron preparations (ferumoxytol, ferric carboxymaltose, and iron isomaltoside 1000) have the advantage that up to 1 g may be administered as a single dose.
   - **C.** IV iron preparations vary in their lability and speed of iron release from the carbohydrate shell, with iron gluconate being the most stable and iron dextran the least stable compound.
   - **D.** IV iron may improve the anemia of chronic kidney disease in up to 30% of patients not receiving ESA therapy who have a low ferritin level.
   - **E.** Hypersensitivity reactions are more common with low-molecular-weight iron dextrans than with high-molecular-weight iron dextran compounds.

Other Blood and Immune Disorders in Chronic Kidney Disease

Matthias Girndt, Gunnar H. Heine

IMMUNE DYSFUNCTION

Patients with chronic kidney disease (CKD) have a high morbidity and mortality from infection. This is partially due to immune dysfunction, although multiple other factors are involved.

Bacterial Infections

Infections are a major cause of hospitalization in patients with CKD; infection-related hospitalization rates are at least three to four times (nondialysis CKD) or eight times (dialysis) higher than in individuals with normal kidney function.[1] The number of days spent in hospital for infections has slightly decreased over the last decade. Nevertheless, they are still higher than those for cardiovascular (CV) disease (4 vs. 2.2 days per patient year).[1] Infection is also an important cause of mortality, accounting for 8% of deaths in dialysis patients. The risks of pulmonary infections and infections of the genitourinary system both increase with decreasing kidney function. For example, patients with stage 4 CKD have a 15-fold higher risk for severe pulmonary infections compared with those with an estimated glomerular filtration rate (eGFR) greater than 60 mL/min/1.73 m^2. Furthermore, mortality from pneumonia is markedly enhanced by concurrent CKD,[2] which was reflected in the extremely high mortality among patients undergoing hemodialysis (HD) during the COVID-19 pandemic[3] (see Chapter 59).

In HD patients, bloodstream infections are another major cause of infection-related hospitalization, particularly in patients with central venous catheters.[4] Catheter-based HD is among the major risk factors for the development of bacterial endocarditis. More than 50% of cases of bacteremia are caused by *Staphylococcus aureus.* Nevertheless, there is also a relevant rate of gram-negative bacteremia in dialysis patients, indicating that contamination or infection of the dialysis access is not the only cause of bloodstream infection.

The high incidence of bacterial infection in CKD patients may be one clinical consequence of immune dysfunction; another is atypical clinical presentations of infections, such as the lack of fever in 20% to 40% of kidney patients with bacteremia. When bacteremia is suspected, blood cultures should be obtained frequently. Another aspect of immune dysfunction is the high rate of false-negative tuberculin (Mantoux) skin tests with anergic skin reactions in the presence of positive interferon-γ release assays, indicating impaired T-lymphocyte function.[5]

Other factors besides immune dysfunction predispose to infection in persons with CKD. Thirty-nine percent of patients with end-stage kidney disease reported by the US Renal Data System are age 65 years or older,[1] and in other countries the percentage exceeds 50%. Besides advanced age, many CKD patients have underlying kidney or extrarenal autoimmune disease that requires therapeutic immunosuppression and other comorbidities that facilitate infection such as diabetes or heart failure. Dialysis patients and patients with cardiorenal syndrome often have excess pulmonary fluid, which may impair alveolar bacterial clearance and contribute to the risk for pneumonia. Repeated breaks in the skin barrier by cannulation provide opportunity for bacterial invasion. Finally, dialysis patients frequently receive intravenous iron preparations, and iron overload is a risk factor for bacterial infection as a result of inhibition of monocyte and macrophage function.

Viral Infections

Viral hepatitis has been a scourge of dialysis ever since kidney replacement therapy became a routine treatment. Only rigorous infection control practices and active vaccination against hepatitis B virus (HBV) made large-scale HD safe. However, impaired immune defense was only one among other causes for the high prevalence of viral hepatitis in this patient group. The viruses can be easily transmitted nosocomially in HD patients without proper precautions. Nevertheless, the early outbreaks of HBV infection showed an abnormal clinical course related to the immune defect in CKD.[6] The acute infection could sometimes only be detected by measurement of transaminases; the typical clinical syndrome of icterus, subfebrile temperatures, and malaise was often absent. Most affected dialysis patients developed chronic persistent infection, which occurs in only 10% of patients with normal kidney function.

The clinical manifestations of hepatitis C virus infection are not significantly influenced by the immune deficiency of kidney failure. The infection usually runs a subclinical course and becomes chronic even in the absence of CKD.

Vaccinations in Chronic Kidney Disease

Immune deficiency leads to a high rate of nonresponse to hepatitis B vaccination. Dialysis patients should always receive a double-dose vaccination and extended vaccination protocols (Fig. 87.1), but even with the most recent vaccines, some 20% of patients do not develop protective antibody levels.[7] This impaired response led to the development of specifically adjuvanted vaccines or intracutaneous application protocols[8] with improved efficiency in former nonresponders.

Other vaccinations are also affected by the immune defect in CKD. The Kidney Disease: Improving Global Outcomes (KDIGO) guideline[9] recommends annual influenza vaccinations. Studies comparing vaccination efficiency in patients with CKD and healthy individuals have methodological limitations; therefore the extent to which immune dysfunction compromises these vaccination results is unclear. Most likely, the efficacy is lower in patients receiving dialysis. A recent systematic review on the protective effects with regard to hard endpoints such as mortality or hospitalization pointed out that the universal recommendation to vaccinate—albeit very plausible—has a weak evidence base.[10] In contrast to the experience in the general population, enhanced-dose influenza vaccine does not seem to be superior to standard vaccines.[11]

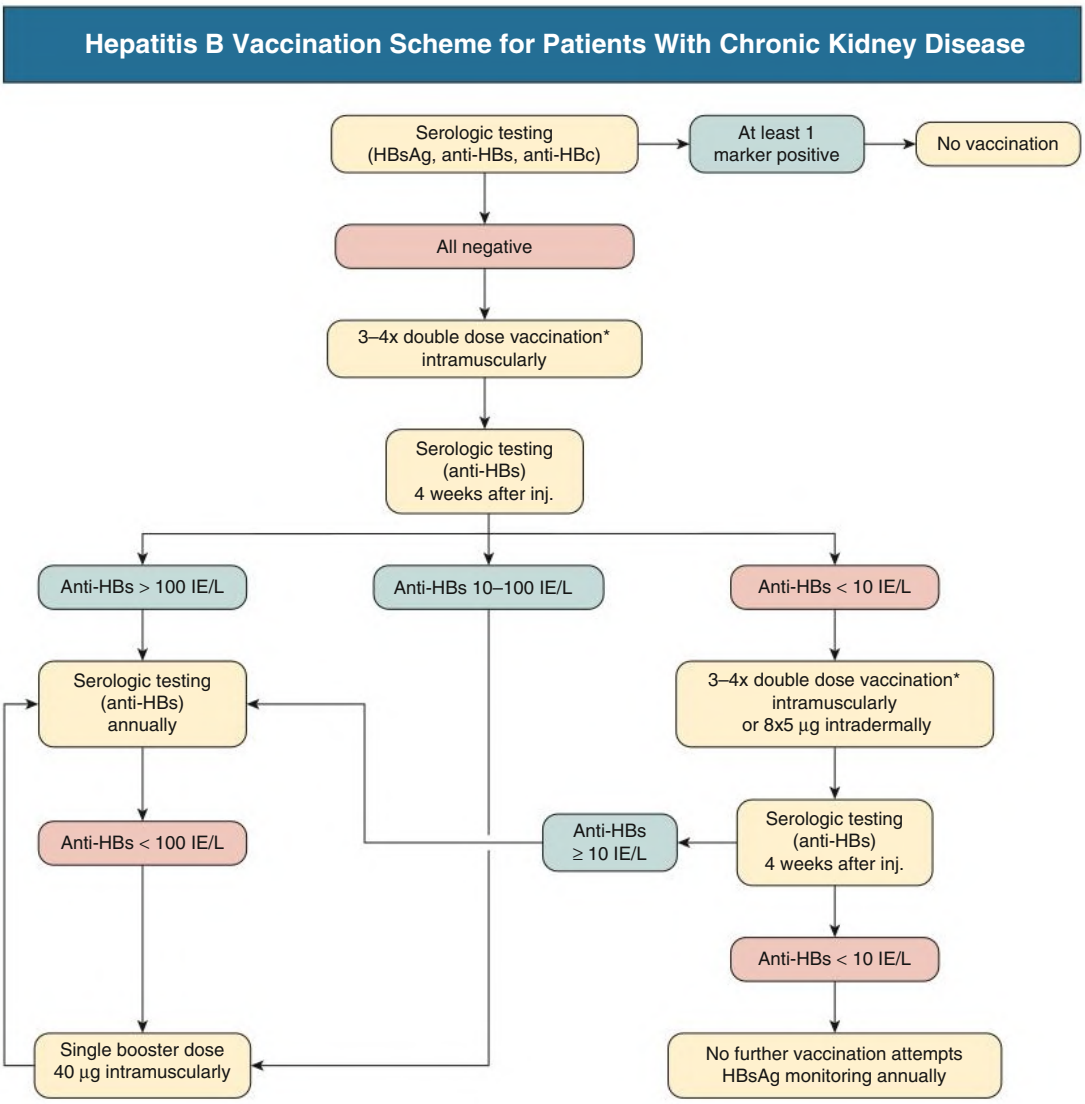

Fig. 87.1 Hepatitis B vaccination scheme for patients with chronic kidney disease (CKD). *The schedule varies with different vaccine preparations. *HBsAg,* Hepatitis B surface antigen.

Vaccines against herpes zoster have proven to be most effective in preventing zoster manifestations in the elderly. It seems to be justified to extend the general recommendation to vaccinate individuals older than 60 years to patients with CKD. The newer recombinant vaccine has not been studied in this patient group; however, the earlier attenuated vaccine led to excellent seroresponses in dialysis patients.[12]

Several studies have been published on SARS-CoV-2 vaccination in patients with CKD and on dialysis; this vaccination is highly desirable in these vulnerable populations (see Chapter 59).

In contrast to antiviral vaccinations, the efficacy of those against bacteria appear to be mildly reduced by CKD. Vaccination against pneumococcal infections is recommended[9] for all adults with eGFR less than 30 mL/min/1.73 m^2. Evidence of efficacy in terms of antibody titers comes from very old studies or series with small patient numbers. Likely, maximum antibody titers are lower and protection lasts shorter in CKD patients,[13] but data on hospitalization or mortality can be derived only from observational studies.[14] Because multiple vaccine preparations are available, the congruence of local epidemiology and the vaccine coverage should be considered (Fig. 87.2). Newer conjugate vaccines have a rather narrow spectrum of serotype coverage while being highly effective in inducing seroprotection; thus there is an argument to vaccinate CKD patients sequentially with conjugate vaccine first, followed in 6 to 12 months by the broad polysaccharide vaccine. Revaccination with the polysaccharide vaccine is recommended after 6 years.

Further recommendations for vaccination in CKD are given in Table 87.1.

INFLAMMATION

Chronic inflammation is typical for patients with stage 4 or 5 CKD or on kidney replacement therapy, and C-reactive protein (CRP) and plasma cytokines increase steadily with every stage of CKD. The majority of HD and peritoneal dialysis patients periodically or permanently have CRP values above the normal limit despite the absence of clinical infection.[15]

Causes of Inflammation

Although early research in this field focused on dialysis membrane biocompatibility, contamination of dialysis fluids, or vascular access as causes of inflammation, chronic inflammation also occurs in patients with stages 3 and 4 CKD. One important reason may be the renal

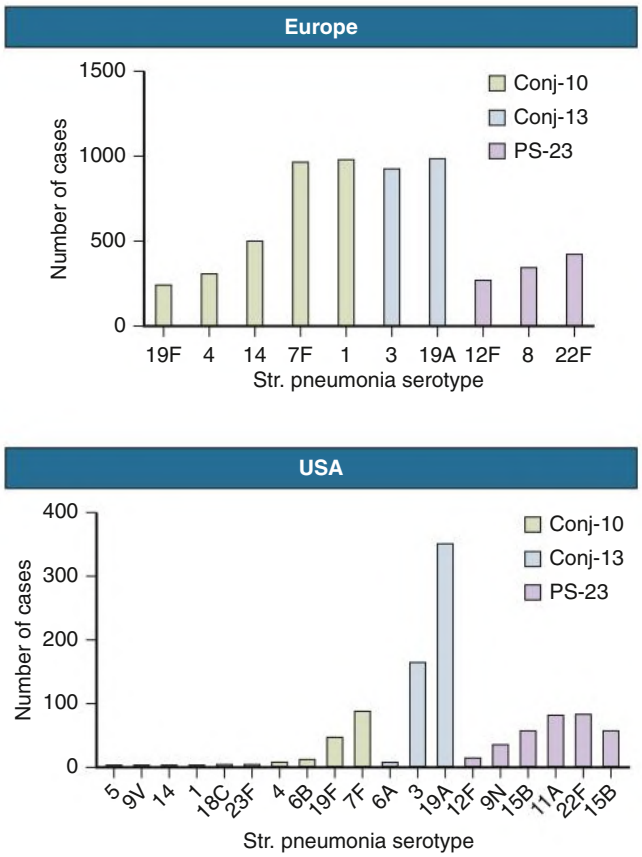

Fig. 87.2 *Streptococcus pneumoniae* serotypes in clinical isolates (as of 2010) from Europe (European Center of Disease Control) and United States (Centers for Disease Control and Prevention) in relation to vaccine serotype coverage. *Conj-10,* 10-valent conjugate vaccine; *Conj-13,* 13-valent conjugate vaccine; *PS-23,* 23-valent polysaccharide vaccine. Low isolate numbers for the serotypes covered by Conj-10 in the United States are the result of successful vaccination programs.

TABLE 87.1 Vaccination Recommendations for Adult Patients With Chronic Kidney Disease

Vaccination Against	Recommendation
HBV	All patients susceptible to HBV infection, double dose (see Fig. 87.1)
Influenza	Annually according to WHO recommendation, standard dose
Streptococcus pneumoniae	All patients, conjugate vaccine, can be boosted by polysaccharide vaccine at 6 mo, revaccination after 6 yr
Tetanus	All patients according to recommendations for general population, standard dose
Diphtheria	All patients according to recommendations for general population, standard dose
Herpes zoster	All patients >60 years
Hepatitis A	Not routinely indicated, can be given prior to travel to affected areas

HBV, Hepatitis B virus; *WHO,* World Health Organization.
Modified from Dinits-Pensy M, Forrest GN, Cross AS, Hise MK. The use of vaccines in adult patients with renal disease. *Am J Kidney Dis.* 2005;46:997–1011.

clearance of circulating proinflammatory cytokines.[16] Impaired kidney function leads to prolonged cytokine serum half-life, thus enhancing and prolonging inflammatory episodes that usually would have abated quickly.

At least 30% of patients with advanced CKD have diabetes mellitus, a comorbidity that promotes inflammation both by itself and through diabetic complications such as ulcers. In addition, many patients with CKD have poor dental health, and periodontitis is associated with systemic inflammation.[17]

Whether inflammation is also related to classic uremic toxicity remains a matter of debate. Typical toxins with increased plasma levels are indoxyl sulfate, paracresyl sulfate, and trimethylamine N-oxide (TMAO). Across stages of CKD, plasma levels of TMAO show a positive correlation with inflammatory markers, and both decrease after kidney transplantation.[18] Several studies show that serum levels of indoxyl sulfate or paracresyl sulfate increase with kidney dysfunction in parallel with inflammatory markers; however, a causal relationship remains to be proven.

The extent of inflammation is at least in part controlled by the genetic predisposition of the individual. This may be clinically relevant in patients with CKD because inherited single-nucleotide polymorphisms in the gene of the antiinflammatory cytokine interleukin (IL)-10 influence the quantity of its production in response to inflammatory stimuli and thus the way a patient can contain and limit inflammation.[19]

Consequences of Inflammation

Inflammation is closely associated with the occurrence of cardiovascular complications (see Chapter 85) and immune dysfunction. When using the response to HBV vaccination as a surrogate for clinical immune function, there is a close correlation between inflammation and decreased immunity. This is confirmed by the finding that the IL-10 gene polymorphism, which influences the extent of inflammation, also predicts vaccination responses in dialysis patients.[19]

IMMUNE CELL ABNORMALITIES

Monocytes

Monocytes are bone marrow–derived cells with specific functions in immune surveillance and antigen presentation. During their differentiation, they briefly circulate in the blood, produce cytokines, and then migrate into tissues to become macrophages.[20] Injury and infection lead to rapid enhancement of circulating monocyte numbers, which then migrate to the site of tissue injury and initiate the local immune response. Monocyte-derived macrophages are constituents of atherosclerotic plaques, and imaging studies have revealed that monocytes patrol along the vascular endothelium, where they detect endothelial defects.[21]

Monocyte subpopulations are defined by the expression of the lipopolysaccharide receptor CD14 and the immunoglobulin Fcγ receptor CD16.[22] The classic monocytes only express CD14 and account for some 80% of all circulating monocytes in healthy individuals; intermediate monocytes express both CD14 and CD16 (~5%–7%), and nonclassic monocytes express high levels of CD16 while showing limited staining for CD14 (~10%–12%). Genetic analysis revealed that $CD14^{++}CD16^{+}$ intermediate monocytes particularly express markers related to antigen presentation, inflammation, and angiogenesis.[23]

In CKD, the intermediate and nonclassic monocyte subtypes are significantly expanded. This finding is related to the CV risk[24]; patients with the highest rate of $CD14^{++}CD16^{+}$ monocytes in blood had the lowest CV event-free survival.

Mouse models confirm differences between monocyte subpopulations in their ability to invade atherosclerotic plaques.[25] In CKD the expansion of proinflammatory monocyte subsets and their epidemiologic association with CV events make a causal role of these cells for atherosclerotic disease likely. Furthermore, monocytes also express components of the angiotensin system. The angiotensin-converting enzyme (ACE) that turns angiotensin I (Ang I) into vasoactive angiotensin II (Ang II) is expressed in atherosclerotic plaques and colocalizes with monocyte-derived macrophages.[26] ACE is also expressed on circulating monocytes, particularly on those with the $CD14^{++}CD16^{+}$ phenotype.[27] Dialysis patients with high expression of ACE on intermediate monocytes have a dramatically enhanced CV mortality risk.[27]

Expression of ACE on monocytes is strongly upregulated by the uremic milieu.[28] A consequence of this might be that monocytes transmigrate into the subendothelial space of arteries and provide high levels of ACE in the atherosclerotic plaque. The local production of Ang II through ACE is thought to contribute to further leukocyte attraction, inflammatory activation, and plaque growth. In addition, expression of ACE on monocytes alters their functional capacities. In vitro assays show that a higher expression of ACE leads to stronger endothelial adhesion and transmigration of the monocytes. This effect appears to be mediated via locally produced Ang II, because adhesion and transmigration could be inhibited by losartan.[28]

Monocytes also express ACE-2, a peptidase that degrades Ang II to Ang1–7, a vasodilatory peptide. Whereas CKD leads to the overexpression of ACE, the ACE-2 enzyme is downregulated compared with healthy individuals.[29] Experimental overexpression of ACE-2 in a rodent model of atherosclerosis limited the progression of disease. These findings suggest that the uremic milieu alters monocyte function in a strongly proatherogenic way.

Monocytes are closely related to circulating blood dendritic cells. Dendritic cells are mainly found in organs and tissues, where they have strong capabilities in antigen presentation and activation of immune reactions. Their immature precursors circulate in blood in low numbers. There are different subtypes of circulating dendritic cells, but investigators have used different marker sets for their detection. This limits comparison among different studies, so that understanding of dendritic cell quantification and pathophysiology remains limited. There is a relation between elevated numbers of $CD14^{++}CD16^{+}$ monocytes in the blood and the propensity of these cells to differentiate into dendritic cells in cell culture.[30] Other studies[31] found significantly lower numbers of dendritic cells in advanced CKD compared with healthy controls. The finding may be related to cardiovascular disease, because studies in patients with coronary heart disease and normal kidney function also reported reduced circulating numbers of dendritic cells.

T Lymphocytes

Impaired vaccination responses against viral antigens such as HBV or influenza, as well as reduced skin reaction in the Mantoux test, result from impaired T-cell activation. T cells are an important component of the antigen-specific adaptive immune defense. Their activation depends on antigen-presenting cells (APCs) that present foreign antigens with major histocompatibility complex and provide important costimulatory signals. Only T cells with specificity of their T-cell receptor toward the particular antigen are activated and proliferate.

Major APCs are dendritic cells, and their precursors are monocytes. Early studies showed that proliferative T-cell responses are impaired in dialysis patients, and this impairment is directly correlated with nonresponses to HBV vaccination. Both replacement of the patient's APCs in in vitro assays with cells from healthy donors and overexpression of costimulatory molecules on the APCs normalize proliferation of T cells, indicating that the major defect leading to reduced T-cell activation is in the APC.[32] However, these rather crude assays did not consider T-cell subpopulations. Helper T cells express the surface marker CD4 and interact with various other cell types. The $CD4^{+}$ helper T cell is particularly needed for activation of B cells for antigen-specific seroresponses to viral antigens, as in HBV vaccination. The $CD8^{+}$ cytotoxic T cells are important for antiviral defense because they are able to lyse infected host cells. In CKD the relation of $CD4^{+}/CD8^{+}$ T cells is reduced.

$CD4^{+}$ helper cells can be further distinguished into cells that mainly support cellular immune reactions (helper T cells Type 1, Th1) and others that are more important for immunoglobulin production by members of the B-cell lineage (Th2). These cell types differ in the pattern of cytokines they produce, with interferon-γ being the major cytokine of Th1 and IL-4 the main cytokine of Th2 cells. CKD leads to a marked deviation of T cell differentiation toward the Th1 phenotype.[33] Most likely the major cause is elevated production of IL-12 by monocytes and APCs in the context of their inflammatory activation.[33]

Another T-lymphocyte subpopulation is regulatory T cells (Tregs) that are important for the downregulation of immune responses once the aim of an antiinfectious response is reached. They prevent ongoing inflammation and the development of autoimmunity. The typical Treg cells originate in the thymus and have a distinct pattern of surface molecule expression. In patients with CKD the number of circulating Treg cells is unaltered, but their capacity to downregulate $CD4^{+}$ helper T-cell activity is impaired.[34]

B Lymphocytes

Impaired vaccination efficacy in CKD suggests impaired function of immunoglobulin-producing B lymphocytes and plasma cells; thus a major dysfunction of this cell type might be expected. However, CKD patients have normal circulating immunoglobulin levels. Their B-cell lymphopenia is modest and probably not very clinically relevant. It is caused by a higher rate of apoptosis of these cells compared with healthy individuals.[35] Lymphopenia appears to result from reduced numbers of the majority of B-cell subpopulations (naive B cells, memory B cells, etc.).[36] Taken together, the alterations of B-lymphocytes in CKD appear to be less pronounced than alterations of other immune cell types. Impaired vaccination responses are caused by altered interaction of APCs, helper T lymphocytes, and the cytokine network in CKD rather than by abnormalities of B lymphocytes.

Granulocytes

Polymorphonuclear granulocytes (neutrophils) are components of the antigen-independent innate immune system. Their main activity is to kill and phagocytose invading pathogens via numerous enzymes that produce bactericidal substances. Among them are defensins, proteolytic enzymes, and enzymes that produce highly active oxygen species such as hypochlorous acid. In CKD patients, these nonspecific defense systems are highly activated, and the cells spontaneously release more reactive oxygen species.[37] Inflammation, activation of different cell types, antiinfectious defense, and vascular disease are closely interwoven. Thus, the elevation of oxygen species H_2O_2 and malondialdehyde has predictive value for CV events and mortality in CKD.[38]

Another important function of granulocytes is phagocytosis, which is mildly compromised in CKD.[39] Further, chemotactic attraction of the cells to the location of infection is modified by substances such as leptin that are retained in CKD.[40]

It is difficult to establish whether these abnormalities can be improved by dialysis. HD inevitably involves extensive contact between blood and foreign surfaces. When cellulose-based membranes were still in use, the activation of the complement system by these membranes led to marked depletion of circulating granulocytes within the

first 20 minutes of a dialysis session.[41] Newer synthetic membranes lead to minimal complement activation, and the leukocyte drop is much less pronounced. These findings on immune cells relate to CKD specifically, and some primary diseases (especially diabetes mellitus) further influence immune cell function.

PLATELET DYSFUNCTION AND PLATELET INHIBITORS IN CHRONIC KIDNEY DISEASE

Normal hemostasis begins with platelet adhesion to vascular endothelium and requires a relatively vasoconstricted vessel wall, integrity of platelet glycoproteins (GPs), and a normal quantity of large molecular weight, multimeric von Willebrand factor (vWF) (Figs. 87.3 and 87.4). Main platelet GPs are GPIb, the platelet receptor for vWF, involved in platelet adhesion, and GPIIb/IIIa, the platelet receptor for fibrinogen, involved in platelet aggregation.

Under static conditions, GPIb and vWF have no affinity for each other. However, these molecules develop a specific affinity for each other at high shear stress, resulting in arterial platelet adhesion. Aggregated fibrinogen-platelet mesh acts as a trap for binding and activation of other plasma clotting factors. The exposure of the preceding clotting factors to tissue factors, present on damaged endothelial cells, catalyzes the conversion of prothrombin to thrombin, which converts fibrinogen to fibrin. Subsequent cross-linking of insoluble fibrin results in a stable hemostatic plug.

Hemorrhagic Diathesis and Uremic Platelet Dysfunction

Patients with CKD have a high risk of bleeding. This hemorrhagic diathesis frequently has cutaneous (easy bruising, ecchymoses, or prolonged hemorrhage from needle puncture or postoperative sites) and mucosal (epistaxis; gastrointestinal or gingival bleeding) manifestations. More dramatic—albeit infrequent—manifestations are hemorrhagic pericarditis/hemopericardium, hemorrhagic pleural effusion/hemothorax, and intracranial and retroperitoneal bleeding.[42]

This hemorrhagic diathesis is not reflected in a prolongation of the prothrombin time or the partial thromboplastin time. Similarly, even though platelet counts may be moderately decreased because of platelet consumption outperforming platelet production, severe thrombocytopenia is rarely seen in uremia; the occurrence of very low platelet counts therefore requires a thorough search for alternative causes.[43] Instead, platelet dysfunction is generally considered as the central contributor to the high bleeding risk, and a high number of pathophysiologic alterations have been suggested to contribute, comprising alterations in platelet function and structure, and extrinsic factors (see Table 87.1). Unfortunately, many studies on platelet functions in CKD date back to the early days of clinical nephrology, when clinical care and dialysis treatment were less sophisticated, and when less advanced laboratory methods were available for evaluation of hemostasis. For the various pathophysiologic alterations listed in Box 87.1, controversial data have been published.

In the search for uremic toxins inducing platelet dysfunction, a direct pathologic role of urea can be ruled out because no correlation exists between blood urea levels and bleeding time,[44] and individuals with high serum urea levels but otherwise normal kidney function have no bleeding tendency.[45]

Among the different extrinsic factors that contribute to platelet dysfunction, the contribution of anemia has gained particular interest. Physiologically, erythrocytes occupy the center of a vessel, displacing platelets from the axial flow toward the vessel walls. This allows platelets to adhere to injured endothelial cells and initiate the formation of a platelet plug. In anemia, platelets are more dispersed, which impairs their adherence to the endothelium. Moreover, in CKD, red blood cells may affect coagulation by releasing adenosine diphosphate (ADP), by

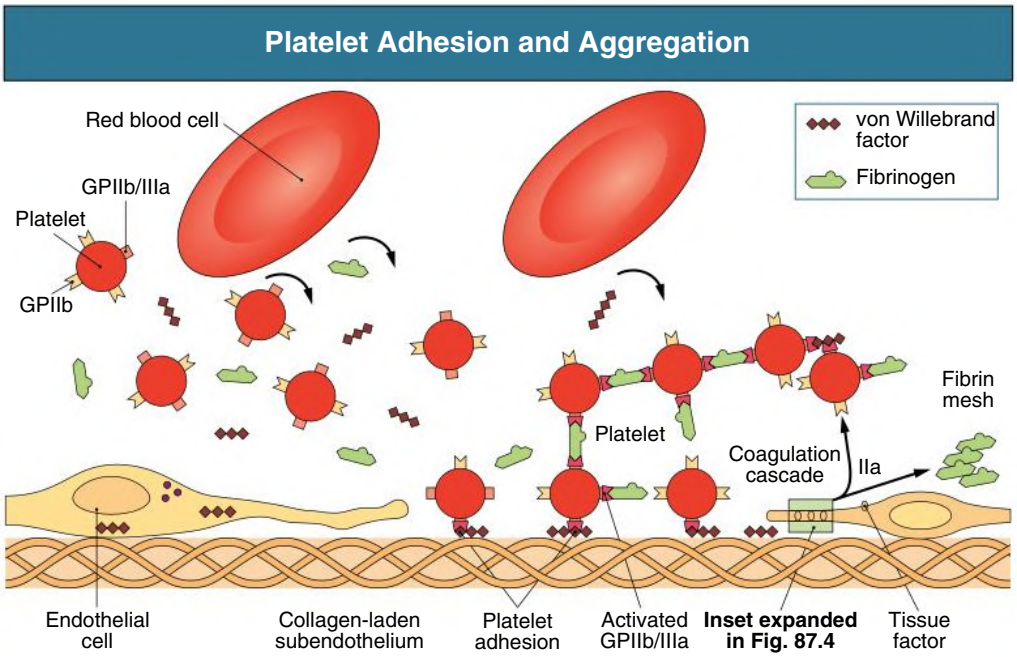

Fig. 87.3 Platelet Adhesion and Aggregation. Platelets are pushed peripherally toward the vascular wall by red blood cells traversing centrally through the bloodstream. Damage to the vessel wall results in a disruption of the nonthrombogenic endothelial cell lining and exposure of subendothelial structures. Whereas collagen supports initial platelet adhesion (and subsequent aggregation), von Willebrand factor (vWF) deposition on the subendothelium serves as the main anchor for platelet adhesion through platelet glycoprotein (GP) IIb receptor. Postadhesion conformational change in platelet GPIIb/IIIa receptor (fibrinogen or vWF receptor) results in interlinking platelet aggregation.

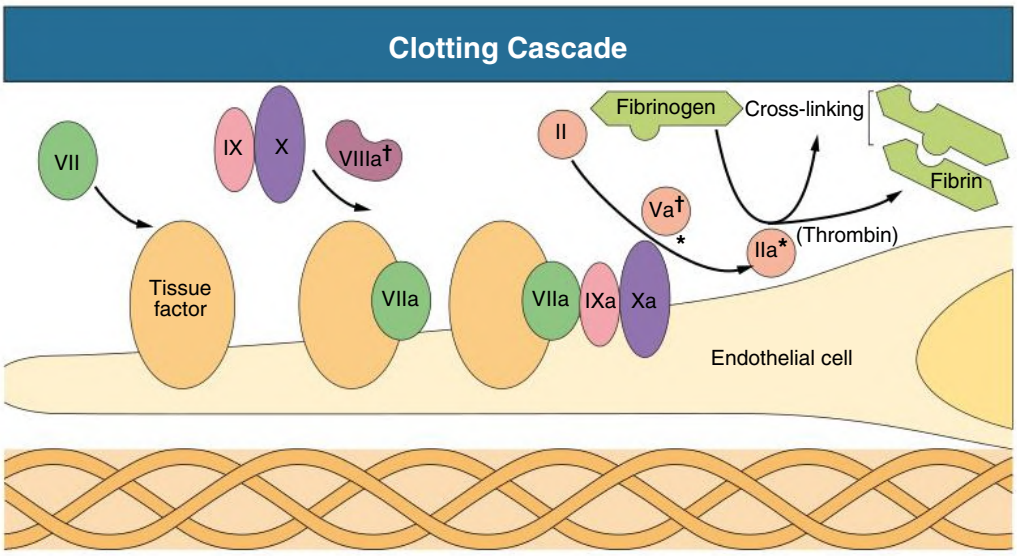

Fig. 87.4 Clotting Cascade. Expansion of the inset in Fig. 87.3 shows the clotting cascade that takes place at the damaged vessel wall. Exposure of subendothelial tissue factor, present on pericytes and fibroblasts, allows eventual activation of prothrombin (factor II) to thrombin. Thrombin converts fibrinogen to fibrin, activates fibrin cross-linking, stimulates further platelet aggregation, and activates anticoagulant protein C. Naturally occurring anticoagulants antithrombin III, protein C, and protein S help maintain control and counterbalance on coagulation. *Site of anticoagulant effect for antithrombin III. †Site of anticoagulant effect for protein C–protein S complex. BOX 87.1 Proposed Contributors to Platelet Dysfunction in Uremia

Intrinsic Factors That Contribute to Platelet Dysfunction

- Dysfunction of glycoprotein IIb/IIIa
- Abnormal expression of platelet glycoprotein
- Altered release of adenosine monophosphate and serotonin from platelet α-granules
- Faulty arachidonic acid and depressed prostaglandin metabolism, decreased platelet thromboxane A2 generation
- Abnormal platelet cytoskeletal assembly with reduced incorporation of actin and diminished association of actin binding proteins (α-actin and tropomyosin) with the cytoskeleton

Extrinsic Factors That Contribute to Platelet Dysfunction

- The action of uremic toxins
- Anemia
- Increased nitric oxide and cyclic guanosine monophosphate production
- Functional von Willebrand factor abnormalities
- Decreased platelet production
- Abnormal interactions between the platelet and the endothelium of the vessel wall

Modified from Berns JS. Platelet dysfunction in uremia. UpToDate. https://www.uptodate.com/contents/platelet-dysfunction-in-uremia.

inactivating PGI_2, and by scavenging nitric oxide (NO), which are all central regulators of platelet function.[43]

Treatment of Uremic Platelet Dysfunction

Despite the previously discussed pathophysiologic considerations, few data establish the extent to which initiation of kidney replacement therapy reduces the risk for bleeding in CKD.

In the early decades of HD, the interaction of blood with cellulose-based dialyzer membranes resulted in complement activation and transient thrombocytopenia during the dialysis procedure. When using more biocompatible dialyzer membranes, such complement-induced platelet reduction no longer has clinical relevance. Nonetheless, HD treatment may still affect bleeding disorders; although potentially removing uremic toxins, which affect platelet function, it requires systemic anticoagulation and exposes patients to the potential risk for heparin-induced thrombocytopenia (HIT). Moreover, HD may disrupt the platelet cytoskeleton, induce repeated platelet stress, decrease the percentage of RNA-rich platelets, and reduce the percentage of available reticulated platelets.[46] As RNA-rich and reticulated platelets are more able to be activated, the accumulation of less RNA-rich and less reticulated platelets indicates the presence of less reactive platelets. Although treatment of anemia may improve some parameters of platelet dysfunction,[46] it has not been demonstrated to ameliorate bleeding or risk for bleeding.

In summary, dialysis and anemia treatment will not completely normalize platelet function. Therefore, drug treatment should be considered for those patients who have active bleeding or are scheduled to undergo an invasive diagnostic or therapeutic procedure with bleeding risk.

Desmopressin

Desmopressin (1-deamino-8-D-arginine-vasopressin [DDAVP]) is a synthetic derivative of the antidiuretic hormone with little vasopressor activity. It acts by stimulating the release of large factor VIII–von Willebrand factor multimers from endothelial cells into the plasma and potentially by increasing the membrane glycoprotein expression of platelets.

At a dose of 0.3 μg/kg (if given intravenously [in 50 mL of saline over 15–30 minutes] or subcutaneously]), desmopressin may improve the bleeding time over the subsequent 4 to 8 hours. Typical side effects include water retention, hyponatremia, moderate thrombocytopenia, facial flushing, mild transient headache, nausea, abdominal cramps, and mild tachycardia; thrombotic events are rarely observed.[42]

Although its efficacy on laboratory measures of platelet function is undisputed, its clinical efficacy for preventing or treating bleeding remains unproven. One study that recruited 162 participants without severely reduced kidney function who underwent ultrasound-guided kidney biopsy suggested that prebiopsy desmopressin administration may decrease the risk of bleeding and hematoma size.[47] However, given this rather limited evidence for a clinical benefit of desmopressin, there is broad consensus that desmopressin is not mandatory before a routine kidney biopsy. Additionally, depletion of endothelial stores of the factor VIII–von Willebrand factor multimers after a second DDAVP injection may result in tachyphylaxis, which precludes its chronic use.

Cryoprecipitate

In many uremic patients, cryoprecipitate may improve the bleeding time within 1 hour after infusion. This effect is supposed to be mediated by the provision of factor VIII–von Willebrand factor multimers, fibrinogen, and by other factors that enhance platelet aggregation. However, this effect is short lasting (4–24 hours). Moreover, cryoprecipitate may have infectious, hemorrhagic, and anaphylactic complications, and not all patients respond to cryoprecipitate.[42,43,46] Thus, use of cryoprecipitate should be limited to patients with life-threatening bleeding who are resistant to treatment with desmopressin and blood transfusions.

Tranexamic Acid

As an antifibrinolytic agent, tranexamic acid (TXA) is licensed for treatment of heavy bleeding, as well as before dental interventions in patients with coagulopathies. Its use in CKD has been reported in several (mostly small) cohort studies, which often focused on surrogate markers of hemorrhagic diathesis. Therefore, TXA may be considered for life-threatening bleeding events in CKD patients. However, it should be reserved for those in whom other treatments have failed to control bleeding, because kidney excretion is the main route of TXA clearance. TXA has an unpredictable pharmacokinetic profile in advanced CKD patients, who are at particular risk for neurologic side effects of TXA (i.e., seizures).[48]

RECOMBINANT ACTIVATED FACTOR VII

Recombinant activated factor VII (rFVIIa) was developed for treatment of hemorrhage in individuals with hemophilia with antibodies inactivating factor VIII or IV. Because of the central role of activated factor VII in coagulation, rFVIIa has been used off-label in a variety of other severe bleeding disorders, including some case reports that claimed successful use of rFVIIa for treatment of bleeding in CKD patients.[43] This very limited evidence, together with a substantial risk for thromboembolic events, mandates very prudent use of rFVIIa, which should be considered only in very severe bleeding when other interventions have failed.

ESTROGENS

Estrogens may improve bleeding time in CKD patients in a dose-dependent manner. Their mode of action involves a reduced production of L-arginine, which is a precursor of NO. Thus, estrogens may lower elevated NO production in CKD patients and subsequently reduce NO-induced guanylyl cyclase stimulation and cyclic guanosine monophosphate (cGMP) synthesis, which will finally increase thromboxane A and ADP availability. Estrogens may additionally lower hemorrhagic diathesis by affecting production of coagulation factors and their inhibitors.

Estrogens may be given intravenously, orally, or cutaneously. Compared with other approaches, estrogen treatment may affect bleeding tendency for a prolonged time. However, its long-term safety has again not been assessed in prospective studies.

IMPLICATIONS FOR ANTIPLATELET AGENT THERAPY

Uremic platelet dysfunction and the increased bleeding risk also imply that treatment with antiplatelet agents—particularly aspirin, clopidogrel, prasugrel, and ticagrelor—may induce more bleeding events among CKD patients than in the general population. At the same time, CKD patients are at high CV risk, and use of aspirin or other antiplatelet agents may reduce their risk for myocardial infarctions and stroke.

A recent KDIGO guideline[9] recommends that "adults with CKD at risk for atherosclerotic events be offered treatment with antiplatelet agents unless there is an increased bleeding risk that needs to be balanced against the possible CV benefits." However, it remains unclear how to identify the patients who may benefit from antiplatelet agents, and risk scores from the general population work poorly among CKD patients.

Antiplatelet agents should not routinely be prescribed to all CKD patients because the increased risk for major bleeding appears to outweigh the CV benefits, at least in CKD patients with low risk for atherosclerotic events.[49] Their use among CKD patients with overt atherosclerotic vascular disease is strongly recommended (see Chapter 85). However, dual-antiplatelet therapy should be limited to the very early period after acute myocardial infarction or after coronary stenting among CKD patients, whose bleeding risk with dual-antiplatelet therapy is much higher than in patients with intact kidney function.

CIRCULATING COAGULATION FACTORS

Despite their elevated bleeding risk, patients with advanced CKD also may show features of a hypercoagulable state. Although general measures of the coagulation system—prothrombin time and partial thromboplastin time—are within normal ranges, venous thromboembolism (VTE) occurs more frequently in patients with low glomerular filtration rate and/or high albuminuria than among individuals with intact kidney function. A variety of factors may contribute, which include elevated levels of factor VIII and vWF, and a variety of comorbidities, including immobilization, congestive heart failure, and obesity. Iatrogenic factors may additionally play a part in CKD-associated hypercoagulation, such as drug treatment (erythropoietin, corticosteroids), intravascular interventions, and devices.

THERAPEUTIC INTERVENTION

Components of the coagulation system are targets of many drugs for prevention or treatment of thrombotic disease, including unfractionated and low-molecular-weight heparin (LMWH), vitamin K antagonists (VKAs), and non–vitamin K antagonist oral anticoagulants (NOACs).

First, heparin is routinely used during HD for preventing clotting in the extracorporeal circulation. Thus, nearly all HD patients are exposed to potential side effects of heparin, which include an increased bleeding risk and some less frequent adverse events, of which the development of HIT is the most serious complication. HIT is a clinical syndrome induced by antibodies that bind to heparin and platelet factor IV complexes on the platelet surface and thereby cause platelet activation. Clinically, HIT often manifests with arterial or venous

thrombosis; less frequent complications are venous limb gangrene, adrenal hemorrhagic necrosis, necrotizing skin lesions at heparin injection sites, and acute systemic reactions within a few minutes after exposure to unfractionated heparin or LMWH injections. Of note, many patients have heparin-dependent antibodies without clinically apparent HIT. Therefore, to avoid overdiagnosing HIT, immunologic tests should not be ordered in patients with a low clinical likelihood but focused on patients in whom HIT is suspected clinically (as suggested by the 4T score; Table 87.2). This is of particular importance for HD patients, in whom an incorrect diagnosis may result in the withdrawal of heparin treatment during HD and in the initiation of less established (and more expensive) anticoagulation strategies. In the absence of CKD-specific pathways, the diagnosis of HIT should follow recommendations from the general population. Here, the likelihood of HIT should first be estimated with clinical prediction tools, and use of antigen assays for confirmation of HIT antibodies should focus on patients with high and intermediate clinical likelihood (Fig. 87.5). Importantly, these antigen assays for detection of HIT antibodies have a high sensitivity but poor specificity. Wherever available, functional assays (serotonin release assays or heparin-induced platelet activation) should be used to confirm positive findings from antigen assays in the majority of patients with suspected HIT.

Once a patient has a high or intermediate clinical probability of HIT, all heparin treatment must be stopped and alternative anticoagulation initiated. The most relevant treatment options are listed in Table 87.3. Of note, no VKA should be initiated at this stage because these agents may reduce activation of anticoagulatory protein C and thus further perpetuate the prothrombotic state.

TABLE 87.2 4Ts Score to Determine the Likelihood of Heparin-Induced Thrombocytopenia

	Score = 2	Score = 1	Score = 0
Thrombocytopenia: compare the highest platelet count within the sequence of declining platelet counts with the lowest count to determine the percent of platelet fall (select only one option)	>50% platelet fall *and* nadir of ≥20,000/μL *and* no surgery within preceding 3 days	>50% platelet fall *but* surgery within preceding 3 days *or* any combination of platelet fall and nadir that does not fit criteria for score 2 or score 0 (e.g., 30%–50% platelet fall or nadir 10–19)	<30% platelet fall Any platelet fall with nadir <10
Timing (of platelet count fall or thrombosis[a]) Day 0 = First day of most recent heparin exposure (select only one option)	Platelet fall day 5–10 after start of heparin Platelet fall within 1 day of start of heparin *and* exposure to heparin within past 5–30 days	Consistent with platelet fall days 5–10 but not clear (e.g., missing counts) Platelet fall within 1 day of start of heparin *and* exposure to heparin in past 31–100 days Platelet fall after day 10	Platelet fall day 4 or earlier without exposure to heparin in past 100 days
Thrombosis (or other clinical sequelae) (select only one option)	Confirmed new thrombosis (venous or arterial) Skin necrosis at injection site Anaphylactoid reaction to intravenous heparin bolus Adrenal hemorrhage	Recurrent venous thrombosis in a patient receiving therapeutic anticoagulants Suspected thrombosis (awaiting confirmation with imaging) Erythematous skin lesions at heparin injection sites	Thrombosis suspected
Other cause for thrombocytopenia[b] (select only one option)	No alternative explanation for platelet fall is evident	Possible other cause is evident: sepsis without proven microbial source, thrombocytopenia associated with initiation of ventilator, other	*Probable other cause present:* Within 72 h of surgery Confirmed bacteremia/fungemia Chemotherapy or radiation within past 20 days DIC as a result of non-HIT cause PTP Platelet count <20 *and* given a drug implicated in causing D-ITP[c] (see list) Nonnecrotizing skin lesions at LMWH injection site (presumed DTH) Other

[a]Timing of clinical sequelae, such as thrombocytopenia, thrombosis, or skin lesions.
[b]Two points if necrotizing heparin-induced skin lesions even if thrombocytopenia not present.
[c]Drugs implicated in D-ITP: *Relatively common:* glycoprotein IIb/IIIa antagonists (abciximab, eptifibatide, tirofiban), quinine, quinidine, sulfa antibiotics, carbamazepine, vancomycin. *Less common:* actinomycin, amitriptyline, amoxicillin/piperacillin/nafcillin, cephalosporins (cefazolin, ceftazidime, ceftriaxone), celecoxib, ciprofloxacin, esomeprazole, fexofenadine, fentanyl, fusidic acid, furosemide, gold salts, levofloxacin, metronidazole, naproxen, oxaliplatin, phenytoin, propranolol, propoxyphene, ranitidine, rifampin, suramin, trimethoprim. *Note:* This is a partial list. See Fig. 87.5 for interpretation of score results.
DIC, Disseminated intravascular coagulation; *D-ITP,* drug-induced immune thrombocytopenia; *DTH,* delayed-type hypersensitivity; *HIT,* heparin-induced thrombocytopenia; *LMWH,* low-molecular-weight heparin; *PTP,* posttransfusion purpura.

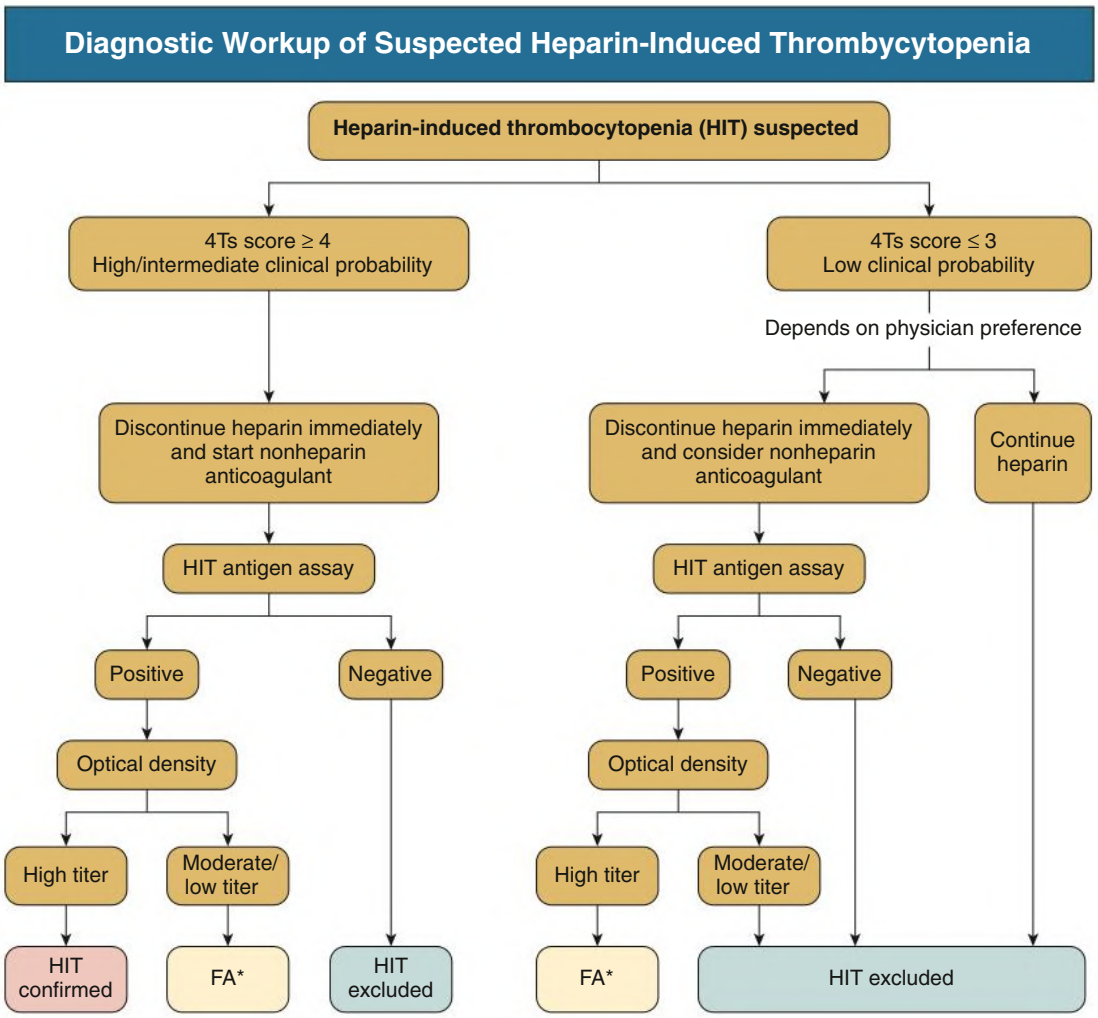

Fig. 87.5 Diagnostic Workup of Suspected Heparin-Induced Thrombocytopenia (HIT). Because of the high number of patients with antibodies against heparin without clinical HIT, a diagnostic algorithm is needed to have a high a priori likelihood of HIT before ordering antibody tests. There is no algorithm specific to patients with chronic kidney disease, and the diagnosis should be made as in patients with normal kidney function. *Confirm with functional assay (FA), if available. "4T" refers to a risk score based on four clinical parameters (thrombocytopenia, timing of platelet count fall or thrombosis, thrombosis [or other clinical sequelae], and other cause for thrombocytopenia). See Table 87.2 for a detailed description.

Additionally, anticoagulants are approved for prevention of thromboembolic stroke in patients with atrial fibrillation, for prevention and treatment of VTE (particularly deep vein thrombosis and pulmonary embolism), and for prevention of clotting in patients with mechanical heart valves. In the latter case, the need for lifelong anticoagulation with VKA is indisputable. Similarly, in patients with proximal deep vein thrombosis and symptomatic pulmonary embolism, anticoagulation is indicated for a minimum of 3 months. Recommendations on extended anticoagulation are mainly derived from the general population, in whom indefinite anticoagulation with either VKA or (preferably) NOACs (Table 87.4) may be considered in patients with unprovoked proximal deep vein thrombosis and symptomatic pulmonary embolism, whereas anticoagulation should be stopped after 3 months in patients with provoked VTE with one or more transient risk factors. In patients with active cancer and VTE, data from the general population suggest indefinite anticoagulation with LMWH or NOACs. When considering indefinite anticoagulation in patients with advanced CKD, their elevated bleeding risk must be considered. Therefore, if extended oral anticoagulation is decided after VTE in a CKD patient without cancer, a reduced dose of the NOACs apixaban (2.5 mg twice daily) or rivaroxaban (10 mg once daily) should be considered after 6 months of therapeutic anticoagulation, which is supported both by evidence from randomized trials and by guidelines.[50] This is of particular importance, as dose reductions of NOACs in CKD patients with VTE do not fully follow recommendations for CKD patients with atrial fibrillation. Particularly, no dosage adjustment is recommended, but "use with caution" is recommended by the manufacturers of apixaban and rivaroxaban for any degree of reduced kidney function in the treatment of deep vein thrombosis and/or pulmonary embolism, whereas the manufacturer of edoxaban recommends 30 mg instead of (standard-dose) 60 mg edoxaban in patients with creatinine clearance of 15 to 50 mL/min.

For patients with advanced CKD, the use of anticoagulants in atrial fibrillation is controversial (see Chapter 85). In the general population, patients who have one or more risk factors for cerebral stroke or systemic embolization (defined as a CHA_2DS_2-VASc score of ≥1 in men and ≥2 in women) should receive oral anticoagulation. Similarly, use of warfarin (if adjusted to target an international normalized ratio [INR] of 2.0–3.0) has been shown to reduce stroke risk substantially in patients with stage 3a/3b CKD.[51] In these patients, NOACs are at least

TABLE 87.3 Characteristics of Anticoagulants Used to Treat Patients With Heparin-Induced Thrombocytopenia

Characteristic	Argatroban	Danaparoid	Bivalirudin	Fondaparinux
Target	Thrombin	Factor Xa (predominantly)	Thrombin	Factor Xa
Elimination	Hepatobiliary	Renal	Enzymatic (80%)/renal (20%)	Renal
Approved for patients with HIT[a]	Treatment/PCI	Treatment	PCI/cardiac surgery	No
Method of administration	IV	IV, SC	IV	SC
Monitoring	aPTT ACT	Anti-Xa level	aPTT ACT or ECT (high doses)	Anti-Xa level
Effect on INR	+++	0	++	0
Immunologic features	None	5% cross-reactivity with HIT Ab[b]	Potentially cross-reactive with antilepirudin Ab	May cause HIT[c]
Antidote available	No	No	No	No
Dialyzable	20%	Yes	25%	20%

[a]In some countries (check with local health regulatory authorities).
[b]Clinical significance is uncertain and routine testing for cross-reactivity is not recommended.

Modified from Steffel J, Verhamme P, Potpara TS, et al. 2018 European Heart Rhythm Association Practical Guide on the use of non–vitamin K antagonist oral anticoagulants in patients with atrial fibrillation. *Eur Heart J.* 2018;39(16):1330–1393.

as efficient as VKAs for prevention of thromboembolic events but may cause fewer intracerebral bleeding events. For patients with creatinine clearance less than 30 mL/min, few data demonstrate the efficacy (i.e., prevention of thromboembolic events) and safety (i.e., major bleeding events) of either VKAs or NOACs because most prospective clinical trials excluded patients with advanced CKD. The notable exception is very-low-dose edoxaban, which was tested in the ELDER-CARE study that also included patients with stage 4 CKD. In these patients, 15 mg edoxaban consistently protected against ischemic stroke without causing a prohibitively high bleeding risk.[52] Moreover, VKA accelerates vascular calcification[53,54] and possibly also CKD progression, in particular in higher doses.[55] In dialysis patients with atrial fibrillation, retrospective cohort studies yielded conflicting findings on whether oral anticoagulation lowers stroke incidence (see Chapter 85).[56,57]

For the time being, patients with atrial fibrillation and at least moderate risk for thromboembolism (defined by CHA_2DS_2-VASc score ≥2 for women, and ≥1 for men) should be offered NOACs if they have mild to moderate CKD (CKD 1–3b), unless they have prohibitive high

risk for bleeding. For stage 4 and 5 CKD patients with atrial fibrillation, lack of evidence precludes strong recommendations whether to use NOACs or no anticoagulation, with the potential alternative option of left atrial appendage closure. Based upon data from a first randomized clinical trial, VKAs appear inferior to dose-reduced NOACs in dialysis patients, but it is uncertain whether NOACs are preferable to no anticoagulation.[57]

Both LMWH and NOACs require dose adjustment in patients with CKD because they undergo renal excretion. As of 2022, only one NOAC (apixaban) has been licensed for use among dialysis patients in the United States, but not yet in Europe. Compared with other NOACs, apixaban is characterized by the least accumulation in CKD, but still requires (like all NOACs) dose adjustment for kidney function. Notably, pharmacokinetic studies (and subsequent recommendations on NOAC dosages) used creatinine clearance estimated with the Cockcroft-Gault equation. In clinical practice, eGFR is now mostly calculated using the Modification of Diet in Renal Disease (MDRD) or Chronic Kidney Disease–Epidemiology (CKD-EPI) formula. Substituting the latter for the former may cause large dosage errors, particularly when physicians fail to consider that the more recent equations yield estimates standardized for a body surface area of 1.73 m^2, and nonstandardized measures of kidney function (as provided by the Cockcroft-Gault equation) are suggested for dose adjustment.

SELF-ASSESSMENT QUESTIONS

1. Which of the following diagnostic findings is reliable (sensitive and specific enough to be useful) in patients with CKD even in the presence of their typical immune dysfunction?
   - **A.** Fever as a sign of bacteremia
   - **B.** Radiologic infiltration on chest radiograph for pneumonia
   - **C.** Mendel-Mantoux skin reaction for tuberculosis
   - **D.** Blood culture for bacteremia
   - **E.** C-reactive protein for infection
2. Viral hepatitis is a typical complication of hemodialysis treatment. Which statement correctly describes viral hepatitis in advanced CKD?
   - **A.** HBV infection leads to chronic infection in the majority of affected CKD patients.
   - **B.** Acute HBV infection in CKD patients is typically severe, characterized by jaundice and fever.
   - **C.** HBV infection can be easily prevented in CKD patients by vaccination, as recommended to the general population.
   - **D.** The clinical course of hepatitis C infection is largely different in CKD patients and those with normal kidney function.
   - **E.** Standard hygienic precautions have largely failed to reduce HBV transmission in dialysis centers. Only vaccination succeeded in preventing nosocomial transmission.
3. The hemorrhagic diathesis in CKD patients is typically mirrored by which of the following?
   - **A.** Prolongation of the prothrombin time
   - **B.** Prolongation of the partial thromboplastin time
   - **C.** Severely thrombocytopenia
   - **D.** Hyperchromic anemia
   - **E.** None of these
4. The spectrum of interventions that may allow reducing hemorrhages in advanced CKD does *not* include which of the following?
   - **A.** Desmopressin
   - **B.** Conjugated estrogens
   - **C.** Tranexamic acid
   - **D.** Cryoprecipitates
   - **E.** Clopidogrel

Bone and Mineral Disorders in Chronic Kidney Disease

Marc Vervloet, Markus Ketteler, Jürgen Floege

DEFINITION

Disturbances of mineral metabolism are ubiquitous in chronic kidney disease (CKD) and lead to serious and debilitating complications unless these abnormalities are addressed and treated. The spectrum of the condition includes abnormal concentrations of serum calcium, phosphate, and magnesium as well as disorders of parathyroid hormone (PTH), fibroblast growth factor-23 (FGF-23), and vitamin D metabolism. These abnormalities and other factors related to the uremic state affect the skeleton and result in the complex disorders of bone known as *renal osteodystrophy*. This term should be used exclusively to define the bone disease associated with CKD, but it is important to acknowledge that aging-related and postmenopausal osteoporosis can exist in parallel. The clinical, biochemical, and imaging abnormalities previously identified as correlates of renal osteodystrophy are now defined more broadly as a syndrome called *chronic kidney disease–mineral and bone disorder* (CKD-MBD).[1] The spectrum of skeletal abnormalities seen in renal osteodystrophy includes (Fig. 88.1):

- Osteitis fibrosa, a manifestation of hyperparathyroidism characterized by increased osteoclast and osteoblast activity, peritrabecular fibrosis, and increased bone turnover.
- Osteomalacia, a manifestation of defective mineralization of newly formed osteoid most often caused by aluminum deposition; bone turnover is decreased.
- Adynamic bone disease (ABD), a condition characterized by abnormally low bone turnover.
- Osteopenia or osteoporosis.
- Combinations of these abnormalities termed *mixed renal osteodystrophy*.
- Other abnormalities with skeletal manifestations (e.g., chronic acidosis, β_2-microglobulin amyloidosis [Aβ_2M amyloidosis]).

EPIDEMIOLOGY

The prevalence of the various types of renal osteodystrophy in patients with end-stage kidney disease (ESKD) is illustrated in Fig. 88.2.[2] In patients on hemodialysis (HD), osteitis fibrosa is declining, whereas ABD is increasing in prevalence, at least in White patients.[3] In Black patients on dialysis, osteitis fibrosa is still the most prevalent form. In patients on peritoneal dialysis (PD), those with diabetes, and the elderly, adynamic bone lesion has been the dominant form of renal osteodystrophy for decades. Osteomalacia represents only a small fraction of cases in either group but is more common in certain ethnic groups, particularly South Asians. Skeletal abnormalities associated with CKD can begin at relatively preserved levels of estimated glomerular filtration rate (eGFR; ~50 mL/min/1.73 m^2).

PATHOGENESIS

Several biochemical and hormonal abnormalities associated with CKD contribute to renal osteodystrophy and can be affected by efforts at prevention and treatment. The major factors may vary as CKD progresses (Fig. 88.3). Similarly, the predominance of one particular pathogenetic mechanism over another may contribute to the heterogeneity of bone disorders. We therefore discuss separately the two major entities: high- and low-turnover osteodystrophy.

OSTEITIS FIBROSA: HYPERPARATHYROIDISM—HIGH-TURNOVER RENAL BONE DISEASE

Elevated levels of PTH in blood, hyperplasia of the parathyroid glands, and elevations in FGF-23 are seen once eGFR declines below approximately 50 mL/min/1.73 m^2. Although the level of free (i.e., non–protein bound) calcium in blood is normally the principal determinant of PTH secretion, several metabolic disturbances associated with CKD also alter the secretion of PTH.

Abnormalities of Calcium Metabolism

There are three main body pools of calcium: the bony skeleton (mineral component), the intracellular pool (mostly protein bound), and the extracellular pool (see Chapter 11). The calcium in the extracellular pool is in continuous exchange with that of bone and cells and is altered by diet and excretion. Calcium metabolism mainly depends on the close interaction of two hormone systems, PTH and vitamin D, although a minor and ill-defined role for calcitonin may exist as well. CKD leads to perturbations of both major systems, with adverse consequences on the skeleton. Total serum calcium tends to decrease in parallel with GFR because of phosphate retention, decreased kidney production of 1,25-dihydroxyvitamin D (calcitriol), reduced intestinal calcium absorption, and skeletal resistance to the calcemic action of PTH. However, free calcium levels remain within the normal range in most patients[4] because of compensatory hyperparathyroidism. Because calcium is a major regulator of PTH secretion, persistent hypocalcemia is a powerful stimulus for development of hyperparathyroidism and also contributes to parathyroid growth.

Abnormalities of Phosphate Metabolism

With progressive CKD, phosphate is retained, at least, transiently, by the failing kidney. However, hyperphosphatemia usually does not become evident before stage 4 CKD. Until then, compensatory hyperparathyroidism and increases in circulating FGF-23 result in increased phosphaturia, maintaining serum phosphate levels in the normal range.[5]

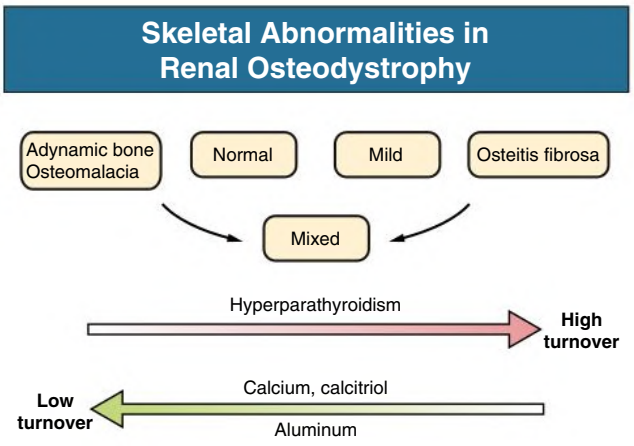

Fig. 88.1 Spectrum of Renal Osteodystrophy. The range of skeletal abnormalities in renal bone disease encompasses syndromes with both high and low bone turnover.

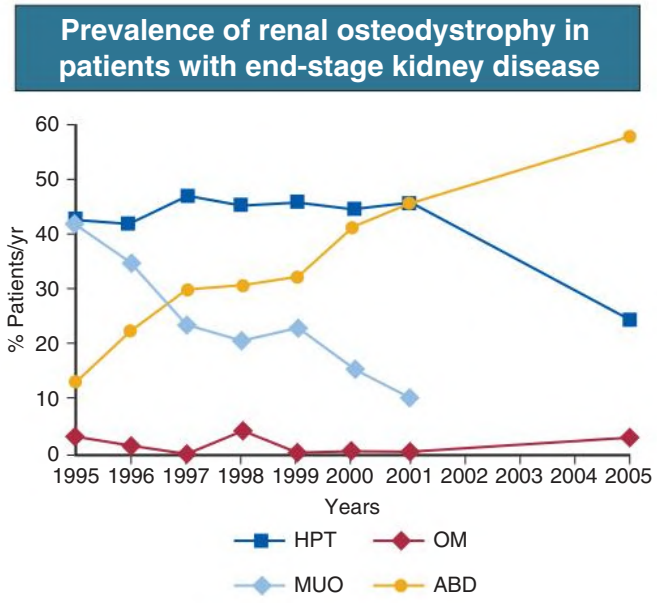

Fig. 88.2 Prevalence of renal osteodystrophy in patients with end-stage kidney disease. *ABD,* Adynamic bone disease; *HPT,* high-turnover renal osteodystrophy; *MUO,* mixed uremic osteodystrophy; *OM,* osteomalacia. The importance of bone health in end-stage renal disease: Out of the frying pan, into the fire? *Nephrol Dial Transplant.* 2004;19[Suppl 1]:i9–13.)

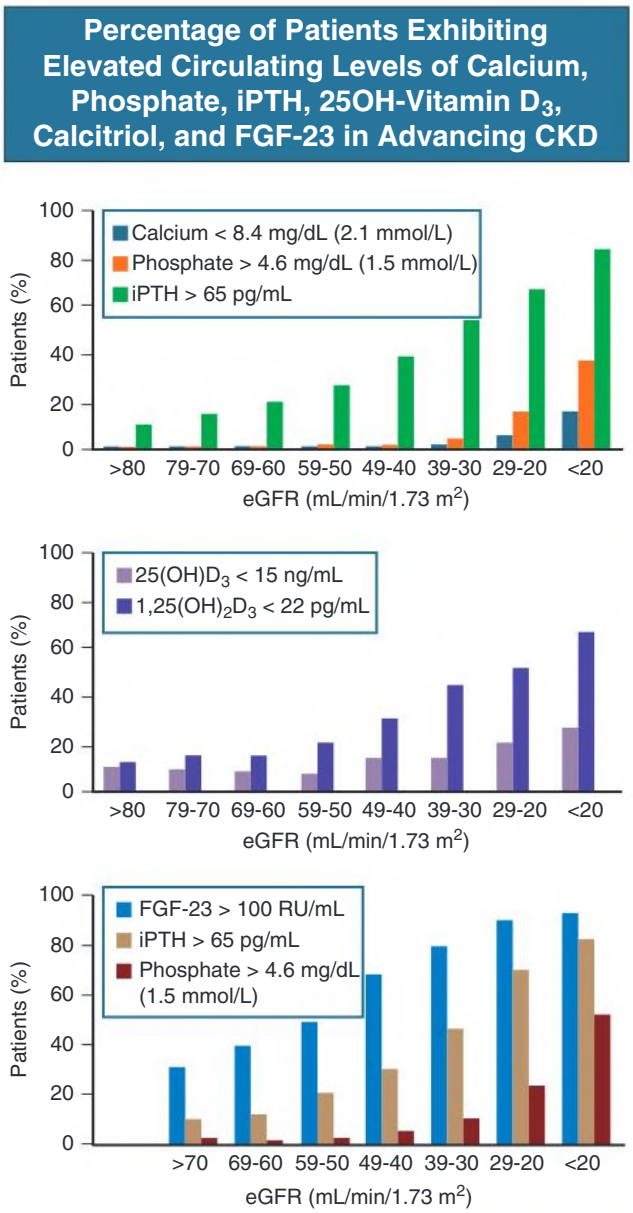

Fig. 88.3 Percentage of patients exhibiting elevated circulating levels of calcium, phosphate, intact parathyroid hormone (iPTH), 25OH-vitamin D_3, calcitriol, and fibroblastic growth factor-23 (FGF-23) in advancing chronic kidney disease (CKD). Particularly in early CKD stages, there is wide variability at the individual level, and some patients, for example, may exhibit increased FGF-23 and normal iPTH, whereas others may have elevated iPTH levels with normal FGF-23 or elevations of both. *eGFR,* Estimated glomerular filtration rate. (Data from Levin A, Bakris GL, Molitch M, et al. Prevalence of abnormal serum vitamin D, PTH, calcium, and phosphorus in patients with chronic kidney disease: Results of the study to evaluate early kidney disease. *Kidney Int.* 2007;71:31–; and Isakova T, Wahl P, Vargas GS, et al. Fibroblast growth factor 23 is elevated before parathyroid hormone and phosphate in chronic kidney disease. *Kidney Int.* 2011;79:1370–1378.)

Phosphate retention leads to hyperparathyroidism by decreasing serum free calcium, which, in turn, stimulates the secretion of PTH (Fig. 88.4). In addition, phosphate interacts with the calcium sensing receptors on parathyroid cells, attenuating the suppressive effects of calcium on PTH.[6] Thus, a new steady state is achieved in which serum phosphate is restored to normal at the expense of a sustained high level of PTH. This cycle is repeated as kidney function declines until sustained and severe hyperparathyroidism is present. Second, phosphate retention leads to decreased kidney production of calcitriol, either directly or by increasing the levels of FGF-23 (which decreases the activity of 1α-hydroxylase). The decrease in calcitriol allows increases in PTH gene transcription and also decreases intestinal calcium absorption, leading to hypocalcemia, which, in turn, also stimulates PTH secretion. Third, hyperphosphatemia is associated with resistance to the actions of calcitriol in the parathyroid glands, which also favors development of hyperparathyroidism and induces resistance to the actions of PTH in bone. Finally, phosphate per se appears to affect PTH secretion independently of changes in serum calcium or serum calcitriol.[7,8] Phosphate may have an effect on parathyroid growth independent of serum calcium.[9,10] Regardless of the mechanism by which phosphate retention causes hyperparathyroidism, experimental studies suggest that restriction of dietary phosphate in proportion to the

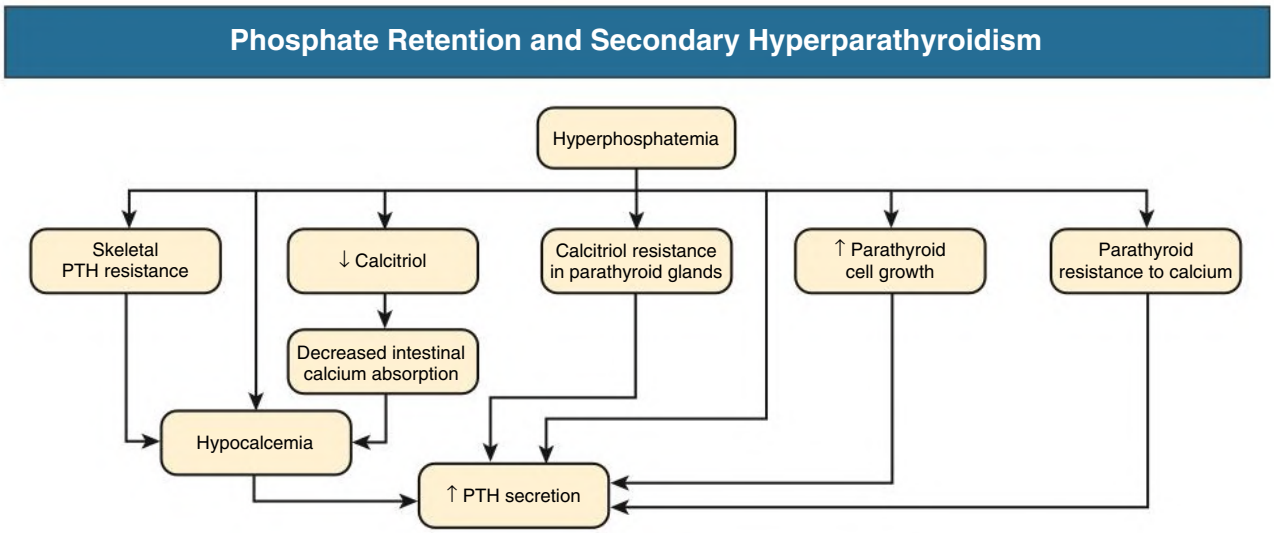

Fig. 88.4 Role of Phosphate Retention in the Pathogenesis of Secondary Hyperparathyroidism. Hyperphosphatemia stimulates parathyroid hormone (PTH) secretion indirectly by inducing hypocalcemia, skeletal resistance to PTH, low levels of calcitriol, and calcitriol resistance. Hyperphosphatemia also has direct effects on the parathyroid gland to increase PTH secretion and parathyroid cell growth.

decrease in GFR can prevent development of hyperparathyroidism, but it is uncertain whether this is clinically relevant. FGF-23 also appears to act directly on the parathyroid gland, with inhibitory effects on PTH secretion and parathyroid growth.[11,12] This effect is dependent on parathyroid presence of the coreceptor α-klotho, although expression of this coreceptor is reduced in CKD. Elevated FGF-23 levels also lead to a substantial reduction in calcitriol production, which, in turn, contributes to hyperparathyroidism. These various actions may partially explain the association between higher levels of FGF-23 and adverse clinical outcomes.[13]

Abnormalities of Vitamin D Metabolism

The conversion of 25-hydroxyvitamin D to its active metabolite 1,25-dihydroxyvitamin D occurs mainly in the kidney by the enzyme 1α-hydroxylase. Extrarenal production of calcitriol also occurs and contributes to the circulating levels of calcitriol. Kidney calcitriol production progressively declines in parallel with eGFR as a result of several mechanisms (Fig. 88.5).

Calcitriol production is compromised in CKD by a reduction in 25-hydroxyvitamin D levels[14] and the decrease in GFR, which further limits the delivery of 25-hydroxyvitamin D to the site of the 1α-hydroxylase in the proximal tubule. Early increases of FGF-23 in CKD likely have a prominent role on vitamin D metabolism because it inhibits 1α-hydroxylase activity but also promotes catabolism of vitamin D. Phosphate retention, besides increasing FGF-23, may also directly decrease the activity of 1α-hydroxylase. The ensuing reductions in calcitriol levels directly and indirectly contribute to the pathogenesis of hyperparathyroidism as described earlier (Fig. 88.6). Low levels of calcitriol directly release the gene for PTH from suppression by the vitamin D receptor and allow increased PTH secretion. In many tissues, vitamin D regulates its own receptor by positive feedback; in CKD, the vitamin D receptor content is decreased in parathyroid tissue. Administration of calcitriol increases the vitamin D receptor content in the parathyroid glands coincident with the suppression of PTH secretion. Studies in vitro have shown that calcitriol is a negative growth regulator of parathyroid cells and therefore calcitriol deficiency in patients with CKD may facilitate parathyroid cell proliferation. Other direct consequences of low levels of calcitriol contributing to the pathogenesis of secondary hyperparathyroidism include an increase in the parathyroid set-point for calcium-regulated PTH secretion and possibly a decrease in the expression of calcium receptors.

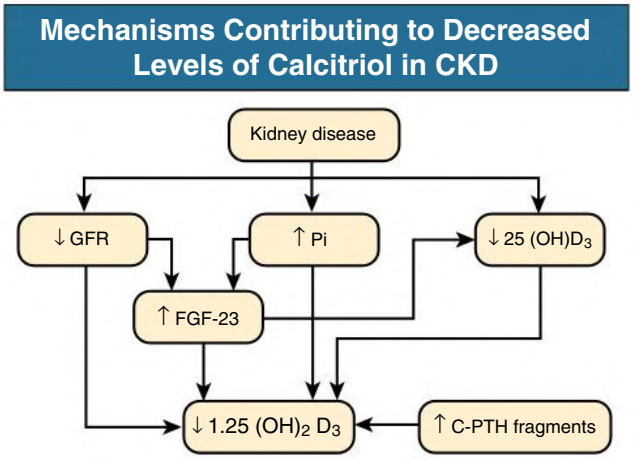

Fig. 88.5 Mechanisms contributing to decreased levels of calcitriol in chronic kidney disease (CKD). *C-PTH,* Carboxyl-terminal parathyroid hormone; *FGF-23,* fibroblast growth factor-23; *GFR,* glomerular filtration rate; *Pi,* inorganic phosphate.

Low levels of calcitriol also may indirectly promote the development of hyperparathyroidism by reducing intestinal absorption of calcium, leading to hypocalcemia and stimulation of PTH release.

Abnormalities of Parathyroid Gland Function

CKD is associated with intrinsic abnormalities in parathyroid gland function, in addition to those caused by hypocalcemia, low levels of calcitriol, and skeletal resistance to the actions of PTH (Box 88.1).

Parathyroid hyperplasia is an early finding in CKD. In experimental models, hyperplasia begins within a few days after the induction of CKD and can be prevented by dietary phosphate restriction or by the use of calcimimetic agents.[10,15] Resected parathyroid glands from patients with severe hyperparathyroidism have nodular areas throughout the gland, which represent monoclonal expansions of parathyroid cells. Within these nodules, there is decreased expression of vitamin D receptors, calcium receptors, and α-klotho expression, the cofactor for FGF-23 signaling, reducing the ability of drugs such as active vitamin D and calcimimetics to bind to and treat the gland hyperplasia.

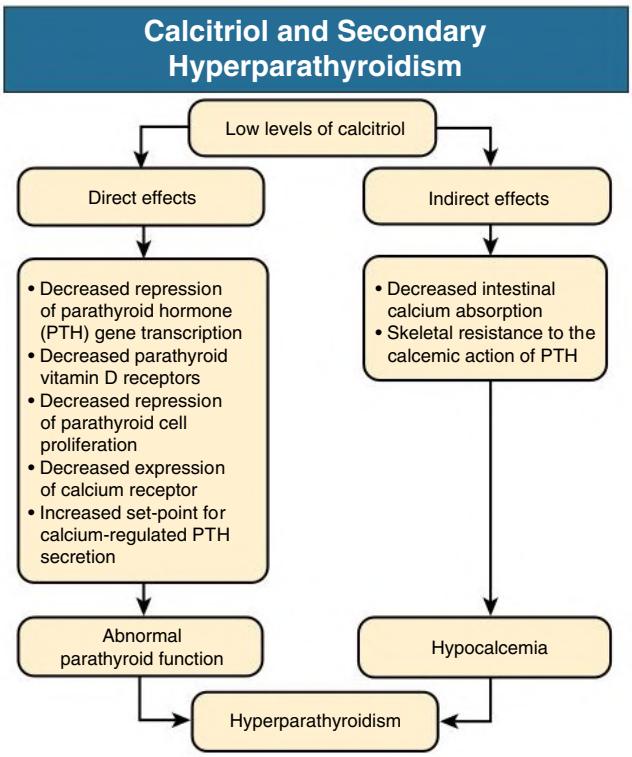

Fig. 88.6 Role of low levels of calcitriol in the pathogenesis of secondary hyperparathyroidism.

The parathyroid calcium receptor is centrally involved in the regulation of PTH secretion by calcium.[16] Its expression and synthesis are decreased in the parathyroid glands from hyperparathyroid patients. In addition, phosphate impairs the calcium sensitivity of the receptor. These mechanisms lead to increased concentrations of calcium to suppress PTH release from the parathyroid cells of uremic patients compared with healthy subjects. Thus, the presence of severe CKD appears to increase the concentration of calcium that is required to substantially decrease PTH release from the parathyroid.

Abnormal Skeletal Response to Parathyroid Hormone

In patients with CKD, there is an impaired response of serum calcium to the administration of PTH and a delay in the recovery from induced hypocalcemia in the presence of larger increments in PTH levels. Thus, in CKD the skeleton is relatively resistant to the calcemic actions of PTH. The resultant decrease in serum calcium levels stimulates PTH secretion and contributes to the pathogenesis of secondary hyperparathyroidism. Factors involved in the skeletal resistance to PTH in CKD include decreased levels of calcitriol, downregulation of the PTH receptor, and phosphate retention. In addition, circulating fragments of PTH, truncated at the *N*-terminus, have been suggested to oppose the calcemic actions of PTH, possibly acting at a presumed receptor for the C-terminal region of PTH.[17,18]

Clinical Manifestations of High-Turnover Renal Osteodystrophy

Clinical manifestations of hyperparathyroidism are usually nonspecific and often preceded by biochemical or imaging abnormalities. One specific feature is the increased risk of fractures, typically of long bones, sometimes associated with brown tumors (see later discussion). Nonspecific aches and pains are more common; occur in the lower back, hips, and legs, aggravated by weight bearing; and can be debilitating. Acute, localized bone pain can occur and may be suggestive of acute arthritis. Pain around joints may be caused by acute periarthritis, which is associated with periarticular deposition of calcium phosphate crystals, especially in patients with marked hyperphosphatemia. The symptoms may be confused clinically with gout or pseudogout and often respond to nonsteroidal anti-inflammatory drugs (NSAIDs). The gradual onset of muscle weakness is also common in patients with ESKD. Many factors are probably involved in its pathogenesis, including hyperparathyroidism and abnormalities of vitamin D. $A\beta_2M$ (see later discussion) should be considered in the differential diagnosis in very-long-term dialysis patients.

Bone abnormalities may occur in patients with severe hyperparathyroidism, particularly in children, and are manifested on radiographs by subperiosteal erosions, resorption of terminal digits. In adults, deformities arise as a result of fractures. Fractures of the axial skeleton can lead to kyphoscoliosis or chest wall deformities. Slipped epiphysis may occur in children, and frank rachitic features are occasionally evident. Growth retardation is also common in children, and although some improvement has been shown with calcitriol, this is not universal.

Extraskeletal calcifications are frequently encountered in patients with advanced CKD and are aggravated by persistent elevation of the calcium-phosphate product. Most commonly, vascular calcifications are seen, but calcifications may occur in other sites, such as the lung, myocardium, and periarticular areas (Fig. 88.7).

In the skin, hyperparathyroidism can manifest as pruritus (see Chapter 91). Rarely, it can also underlie the development of calciphylaxis (calcific uremic arteriolopathy; see Figs. 91.6 and 91.7).

BOX 88.1 Parathyroid Abnormalities in Chronic Kidney Disease

- Parathyroid gland hyperplasia: diffuse, nodular
- Decreased expression of vitamin D receptors
- Decreased expression of calcium receptors
- Decreased expression of α-klotho
- Increased set-point of calcium-regulated parathyroid hormone secretion

Diagnosis and Differential Diagnosis

In addition to the clinical manifestations of renal osteodystrophy, a variety of biochemical and radiographic techniques are helpful to establish the specific diagnosis and guide the initiation and adjustment of therapy. Although bone biopsy is not widely used in clinical practice, it remains the gold standard for the diagnosis of renal osteodystrophy and the most specific guide for treatment decisions.

Serum Biochemistry

The levels of free calcium and phosphate in serum are usually normal in patients with mild to moderate CKD. Normally in stage 4 CKD the levels of serum calcium tend to fall and hyperphosphatemia manifests. Hypercalcemia may result from the administration of large doses of calcium-containing antacids or vitamin D metabolites or from severe hyperparathyroid bone disease. It is important to identify the cause of hypercalcemia in patients with CKD (see Chapter 11) because the management will vary greatly according to the cause. Also, the levels of serum calcium and phosphate, when used alone, are not useful in predicting the specific type of bone disease.

Parathyroid Hormone

Measurements of PTH are important for diagnostic purposes and therapeutic guidance in the management of renal osteodystrophy. With kidney impairment, there is accumulation of circulating PTH fragments, which complicates the interpretation of PTH assays, including the two-site immunometric assays, which were thought to measure

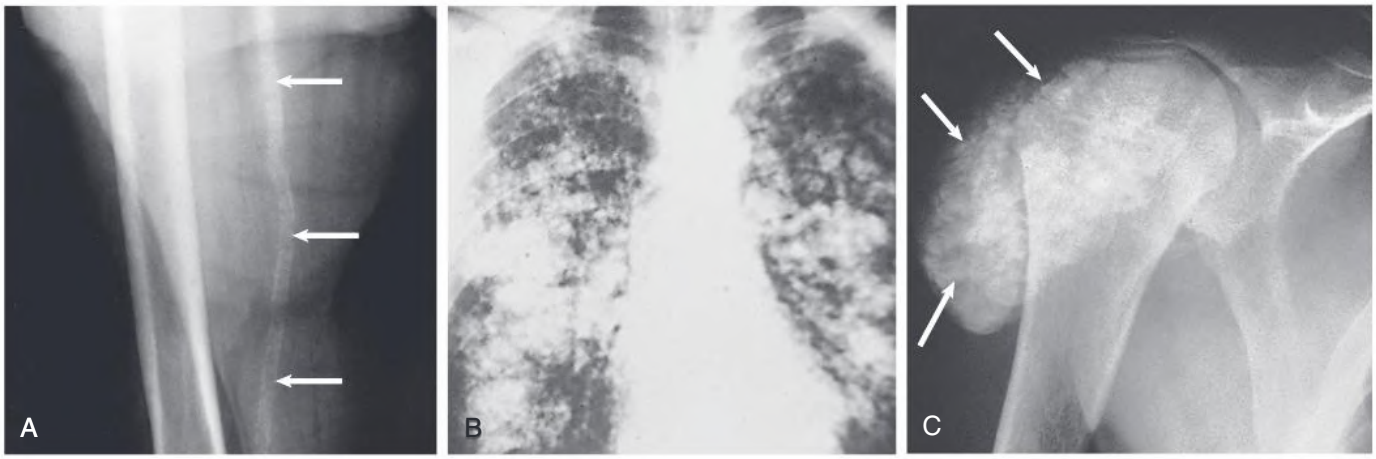

Fig. 88.7 Extraskeletal Calcification in Kidney Failure. (A) Arterial calcification *(arrows).* (B) Pulmonary calcification. (C) Periarticular calcification *(arrows).*

"intact" PTH (iPTH). Refinements in PTH assays have demonstrated that these iPTH assays also measure some large fragments of PTH, which are truncated at the *N*-terminus. More specific assays for so-called "biointact" PTH (PTH 1–84) have been developed that exclude these fragments from measurement, but their clinical superiority over iPTH is not established.[19–21] Standardization needs to be improved among different PTH assays from various laboratories and various manufacturers of assay reagents. With existing iPTH assays (upper limit of the reference range, ~60 pg/mL), only values at the extremes are useful in the noninvasive diagnosis of renal osteodystrophy. In dialysis patients, iPTH levels greater than approximately 600 pg/mL are characteristic of patients with osteitis fibrosa. The threshold values for earlier stages of CKD are not well defined, but there is an element of skeletal resistance to PTH in patients with CKD, and higher levels of PTH promote phosphaturia. Therefore, supranormal levels of PTH appear to be adaptive even in earlier stages of CKD. Serial measurements of PTH are useful in the initial evaluation of patients with renal osteodystrophy and are essential to assess response to therapy and to avoid overtreatment and undertreatment because either can have detrimental effects on bone. There are marked differences among commercial PTH assay results so that precise recommendations of desired ranges cannot reliably be provided and results obtained in different laboratories cannot be easily compared.[22]

Vitamin D Metabolites

The levels of calcitriol in patients with CKD are not helpful in differentiating the histologic lesions of renal osteodystrophy. Measurements of calcitriol are not used routinely for diagnostic purposes unless extrarenal production of this metabolite is suspected, as in granulomatous disorders (see Chapter 11).

Vitamin D deficiency in CKD rarely results in osteomalacia in the United States and Europe but may contribute to hyperparathyroidism. In patients with CKD and marked proteinuria, there is loss of vitamin D–binding protein in the urine, which may result in decreased levels of 25-hydroxyvitamin D. Vitamin D deficiency may be encountered in patients with limited sun exposure, in those with intestinal malabsorption or malnutrition, and in susceptible racial groups, particularly South Asians. Assessment of vitamin D nutrition is by measurement of serum 25-hydroxyvitamin D_3.

Markers of Bone Formation and Bone Resorption

Levels of circulating alkaline phosphatase (AP) offer an approximate index of osteoblast activity in patients with CKD. High levels are commonly present in hyperparathyroid bone disease. The discriminatory power of AP measurements is enhanced by measurement of γ-glutamyl transferase (γGT), which lowers the likelihood of the liver of source of elevated AP if γGT is normal, and bone-specific AP (BAP) isoenzyme, especially in conjunction with PTH values. Serial measurements of AP may be useful in assessing the progression of bone disease. Amino-terminal propeptide of type I procollagen (PINP) may be useful as a biomarker of bone formation, but the level of the monomeric form is dependent on kidney function, which complicates its interpretation in CKD. However, assays detecting trimeric (intact) P1NP do not have this limitation. Tartrate-resistant acid phosphatase and collagen degradation products are both markers of osteoclastic activity but are considered investigational at present.

Radiology of the Skeleton

Routine radiographic examination of the skeleton is relatively insensitive for the diagnosis of renal osteodystrophy, and radiographs can appear virtually normal in patients with severe histologic evidence of renal osteodystrophy. However, subperiosteal erosions are often present in severe secondary hyperparathyroidism, detected in the hands (Fig. 88.8), clavicles, and pelvis. Skull radiographs may show focal radiolucencies and a ground-glass appearance, known as *pepper pot skull.* Osteosclerosis of the vertebrae is responsible for the "rugger-jersey" appearance of the spine (Fig. 88.9). Very rarely, brown tumors, focal collections of giant cells and typical of severe hyperparathyroidism, are seen as well-demarcated radiolucent zones in long bones, clavicles, and digits (Fig. 88.10) and may be confused with osteolytic metastases. Looser zones or pseudofractures are characteristic of osteomalacia. Routine skeletal radiographs are not indicated unless there are symptoms. Novel imaging techniques such as magnetic resonance imaging (MRI), positron-emission tomography (PET), and high-resolution peripheral quantitative computed tomography (CT; HR-pQCT) are considered research tools, but some may find their way to clinical practice in the future.

Measurements of Bone Density

Dual-energy x-ray absorptiometry (DEXA) is widely used to assess bone density. Although DEXA does not identify the nature of the underlying osteodystrophy or distinguish this from osteoporosis, it does allow prediction of fracture risk in patients with any stage of CKD, including those after kidney transplantation. Vascular and soft tissue calcifications may contribute to errors in bone density measurements.

Fig. 88.8 Subperiosteal Erosions in Secondary Hyperparathyroidism. Severe subperiosteal erosions as a manifestation of hyperparathyroidism *(arrows)*. The extensive scalloped appearance of the middle phalanx on the left *(arrowheads)* represents a small brown tumor.

Fig. 88.9 "Rugger-Jersey Spine" in Secondary Hyperparathyroidism. Vertebral bodies show the increased density of the ground plates and central radiolucency, which gives the striped appearance of a rugby jersey.

Bone Biopsy

Biopsy of bone and the microscopic analysis after double tetracycline labeling provide a definitive and quantitative diagnosis of renal osteodystrophy.[23] To standardize reports on bone histology, the Kidney Disease: Improving Global Outcomes (KDIGO) Chronic Kidney Disease–Epidemiology Collaboration (CKD-MBD) work group proposed the TMV classification, an assessment of turnover (T), mineralization (M), and bone volume (V).[1] Bone formation rate is assessed by the administration of two different tetracyclines spaced apart (e.g., tetracycline 500 mg three times daily for 2 days, followed by a 10-day interval, then demeclocycline 300 mg three times daily for 3 days, but several other labeling schemes exist) and biopsy 4 days later. Quantitation of bone mineralization rate is achieved by measuring the distance and surface between the two fluorescent tetracycline bands.

Although noninvasive testing is useful to distinguish low or normal from high bone turnover, there is considerable overlap, and therefore biopsy might be required for definitive diagnosis when biochemistry

Fig. 88.10 Brown tumor *(arrow)* in a hemodialysis patient with severe hyperparathyroidism. The tumor can easily be confused with a lytic bone metastasis.

is not conclusive (e.g., PTH in recommended range but BAP elevated, hypercalcemia with PTH only modestly elevated, or bone pain), and especially so when treatment decisions depend on bone histology.

Osteitis fibrosa (hyperparathyroid bone disease) is characterized by increased bone turnover, increased number and activity of osteoblasts and osteoclasts, and variable amounts of peritrabecular fibrosis (Fig. 88.11A). Osteoid may be increased but usually has a woven pattern distinct from the normal lamellar appearance. Osteomalacia is characterized by increased osteoid seam width, increase in the trabecular surface covered with osteoid, and decreased bone mineralization as assessed by tetracycline labeling (see Fig. 88.11D). The presence of aluminum can be detected on the mineralization front by specific staining (see Fig. 88.11C). Aluminum-related bone disease is defined by aluminum staining exceeding 15% of the trabecular surface and a bone formation rate of less than 220 mm^2/day. Features of osteitis fibrosa may occur together with features of osteomalacia; the combination is termed *mixed renal osteodystrophy*.

Treatment of High-Turnover Bone Disease

Prevention is the primary goal in management of renal osteodystrophy. Therapy for hyperparathyroidism ideally should be initiated in CKD stage 3 so parathyroid gland hyperplasia can be prevented. Because renal osteodystrophy is usually asymptomatic early in the course of CKD, the relevance of secondary hyperparathyroidism is frequently overlooked. By the time CKD is advanced, patients may have already developed significant skeletal abnormalities or nodular parathyroid hyperplasia, and then more aggressive therapy is required to prevent the long-term consequences of renal osteodystrophy. The successful approach to the prevention and management of this disorder involves the integration of a variety of measures directed toward the suppression of PTH secretion and prevention of parathyroid hyperplasia.

Prevention of Hypocalcemia

Hypocalcemia should be corrected because it is a potent stimulus for PTH secretion. Low albumin may mask hypocalcemia unless free calcium is measured. The initial approach to therapy for hypocalcemia in patients with mild to moderate CKD is the administration of calcium supplements such as calcium carbonate, taken between meals with

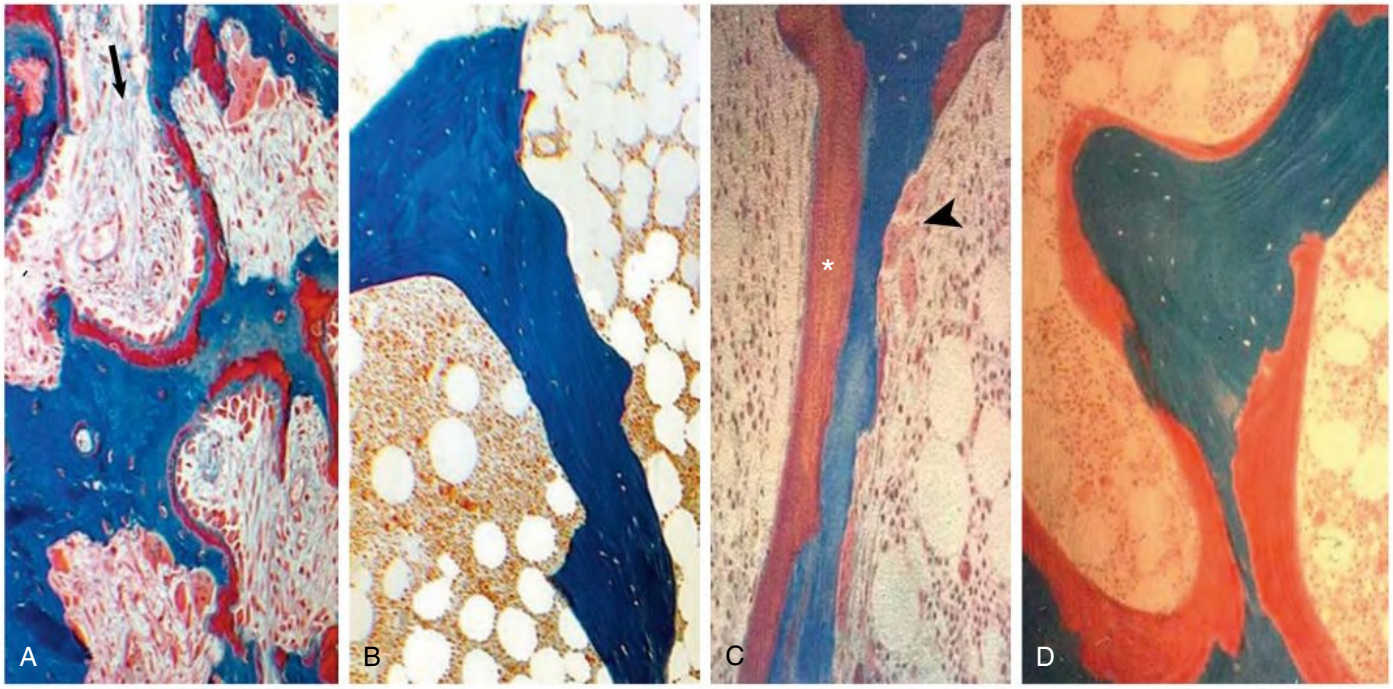

Fig. 88.11 Bone Histology in Renal Osteodystrophy. (A) Osteitis fibrosa: characteristic manifestations of severe hyperparathyroidism with increased multinucleated osteoclasts and osteoblast activity and peritrabecular fibrosis (stained blue, *arrow*). (B) Adynamic bone disease: there is no cellular activity along the bone surface and no osteoid visible. (C) Mixed renal osteodystrophy: there is evidence of active osteoclasts on one bone surface *(arrowhead)* and evidence of thickened osteoid (stained red; *asterisk*) indicating a mineralization defect on the other. (D) Osteomalacia: marked excess of unmineralized osteoid (stained red) surrounding the mineralized bone (stained blue).

increasing doses as required. Vitamin D status should be assessed by measuring 25-hydroxyvitamin D, and deficiency should be corrected if the level is less than 30 ng/mL; 1,25-dihydroxyvitamin D has an 8-hour half-life and so is not helpful for assessing vitamin D status. The efficacy of therapy can be assessed with follow-up determinations of serum calcium and PTH. Adjunctive therapy with active vitamin D sterols should be considered if hyperparathyroidism or hypocalcemia persists. In patients with ESKD, active vitamin D sterols are often required. In dialysis patients, the goal is to achieve levels of iPTH that are approximately two to nine times greater than the upper limit of the assay used.[24] Also, iPTH trends over time should be closely monitored. In CKD stages 3 to 5, progressive rises in iPTH above the normal range should be abrogated by correction of hypocalcemia, vitamin D deficiency, and hyperphosphatemia. The latter should be corrected before the correction of hypocalcemia.

Control of Phosphate

Control of phosphate is the cornerstone of effective management of secondary hyperparathyroidism. In mild to moderate CKD, a normal serum phosphate concentration does not necessarily indicate normal parathyroid status, and except for the late stages of CKD, normophosphatemia may be maintained at the expense of elevated serum PTH and FGF-23. Although it is debated whether phosphate-lowering strategies (like dietary restrictions and phosphate binders) are useful if phosphate levels are within the normal range, overt hyperphosphatemia clearly contributes to hyperparathyroidism.

Dietary Phosphate Restriction

Dietary phosphate restriction can prevent excessive PTH synthesis, secretion, and parathyroid cell proliferation in experimental animals with mild CKD, but the clinical effectiveness of this approach is not proven. Accordingly, restriction of dietary phosphate intake might be considered in patients with CKD stage 2 or 3. The input of a dietician is essential. Protein restriction and limiting dairy products, in particular processed foods containing high amounts of added phosphate, are the mainstays of the regimen. Phosphate-protein restriction increases the serum levels of calcitriol in patients with mild to moderate CKD. However, restriction of phosphate by severe dietary protein restriction below 0.8 g/kg/day may lead to protein-calorie malnutrition.

Phosphate Binders

Although dietary phosphate restriction is usually sufficient in early CKD to treat hyperphosphatemia, this becomes more difficult as kidney function deteriorates. Agents that bind ingested phosphate in the intestinal lumen to limit its absorption are then usually indicated, in addition to dietary restriction. Compounds used for this purpose include calcium-containing antacids; magnesium salts; non–calcium-containing, non–aluminum-containing phosphate binders; and aluminum salts (Fig. 88.12). Several phosphate binders, especially in advanced CKD, have to be given in large numbers (often accounting for 50% of the daily pill burden) and consequently patient adherence with the medication is a major problem, especially because gastrointestinal (GI) side effects (e.g., nausea, vomiting, constipation, diarrhea) occur frequently.

Aluminum-containing antacids are effective phosphate binders, but their long-term use is discouraged in patients with CKD because of the risk for aluminum toxicity. Ingestion of aluminum-containing antacids together with foods containing citric acid (e.g., fruit juices and foods with sodium, calcium, or potassium citrate) may significantly increase aluminum absorption and therefore should be avoided.

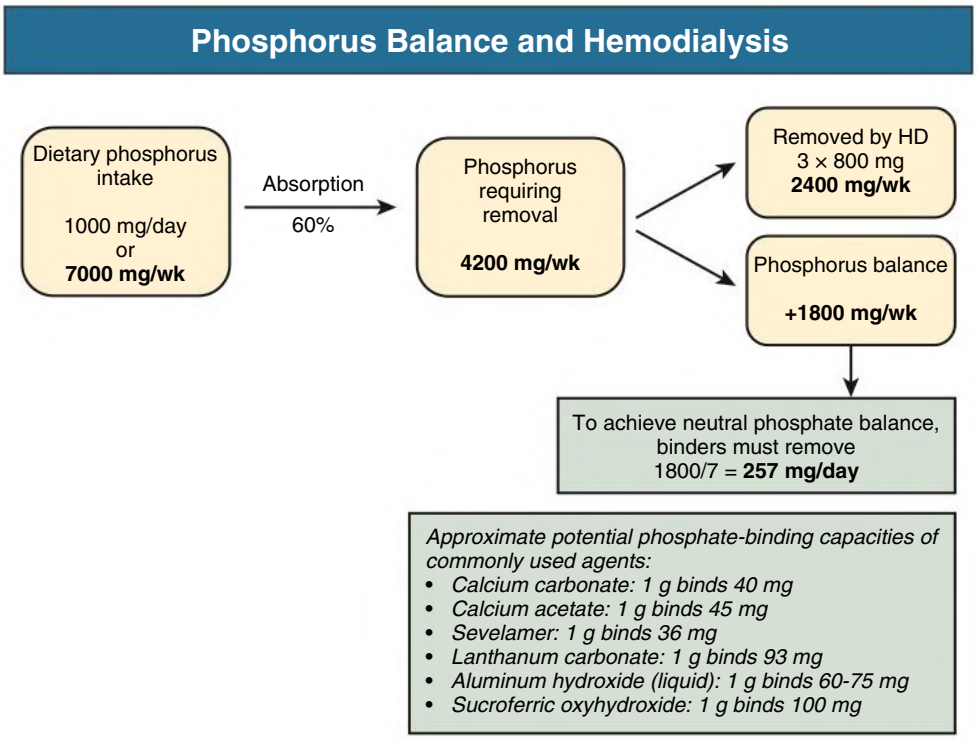

Fig. 88.12 Phosphate balance and phosphate binders used in hemodialysis (HD) patients.

Calcium carbonate or calcium acetate taken with meals effectively binds phosphates and limits their absorption. They are effective phosphate binders in 60% to 70% of patients on HD. The doses required to prevent hyperphosphatemia may vary according to patient compliance with dietary phosphate restriction as well as the CKD stage. Hypercalcemia and calcium loading are potentially serious side effects. Current recommendations are to limit the ingestion of elementary calcium to 1500 mg/day. Consideration of overall calcium balance may be important with the use of calcium-containing phosphate binders.

Magnesium salts are effective phosphate binders for patients who become hypercalcemic with calcium-containing phosphate binders, but they should be administered with caution in CKD patients not on dialysis because hypermagnesemia may have serious adverse effects. In patients on dialysis, magnesium carbonate (elemental magnesium 200–500 mg/day) has been used successfully, with prevention of hypermagnesemia through a reduction in dialysate magnesium concentration, or at least monitoring of magnesium levels.

Sevelamer carbonate is a nonabsorbable, calcium-free polymer, which provides effective phosphate control in a dose range of 2.4 to 4.8 g/day, but higher doses might be needed. Sevelamer may offer a advantage over calcium-containing phosphate binders in terms of limiting the calcium load. The use of sevelamer is associated with decreased progression of vascular calcification.[25] Sevelamer may be combined with both calcium- and magnesium-containing phosphate binders if necessary. Lanthanum carbonate also is an effective phosphate binder. No significant toxicity has been observed, and like sevelamer, its use is associated with less progression of vascular calcification compared with calcium-containing phosphate binders.[26] In general, pill burden is lower for lanthanum compared with sevelamer. Iron-containing phosphate binders include ferric citrate and sucroferric oxyhydroxide. Both compounds have comparable phosphate binding efficacy as lanthanum per pill. Ferric citrate allows significant oral iron uptake and therapy necessitates monitoring of iron stores, whereas iron uptake from sucroferric oxyhydroxide is low.[25]

Use of Vitamin D Metabolites

Calcitriol and other 1α-hydroxylated vitamin D sterols, such as 1α-hydroxyvitamin D_3 (alfacalcidol), 1α-hydroxyvitamin D_2 (doxercalciferol), and 19-nor-1α,25-dihydroxyvitamin D_2 (paricalcitol), are active forms of vitamin D and are effective for controlling secondary hyperparathyroidism. Calcitriol lowers PTH levels and improves bone histology. In patients with very high levels of PTH and markedly enlarged glands with severe nodular hyperplasia, the effectiveness of vitamin D metabolites may be limited because the expression of vitamin D receptor is low in such tissue. Accordingly, it appears rational to initiate treatment of secondary hyperparathyroidism with active vitamin D early in CKD when the parathyroid glands are more sensitive to such therapy and thereby prevent the progression to a refractory stage. Levels of 1,25 dihydroxycholecalciferol generally correlate with 25 hydroxycholecalciferol. Therefore, generally the first step in treatment of secondary hyperparathyroidism is correction of (native) vitamin D deficiency. A beneficial effect of active vitamin D therapy in treatment of secondary hyperparathyroidism in patients with mild to moderate CKD has been shown, but the concern with initiation of active vitamin D therapy at this stage of CKD is acceleration of the progression of kidney disease, should hypercalcemia occur. Because of the effect of calcitriol to increase intestinal phosphate absorption, hyperphosphatemia and elevations in calcium-phosphate product may predispose patients to the development of metastatic calcification; however, it appears that doses of 1α-hydroxyvitamin D_3 or calcitriol up to 0.5 μg/day are not commonly associated with hypercalcemia, hyperphosphatemia, or worsening kidney impairment. Another concern with the use of active vitamin D metabolites before dialysis is that oversuppression of PTH may increase the risk for adynamic bone. Accordingly, vitamin D therapy should be monitored carefully and should not be instituted without documentation of hyperparathyroidism, correction of 25-hydroxyvitamin D deficiency, and prior control of serum phosphate.

In patients with ESKD, indications for therapy with active vitamin D are better defined; however, hypercalcemia and aggravation of

hyperphosphatemia are frequent complications of therapy. In these patients, the PTH suppressive effects of active vitamin D compounds are well established. Several, but not all, observational studies have suggested there may be a survival advantage associated with active vitamin D administration in patients with CKD and with ESKD.[27,28] However, in a prospective Japanese clinical trial in HD patients with relatively low plasma iPTH levels, oral alfacalcidol therapy did not result in lower mortality or cardiovascular event rates.[29] Thus, the principal indication to use active vitamin D is control of secondary hyperparathyroidism.

Role of Calcimimetics

An additional approach to the treatment of hyperparathyroidism in ESKD is the use of calcimimetic agents, such as the oral compounds cinacalcet and evocalcet (approved in Japan), or the intravenously administered etelcalcetide, which targets the calcium-sensing receptor and increases its sensitivity to calcium. In dialysis patients, cinacalcet results in a significant fall in PTH levels and can facilitate the control of hyperparathyroidism. The addition of cinacalcet to standard therapy, which included vitamin D sterols in most participants, in patients with iPTH serum levels exceeding 300 pg/mL while receiving standard therapy allowed significantly more dialysis patients to achieve guideline targets for calcium, phosphate, and iPTH.[30] Cinacalcet is especially useful in patients with marginal or frank hypercalcemia or with hyperphosphatemia because it lowers these levels too. In addition, calcimimetics can be used in conjunction with other therapies and may even be more effective when combined with low-dose active vitamin D, which increases the expression of the calcium sensing receptor. Key side effects include hypocalcemia and nausea and vomiting; the latter can be somewhat improved by administering cinacalcet at night and possibly by switching to another calcimimetic. Cinacalcet may attenuate progression of cardiovascular (CV) calcification.[31] A large clinical trial that examined the effect of cinacalcet compared with placebo on CV events and survival in HD patients with secondary hyperparathyroidism did not show statistical significance of treatment on the primary endpoint. However, this trial had a high risk of missing a beneficial effect of cinacalcet (type II error) because a substantial proportion of the placebo arm initiated commercial cinacalcet and because cinacalcet patients were older on average and thus at higher CV risk than those randomized to placebo.[32] Nonetheless, cinacalcet significantly reduced rates of parathyroidectomies and of calciphylaxis compared with placebo.[32] In CKD patients not on dialysis, the use of calcimimetics is accompanied by significant phosphate retention and is currently not recommended. The parenterally administered etelcalcetide offers improved patient adherence, but GI adverse events were similar to those with cinacalcet.[33]

Role of Parathyroidectomy

Although medical treatments are often effective for the control of hyperparathyroidism, there are patients in whom they are unlikely to be successful, have failed, or are contraindicated and parathyroidectomy should be considered (Box 88.2). Severe hyperphosphatemia in these patients precludes the use of vitamin D because of the risk for metastatic calcification. Some control of iPTH levels may be obtained with calcimimetics, but even these compounds may fail in severe hyperparathyroidism because of downregulated calcium-sensing receptors in the parathyroid glands. However, baseline levels of PTH do not predict response to calcimimetics. Some patients with severe hyperparathyroidism may become hypercalcemic. It is important to be certain that hypercalcemia represents severe hyperparathyroidism and is not caused by adynamic bone or other disease. In some cases, a bone biopsy may be required for a definite diagnosis before proceeding to surgical treatment of hyperparathyroidism. When hypercalcemia in a CKD patient is because of hyperparathyroidism, the level of iPTH generally exceeds 1000 pg/mL and BAP is usually elevated. Surgical parathyroidectomy might be considered in patients with very severe hyperparathyroidism who may receive a kidney transplant in the near future, particularly if they are female and have significant osteopenia. Parathyroidectomy in these patients can help avoid post-transplantation hypercalcemia and hypophosphatemia (caused by PTH-induced phosphaturia), as well as osteopenia. Avoiding hypercalcemia may lead to improved graft function and possibly to less intragraft calcification. Less severe hyperparathyroidism may subside spontaneously after kidney transplantation. Parathyroidectomy might be considered in patients with severe hyperparathyroidism who have evidence of metastatic calcification. The development of calciphylaxis is an urgent indication for parathyroidectomy if PTH levels are elevated (see Chapter 91).

The most commonly used surgical procedures are subtotal removal of the parathyroid glands and total removal of the parathyroid glands with reimplantation of parathyroid tissue in the forearm. Recurrence of hyperparathyroidism occurs in about 10% of patients. Total parathyroidectomy alone is less commonly performed because it results in hypoparathyroidism. Total parathyroidectomy with forearm implantation on the brachioradialic muscle, or subtotal parathyroidectomy in the neck, marking remaining tissue with clips, may be performed. Unregulated tumor-like growth of parathyroid tissue implants has been described and may be related to the monoclonal nature of the nodular hyperplasia of severe hyperparathyroidism. For patients with forearm implantation, it is important to consider which phlebotomy site is used for PTH levels because local levels may differ from systemic.

Recurrence of hyperparathyroidism may respond to further medical therapy, but repeated surgery to remove the forearm implant or a second neck exploration to search for additional glands is often necessary and may be guided by parathyroid imaging.

Synthesis of Therapeutic Strategies

The general recommendations for the prevention and therapy of renal osteodystrophy are summarized in Fig. 88.13, in which therapeutic maneuvers are stratified according to the stage of CKD.

Intervention should be considered in stage 2 or 3 CKD (GFR, 30–90 mL/min/1.73 m^2), and dietary phosphate intake may be restricted once patients enter CKD stage 3. Levels of iPTH should be measured; if elevated above the normal range, the levels of 25-hydroxyvitamin D should be measured and corrected if less than 30 ng/mL. If relevant hyperparathyroidism persists, phosphate binders should be considered if phosphate levels are higher than normal. The effectiveness of calcium-containing phosphate binders in earlier stages of CKD is doubtful. As CKD progresses within stage 3, dietary phosphate restriction should be continued or intensified, with emphasis on inorganic

BOX 88.2 Indications for Parathyroidectomy

- Severe hyperparathyroidism
  - With persistent hyperphosphatemia
  - Unresponsive to calcitriol and calcium
  - With hypercalcemia
  - With intolerance or unresponsiveness to calcimimetics
  - In kidney transplantation candidate if severe and unresponsive to calcitriol and calcimimetics
  - With evidence of metastatic calcification
  - If persistent and clinically relevant >18–24 months after kidney transplantation
- Calciphylaxis with evidence of hyperparathyroidism and no or modest response only to calcimimetic therapy

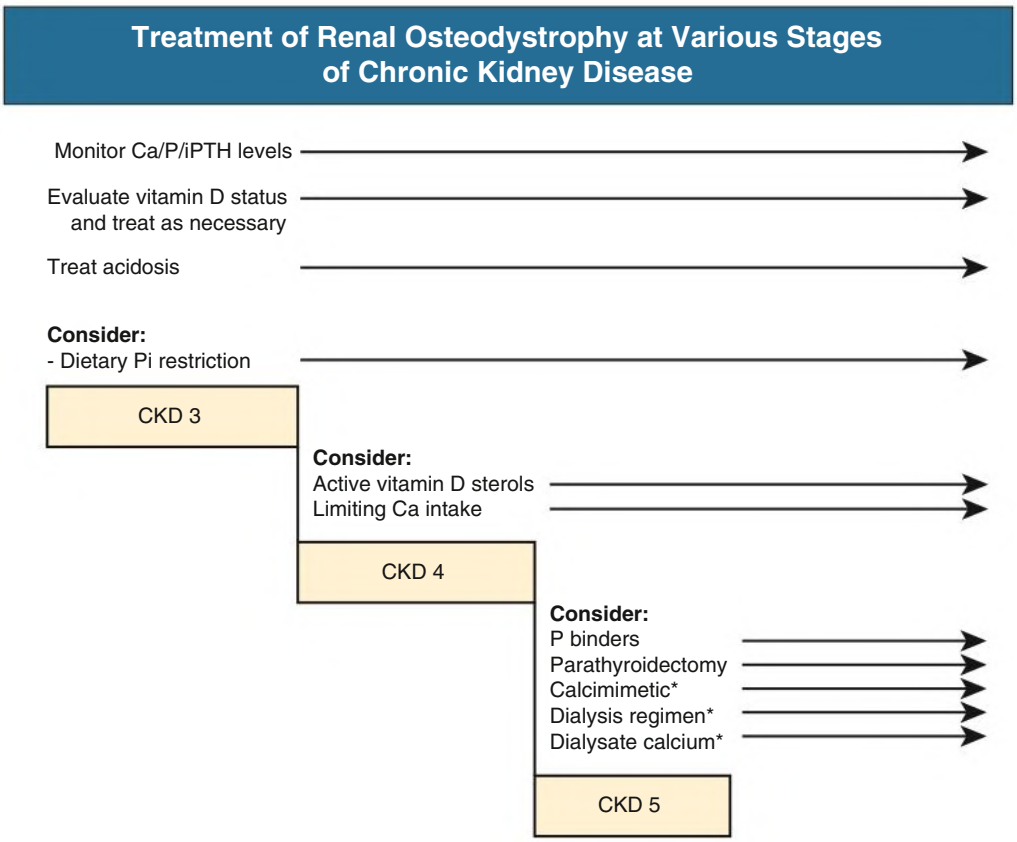

Fig. 88.13 Treatment of renal osteodystrophy at various stages of chronic kidney disease. *Asterisk,* Consider in CKD stage 5D (i.e., dialysis dependent) only. *Ca,* Calcium; *CKD,* chronic kidney disease; *iPTH,* intact parathyroid hormone; *P,* phosphate; *Pi,* inorganic phosphate. (Modified from Martin KJ, Gonzalez EA. Metabolic bone disease in chronic kidney disease. *J Am Soc Nephrol.* 2007;18:875–885.)

phosphate from food additives, and the doses of phosphate binders should be adjusted based on serial measurements of phosphate, with careful attention to avoid hypercalcemia or excessive calcium load. Acidosis, if present, should be treated with oral sodium bicarbonate because persistent acidosis has deleterious effects on the skeleton. The additional sodium load may require further salt restriction or increases in diuretics. Aluminum-based phosphate binders should be avoided. If hyperparathyroidism (iPTH more than two to three times above the upper normal range of the assay) persists despite these measures, consideration should be given to the addition of calcitriol (0.25–0.5 μg/day), active vitamin D analogs, after restoring vitamin D (25OH-vitamin D) deficiency. This therapy should be monitored carefully to avoid hypercalcemia and acceleration of progression of CKD.

In CKD stages 4 and 5, the preceding therapies may need to be intensified and larger amounts of phosphate binders may be required to treat hyperphosphatemia toward normal levels. In patients on dialysis, calcitriol therapy can be intensified, with attention to the serum levels of calcium and phosphate and monitoring of iPTH levels. In CKD stage 5, iPTH levels should be maintained approximately 2 to 9 times above the upper limit of the assay used to maintain normal bone turnover.[24] Within this wide range, treatment decisions on PTH management depend on PTH trends and concurrent levels of phosphate, calcium, and BAP.[24] Calcitriol or other analogs of active vitamin D may be administered orally either daily or intermittently (pulse therapy) or administered intravenously to patients on HD. During therapy with active vitamin D, it is imperative to ensure serum phosphate remains controlled and elevations of serum calcium are avoided. Cinacalcet provides additional effective control of hyperparathyroidism in patients with ESKD and may be used alone or in combination with the other strategies if iPTH levels do not fall into the target range. Parathyroidectomy should be considered in selected circumstances. Bone biopsy may be indicated in selected patients, particularly if biomarkers are inconclusive and important treatment decisions are needed (i.e., long-term use of antiresorptive agents or parathyroidectomy), hypercalcemia remains unexplained, or aluminum overload is suspected. Aluminum overload may require chelation therapy with deferoxamine in selected circumstances, especially if it is symptomatic, but in most patients preventing further aluminum exposure will lead to a gradual reduction in the serum levels of aluminum without the need for chelation. During therapy with potent vitamin D compounds, attention should be given to the dialysate calcium concentrations because higher concentrations may aggravate hypercalcemia. However, the increasingly frequent use of lower dialysate calcium levels, such as 1.25 mmol/L, requires careful monitoring of the patient to ensure compliance with calcium-containing phosphate binders and vitamin D metabolites to avoid progressive negative calcium balance and ongoing stimulation of PTH. Dialysate calcium should remain within the range of 1.25 to 1.50 mmol/L and, when possible, should be individually prescribed.[24]

LOW-TURNOVER (ADYNAMIC) BONE DISEASE

Adynamic bone disease (ABD) describes the morphologic consequences of low-turnover osteopathy in CKD. As CKD progresses, hyperparathyroidism initially develops as an adaptive response to counteract the increasing skeletal PTH resistance and phosphate overload. ABD mainly results from too rigorous suppression of this adaptive response. ABD is increasingly important in CKD-MBD because of the high percentage of affected individuals (>40% in CKD stage 5) and because of its association with CV calcification and mortality.[34,35]

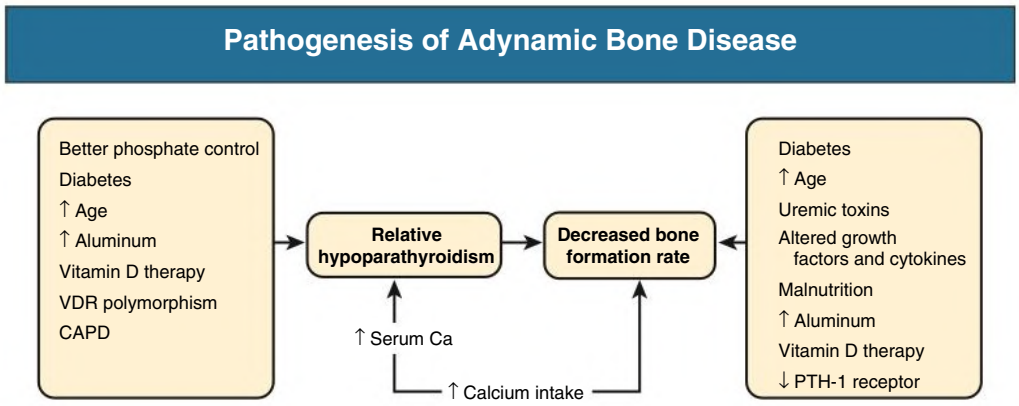

Fig. 88.14 Pathogenesis of adynamic bone disease. *Ca,* Calcium; *CAPD,* continuous ambulatory peritoneal dialysis; *PTH,* parathyroid hormone; *VDR,* vitamin D receptor. (Modified from Couttenye MM, D'Haese PC, Verschoren WJ, et al. Low bone turnover in patients with renal failure. *Kidney Int Suppl.* 1999;73:S70–S76.)

Furthermore, fracture incidence is estimated to be twice as high in individuals with low than in those with high bone turnover. ABD prevalence is markedly increasing in bone biopsy registries of dialysis patients, which may relate to the increasing prevalence of its key risk factors—advanced age and diabetes mellitus. PD also represents a risk factor for ABD, possibly because of a more continuous exposure to high dialysate calcium as opposed to the cyclic exposure associated with HD.

Pathogenesis of Adynamic Bone Disease

Given that the bone develops a relative resistance of the PTH-1 receptor to its ligand PTH as CKD progresses, PTH levels above the normal range are required to maintain adequate bone turnover. Unfortunately, there are no definite ranges of elevated PTH levels that can reliably differentiate an adaptive response (normal bone turnover) from a maladaptive response (increased bone turnover) because PTH resistance individually varies and because it depends on the stage of CKD. Accordingly, ABD is a consequence of inadequately low PTH levels, which cause suppression or cessation of both osteoblast and osteoclast activities, resulting in a reduced bone formation rate and low bone mass. Iatrogenic oversuppression of PTH in CKD mainly results from high-dose active vitamin D analog treatment, from calcium loading (high doses of calcium-containing phosphate binders, high dialysate calcium concentration), or after parathyroidectomy. The effects of calcimimetic treatment on bone turnover have been prospectively evaluated in HD patients, and patients in this cohort had significant high-turnover osteopathy at baseline (average iPTH > 1200 pg/mL). Therapy with cinacalcet decreased elevated bone formation rate and improved bone histologic status.[36] ABD occurred only if iPTH was suppressed below the KDIGO target range of two to nine times the upper reference range of the assay. Finally, diabetes, uremic toxins, malnutrition, and, potentially, C-terminal PTH fragments may be additional factors favoring a state of low bone turnover (Fig. 88.14).

Diagnosis and Differential Diagnosis

Serum Biochemistry

Low iPTH levels (<100–150 pg/mL) are almost always indicative of low bone turnover in CKD stage 5D. However, histologically proven ABD may occur in many dialysis patients with iPTH levels of up to 300 pg/mL and, in exceptions, of up to 600 pg/mL.[37,38] Therefore, PTH levels alone do not reliably identify ABD. Serum levels or activities of AP or BAP are usually normal or low; downward trends may indicate the development of ABD. Serum calcium and phosphate can be normal or elevated, dependent on the choices of cotreatment (phosphate binders, vitamin D metabolites) and nutritional status. Particularly in instances

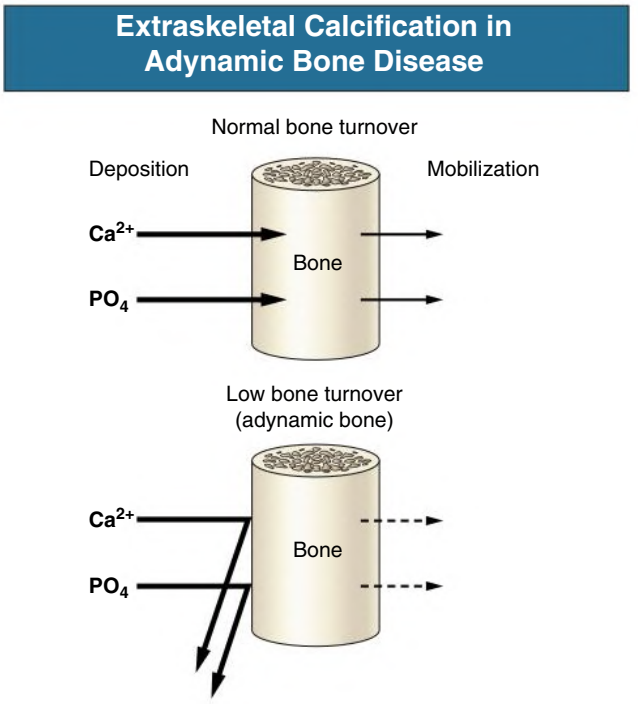

Fig. 88.15 Bone Turnover in Adynamic Bone Disease. Reduced bone turnover leads to increased extraskeletal calcification. Ca^{2+}, Calcium ion; PO_4, phosphate.

of calcium and phosphate loading, hypercalcemia and hyperphosphatemia may be pronounced because adynamic bone is less able to buffer calcium and phosphate loads by osseous deposition (Fig. 88.15).

In CKD stages 3 and 4, there are uncertainties about the diagnosis of ABD and its clinical consequences. It is unclear which PTH levels are required to maintain adequate bone turnover in these stages. It seems reasonable to correct vitamin D deficiency, hyperphosphatemia, and hypocalcemia when PTH levels start to rise, but beyond that, no firm recommendations can be given.

Bone Biopsy

The gold standard for diagnosis of ABD is bone biopsy. According to the TMV classification (see earlier discussion),[1] ABD is characterized by low turnover, normal (or high secondary) mineralization, and low bone (osteoid) volume. The individual indication to perform bone biopsy should be considered in symptomatic patients based on inconsistencies of biochemical parameters associated with unexplained

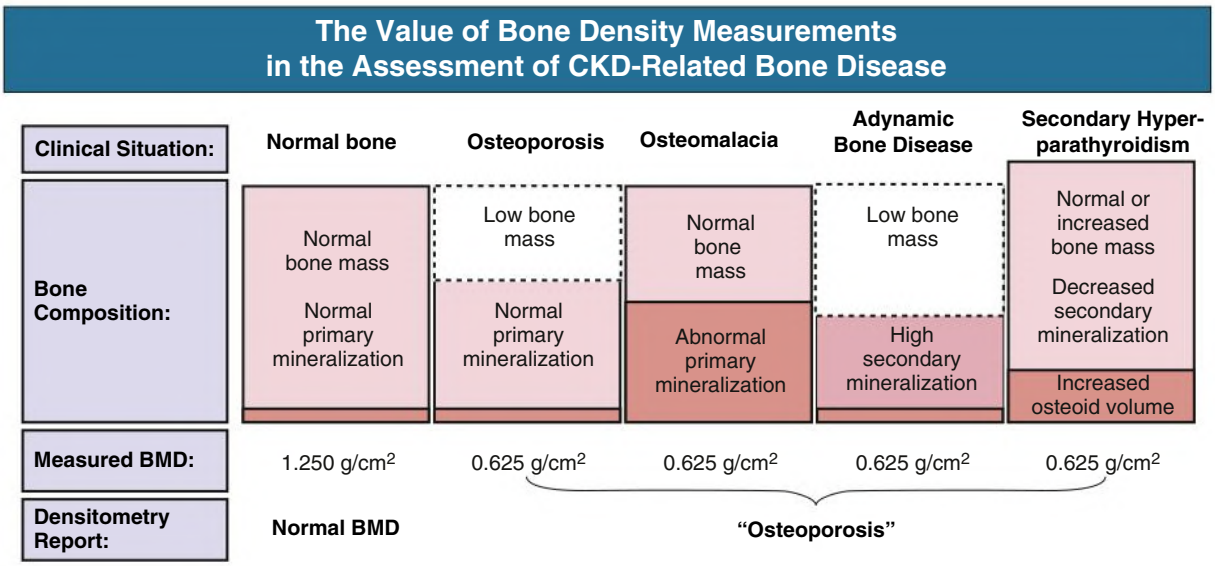

Fig. 88.16 Value of bone density measurements in the assessment of chronic kidney disease (CKD)-related bone disease. *Pink boxes* indicate mineralized bone; *red boxes* indicate osteoid. *BMD,* Bone mineral density. (Courtesy Prof. M.H. Lafage-Proust, St. Etienne, France.)

fractures, bone pain, progressive extraosseous calcifications, or hypercalcemia. The KDIGO initiative recently investigated more than 492 bone biopsy samples and concomitant serum samples to identify biomarker patterns that may allow noninvasive assessment of bone turnover status. ABD was quite strongly associated with low-normal to low BAP levels. In general, PTH and BAP could distinguish low from non-low and high from non-high bone formation rate.[39] However, there is considerable heterogeneity between the extremes. Aluminum toxicity is a relevant differential diagnosis versus ABD. Thus, if the patient's history suggests significant aluminum exposure, aluminum bone deposition should be excluded by measurement of serum aluminum and specific staining of a bone biopsy specimen.

Radiology and Measurements of Bone Density

There are no typical features of ABD in conventional bone radiographs or DEXA. In the latter, bone density may be low, normal, or high, depending on the primary or secondary mineralization state, but it never reflects the actual turnover and is therefore not a helpful diagnostic test (Fig. 88.16). A very high CV calcification burden on conventional radiographs may raise the suspicion of a low bone turnover state, if accompanying biochemical parameters are compatible with this diagnosis. Biopsy-proven ABD is associated with the highest magnitude of vascular calcification in dialysis patients.[34]

Treatment of Adynamic Bone Disease

The key therapeutic approaches in the treatment of ABD are to avoid PTH overexpression and restore adequate PTH levels, without triggering the progressive development of secondary hyperparathyroidism. Such a stepwise treatment approach may include reduction or avoidance of calcimimetics, reduction or avoidance of active vitamin D metabolites, reduction or avoidance of calcium-containing phosphate binders, and reduction of the dialysate calcium concentration (usually to 1.25 mmol/L), first of all based on the magnitude and development of serum PTH levels. Indeed, a recent randomized controlled trial found a histologic improvement of low bone turnover when the dialysate calcium concentrations were decreased from 1.5 or 1.75 mmol/L to 1.25 mmol/L.[40] Any aluminum should be withdrawn. After these interventions, biochemical parameters (PTH, calcium, phosphate, perhaps AP, and especially BAP) should be monitored more frequently than usual.

Studies comparing calcium-containing with non–calcium-containing phosphate binders in dialysis patients[38,41] found that the administration of calcium-containing phosphate binders was associated with a higher proportion of individuals who developed ABD. This development was associated with a fall in serum PTH because of the higher calcium load. In an observational study, high-dose calcium-containing phosphate binder intake was associated with both low bone turnover and increased aortic calcification.[42]

Other therapeutic approaches to ABD have not been systematically studied. They include optimized diabetes control, a change from PD to HD to facilitate a more flexible dialysate calcium prescription, and calcilytics (agents that antagonize the calcium receptor and thus increase endogenous PTH).[43] At present, many patients with ABD remain refractory to these treatments.

Future options for treatment might include recombinant PTH (teriparatide, 1–84 PTH), especially in cases of "irreversible" ABD (i.e., after total parathyroidectomy). Supportive study data on relevant clinical features (e.g., bone histomorphometry, bone mineral density, hypercalcemia) are becoming increasingly available from case reports and non-CKD populations,[44–46] but this approach would be considered an "off-label" treatment for ABD.

OSTEOPOROSIS IN CHRONIC KIDNEY DISEASE

Although abnormal bone is common and fracture risk is increased in CKD patients, the relative contribution of classic osteoporosis (as defined by World Health Organization [WHO] criteria) to the CKD-MBD complex is not well defined. Data from studies of antiosteoporosis agents are mostly available for patients in CKD stages 1 to 3, and subjects with features of CKD-MBD were largely excluded. Nevertheless, postmenopausal women and elderly men are highly prevalent in late-stage CKD populations, and it is thus likely that classic osteoporosis also contributes to their bone disease.

Pathogenesis of Osteoporosis in Chronic Kidney Disease

Osteoporosis may be associated with low, normal, or high bone turnover and is characterized by thin and disconnected trabeculae and loss of the plate-like bone structure. Many patients with CKD have abnormal mineralization and increased osteoid, which is quite atypical for osteoporosis.

Typical pathogenetic factors of osteoporosis, including older age, low estrogen levels, immobilization, and corticosteroid use, are frequent in CKD patients, although some postmenopausal women with late-stage CKD may have relatively normal estrogen levels. However, secondary hyperparathyroidism, relative hypoparathyroidism (as in ABD), and 25-hydroxyvitamin D, as well as 1,25-dihydroxyvitamin D deficiencies, may dominate and "overrule" the bone phenotype of osteoporosis even if classic risk factors are present.

Diagnosis and Differential Diagnosis

Osteoporosis diagnosis relies on an areal bone mineral density (BMD) evaluated by DEXA at the spine or hip below –2.5 standard deviation (SD) from the BMD in young women (T-score). BMD as assessed by DEXA predicts fractures in patients with CKD G4 to G5D but likely also underestimates the actual risk in patients with CKD G4 to G5D because it does not account for impaired bone quality.[47] Furthermore, in advanced CKD, BMD measurements do not differentiate classic osteoporosis versus other CKD-MBD–related bone disease, and low BMD can be found in CKD-MBD–induced high-turnover bone disease, ABD, and osteomalacia (see Fig. 88.16). The value of biomarkers for diagnosing osteoporosis in advanced CKD is not well established; if monitoring is attempted, analytes should be preferred that do not exhibit major kidney retention, such as BAP, intact procollagen type I N-propeptide (PINP; marker of bone collagen synthesis), and tartrate-resistant acid phosphatase 5b (TRAP5b; marker of osteoclast activity). Peripheral quantitative tomography (pQCT) of the radius may be a superior methodology for assessment of CKD patients in the future but awaits validation in sufficiently large patient cohorts.[48] The only reliable methodology to diagnose osteoporosis and discriminate it from other bone manifestations in CKD patients is bone biopsy. In a large bone biopsy study, including 1429 samples from dialysis patients, osteoporosis was diagnosed in 52% of individuals, and 49% of them also had ABD.[49] These proportions may be quite different in patients in earlier CKD stages, but there are no systematic data available on such cohorts.

Treatment of Osteoporosis in Chronic Kidney Disease

Nonpharmacologic approaches to osteoporosis in CKD (i.e., sufficient calcium supply, exercise, fall prevention) do not differ from the general population. Post-hoc analyses indicate that antiosteoporotic medications are safe and efficacious for treatment of postmenopausal women in stages CKD 1 to 3 and high risk for fractures (according to WHO criteria or using the Fracture Risk Assessment [FRAX] tool) and no features of CKD-MBD.[50–53] In such populations, bisphosphonates, denosumab, raloxifene, and teriparatide appear to be feasible therapeutic options. The former three drugs antagonize high bone turnover with an antiresorptive mode of action; teriparatide exerts bone anabolic effects (PTH analog). Bisphosphonates may lead to oversuppression of osteoclasts, but only in patients with advanced CKD. A recent subanalysis of patients in CKD stages 2 to 4 from the Following Rehabilitation, Economics and Everyday-Dialysis Outcomes Measurements (FREEDOM) trial demonstrated a significantly reduced fracture risk with denosumab treatment versus placebo, independent of the stage of CKD.[54] In CKD patients with ABD, bisphosphonates and denosumab may aggravate osteoclast paralysis. In CKD patients with secondary hyperparathyroidism, these antiresorptive agents may upregulate PTH secretion. Patients with advanced CKD (stages 4 and 5) may develop particularly severe hypocalcemia when treated with denosumab; coadministration of vitamin D analogs and calcium may be required to blunt this effect. However, because antiresorptive therapies may be effective in patients with advanced CKD,[47] and the lack of definite evidence that these drugs induce ABD in this population, it may not be necessary to perform a bone biopsy before treatment initiation, if bone turnover markers and repeat DEXA scans indicate a clinical response.

ß2-MICROGLOBULIN–DERIVED AMYLOID

$A\beta_2M$ amyloidosis, also termed *dialysis-associated amyloidosis*, exclusively and rarely affects patients with long-standing stage 5 CKD. Although the process is systemic, clinical manifestations are largely confined to the musculoskeletal system. $A\beta_2M$ amyloidosis in CKD stage 5 should not be confused with a rare hereditary systemic amyloidosis derived from the Asp76Asn variant of β_2-microglobulin, which manifests in the absence of CKD.

Pathogenesis

Fibrils of $A\beta_2M$ amyloid are derived from the circulating precursor protein β_2-microglobulin, the nonvariable light chain of the human leukocyte antigen (HLA) class I complex. The pathogenesis appears to involve three events:

1. Pronounced kidney retention of β_2-microglobulin (11.8 kDa), leading to plasma levels that can be elevated up to 60-fold in dialysis patients[55]; however, even massive overproduction of β_2-microglobulin in mice was not sufficient to induce amyloid deposits and thus further steps must be important.[56]
2. Modifications of the β_2-microglobulin molecule that render it more amyloidogenic.[57]
3. Local factors that contribute to and determine the spatial localization of the amyloidosis.

Epidemiology

Histologic studies from the 1990s observed amyloid deposits in 100% of dialysis patients treated for more than 13 years.[58] Most amyloid deposits never cause clinical problems. $A\beta_2M$ amyloid–related symptoms presently are largely confined to patients who have been dialyzed for more than 15 years.

Clinical Manifestations and Diagnosis

$A\beta_2M$ amyloidosis mainly manifests at osteoarticular sites, particularly synovial membranes; visceral manifestations are rare.[55] Carpal tunnel syndrome is often bilateral and usually requires surgery. Osteoarthropathy of peripheral joints, resulting from amyloid deposition in periarticular bone and the synovial capsule (Fig. 88.17), is

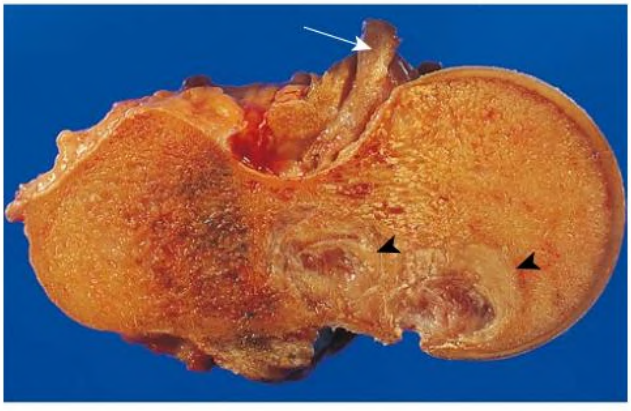

Fig. 88.17 β_2-Microglobulin ($A\beta_2M$) Amyloid Deposition in the Femoral Head. Postmortem specimen from a patient who had undergone long-term hemodialysis. Two large lesions *(arrowheads)*, partly filled with grayish amyloid and partly cystic, are noted in the femoral head. Also note the marked thickening of the synovial capsule from amyloid deposition *(arrow)*.

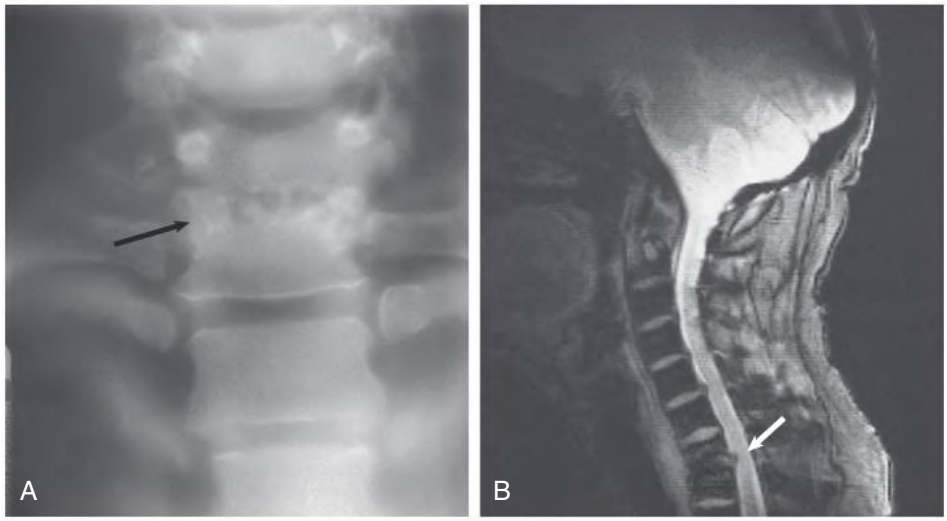

Fig. 88.18 β_2-Microglobulin ($A\beta_2M$) Amyloidosis–Associated Spondyloarthropathy. (A) Destruction of an intervertebral disk *(arrow)* in the neck vertebrae of a long-term hemodialysis patient. (B) Magnetic resonance image of the same patient. Note destruction of the intervertebral space and protrusion of material into the spinal canal *(arrow)*.

characterized by recurrent or persistent arthralgias, stiffness of large and medium-sized joints, and swelling of capsules and adjacent tendons. Recurrent joint effusions and synovitis, often in the shoulders and knees, may occur. The clinical presentation may vary from frank, acute arthritis to slow, progressive destruction of the affected joints. Destructive spondyloarthropathy (Fig. 88.18) resulting from $A\beta_2M$ amyloidosis can manifest as asymptomatic deposits, radiculopathy, stiffness, "mechanical ache," and, finally, medullary compression with resulting paraplegia or cauda equina syndrome. Other manifestations include camptodactyly (a flexion deformity resulting in bent fingers that cannot completely extend or straighten) resulting from amyloid deposits along the flexor tendons of the hands (Fig. 88.19). Patients undergoing dialysis also can have subcutaneous tumorous deposits of $A\beta_2M$ amyloid.

Clinically relevant organ manifestations in patients treated with HD for more than 15 years have described heart failure, odynophagia (painful swallowing), intestinal perforation of both small and large bowel, GI bleeding and pseudo-obstruction, gastric dilation, paralytic ileus, persistent diarrhea, macroglossia or functional tongue disturbances (abnormal taste, mobility, articulation), ureteral stenosis, and nephrolithiasis.

Fig. 88.19 Hand Involvement in β_2-Microglobulin ($A\beta_2M$) Amyloidosis. Hand of a long-term hemodialysis patient showing maximal extension. Note the prominence of shrunken flexor tendons *(arrows)*. This is also known as the *guitar string* sign.

Diagnosis

Serum levels of β_2M do not distinguish between patients with amyloidosis and those without. Ultrasound can detect synovial $A\beta_2M$ amyloidosis as thickening of the joint capsules and tendons and the presence of echogenic structures between muscle groups and joint effusions.[55,57] On radiologic examination, affected joints may present with single or multiple juxta-articular, "cystic" (i.e., amyloid-filled) bone radiolucencies (Fig. 88.20; see also Fig. 88.17). Such bone defects are prone to pathologic fractures. Diagnostic criteria for $A\beta_2M$ amyloid–induced cystic bone radiolucencies include (1) diameter of lesions more than 5 mm in wrists and more than 10 mm in shoulders and hips, (2) normal joint space adjacent to the bone defect, (3) exclusion of small subchondral cysts in the immediate weight-bearing area of the joint and of defects of the "synovial inclusion" type, (4) increase of defect diameter of more than 30% per year, and (5) presence of defects in at least two joints.[59] Scintigraphy, using either radiolabeled serum amyloid P component or β_2-microglobulin,[60] offers more specific detection of amyloid deposits but is not widely available. The definitive diagnosis of $A\beta_2M$ amyloidosis relies on histologic findings. Fat aspiration and rectal biopsy are not helpful in $A\beta_2M$ amyloidosis, but diagnostic material can be obtained from synovial membranes, synovial fluid, or bone lesions.

Treatment and Prevention

Therapy for established $A\beta_2M$ amyloidosis is symptomatic. NSAIDs and physical and surgical measures, such as carpal tunnel decompression, endoscopic coracoacromial ligament release, and bone stabilization in areas of cystic destruction, are all used.[55] Dialytic removal of β_2M is probably of no therapeutic value in established $A\beta_2M$ amyloidosis. Kidney transplantation is the preferred treatment because it leads to rapid symptomatic improvement and halts further progress of the disease, but whether this can actually lead to regression of established $A\beta_2M$ amyloid deposits is uncertain.

A number of strategies exist for prevention of the clinical manifestations of $A\beta_2M$ amyloidosis.[55] The risk for carpal tunnel syndrome is reduced by 40% to 50% in patients treated with high-flux hemo(dia)

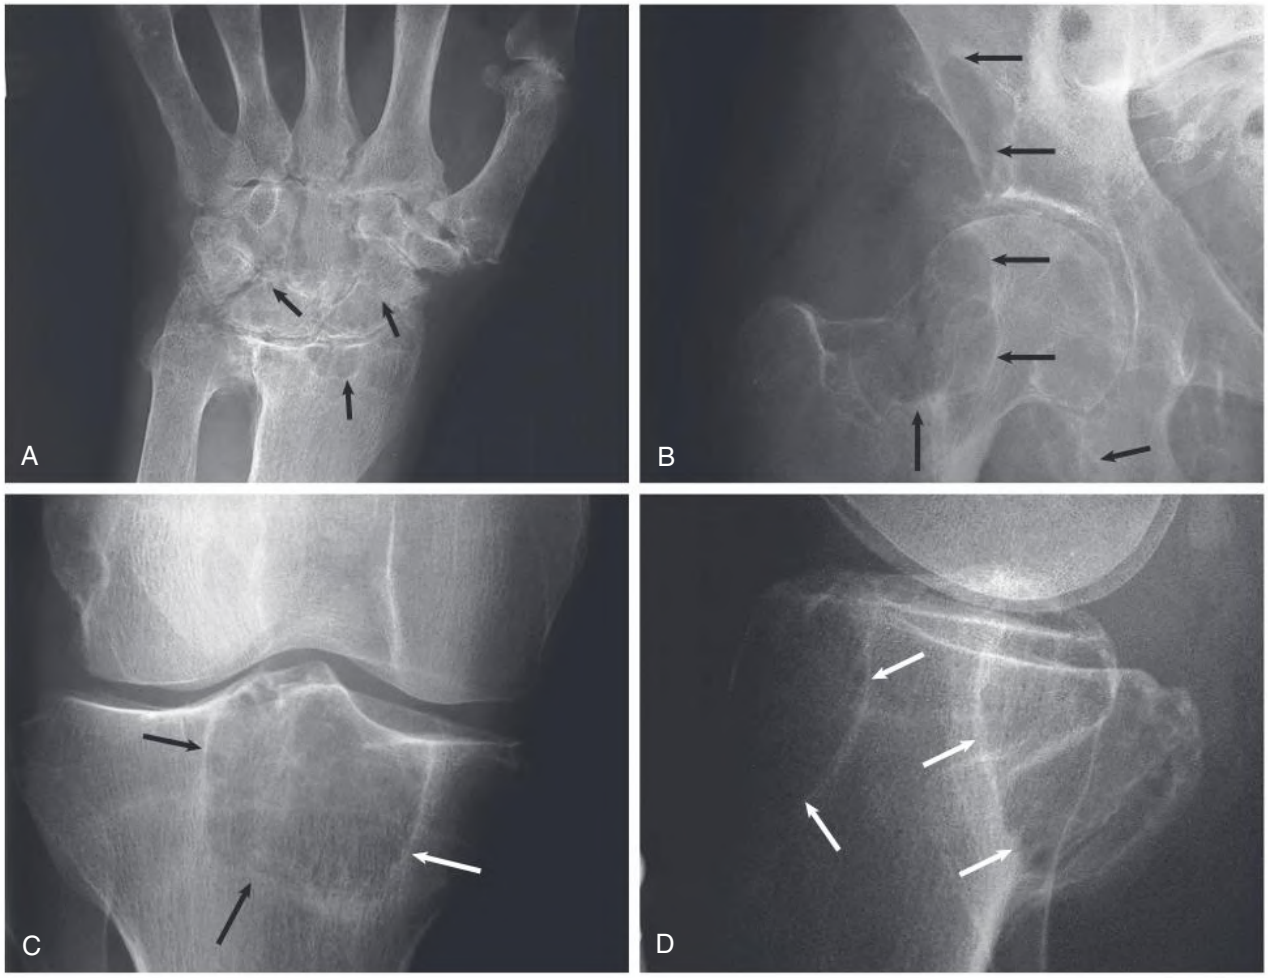

Fig. 88.20 Peripheral Bone Cystic Radiolucencies in β_2-Microglobulin ($A\beta_2M$) Amyloidosis. Radiographic findings in a long-term hemodialysis patient. (A) Multiple cystic lesions *(arrows)* are present in the hand bones. (B) Large cysts *(arrows)* in the neck of the femur and adjacent pelvic bones. filtration and minimal in patients receiving online hemodiafiltration. A dramatic reduction in the prevalence of carpal tunnel syndrome occurred in patients dialyzed with ultrapure dialysate. In another study, an 80% reduction of amyloid signs in a chronic HD population appeared to relate to dialysate factors such as microbiologic purity and the use of bicarbonate buffer.

SELF-ASSESSMENT QUESTIONS

1. A 56-year-old White woman with ESKD secondary to presumed hypertensive nephrosclerosis has been on maintenance HD for 3.5 years. She reports to dialysis treatments regularly and is being adequately dialyzed. Laboratory data over the past few months reveal that intact PTH levels have ranged from 360 to 545 pg/mL, serum calcium 9.5 to 10.5 mg/dL (2.4–2.6 mmol/L), and phosphorus 5.5 to 7.0 mg/dL (1.83–2.33 mmol/L). She has been treated with increasing doses of paricalcitol, dietary phosphate restriction, and calcium carbonate as a phosphate binder. A few days ago, she was seen by her internist regarding vague symptoms that included abdominal pain. At that time, blood tests showed serum phosphorus 7.6 mg/dL (2.5 mmol/L) and calcium 10.1 mg/dL (2.5 mmol/L). The rest of the metabolic profile was within normal limits. A kidney, ureter, and bladder (KUB) film of the abdomen showed calcification of the abdominal aorta. What is the most appropriate next step in the management of this patient's CKD-MBD?
   - **A.** Increase the dose of paricalcitol.
   - **B.** Increase the dose of calcium carbonate to improve phosphate control.
   - **C.** Stop calcium carbonate and add a non–calcium-containing phosphate binder.
   - **D.** Refer for parathyroidectomy.
   - **E.** Decrease dialysate calcium.
2. A 75-year-old White man on HD because of diabetic nephropathy exhibits rapid progression of vascular calcification. His total serum calcium fluctuates around the upper limit of normal, with occasional episodes of mild hypercalcemia. Serum phosphorus is around 7 mg/dL (2.3 mmol/L) despite various changes of his phosphate binder medication. The latest intact PTH level is 105 pg/mL (previous levels ranged from 90–180 pg/mL). Current medication includes fluvastatin, calcium acetate, low-dose aspirin, a β-blocker, and insulin. What is the most appropriate next step in the management of this patient's CKD-MBD?

A. Continue the described therapy.
B. Increase the dose of calcium acetate to improve phosphate control.
C. Repeat dietary counseling.
D. Add low-dose calcitriol (e.g., 0.25 μg/day).
E. Replace calcium acetate with a calcium-free phosphate binder.

3. A 68-year-old White woman with an eGFR of 25 mL/min/1.73 m^2 as a result of presumed hypertensive nephrosclerosis presents for a regular checkup. She has no specific complaints. Medication consists of an ACE inhibitor, a loop diuretic, a β-blocker, and low-dose aspirin. Current laboratory values include intact PTH level 90 pg/mL (reference range <60), serum calcium 8.1 mg/dL (2.0 mmol/L) and phosphorus 5.7 mg/dL (1.8 mmol/L), 25(OH)-vitamin D3 17 μg/L (target range 30–100). What step in the management of this patient's CKD-MBD is *not* appropriate?
A. Educate the patient about phosphate content in food.
B. Initiate therapy with a phosphate binder.
C. Initiate substitution of 20,000 IU vitamin D3 every second week.
D. Educate the patient about food additives.
E. Initiate therapy with a low dose of a calcimimetic.
